Foreword

VOLUME 52 of the TRANSACTIONS OF THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS contains 35 individual sections published during 1930 under the sponsorship of the Society's 15 professional divisions, as well as its annual Record and Index. The technical papers and reports that make up this volume represent the Society's annual contribution to the permanent record of mechanical-engineering achievement. Most of these papers and reports were presented at meetings of the Society and of its professional divisions and local sections. Other papers published by the Society but not included in the Transactions may be located by means of the Record and Index which forms a part of this volume.

The papers published in this volume were issued originally in pamphlet form. These pamphlets appear in sections, each section being sponsored by one of the Society's professional divisions. A member of the Society may register in any three of the fifteen professional divisions and receives in pamphlet form as they are issued the sections of Transactions sponsored by those divisions.

All sections of the Transactions are bound together at the end of the year for the convenience of libraries and of engineers who wish all of the papers in permanent form. Copies of the bound Transactions will be found in depositories located in selected engineering, university, and public libraries throughout the world. A complete list of these depositories will be found on page 97 of the Record and Index. Copies of the bound Transactions have also been set aside for sale.

At the end of Volume 52 will be found the Record and Index of the A.S.M.E. for 1930. This is the permanent record of the Society's activities for the year, and includes lists of committees, reports of meetings and committee activities, and memorial notices of deceased members. The indexes include those of special publications, and of *Mechanical Engineering*. Printing of the Record and Index in this form was ordered by the Council of the Society, and returns to the Transactions material of permanent historical value which has been issued for the past three years (1927–1929) as a separate publication.

NUMBERING AND ARRANGEMENT OF PAPERS IN COMPLETE TRANSACTIONS

In this volume the papers of each section are grouped together and are numbered serially. The different sections follow each other alphabetically. Each paper is designated by a symbol composed of key letters followed by the volume number and paper number. The letters refer to the section of the Transactions to which the paper is assigned. Thus AER refers to the Aeronautic section, IS to the Iron and Steel section, etc. Each of the two books forming parts I and II of Volume 52 contains a complete index of subjects, authors, and discussers to both parts of the volume so that either may be consulted. The arrangement of the index and designations for locating material are explained at the beginning of the index.

CONCERNING BLANK PAGES

The papers in each section of the Transactions are printed separately so that they may be available as reprints. This makes it necessary to print each paper so that the number of pages is a multiple of four. Because of this, blank pages will be found at the ends of papers which do not completely fill the printer's form.

THE PUBLICATIONS COMMITTEE.

Power Plants[1]

AN EXAMINATION of Table 1 indicates that the development of airplane engines during the past year has proceeded apace. The radial air-cooled engine is still the most widely manufactured and used, but it is being pushed in the low-horsepower class by air-cooled in-line engines of various makes.

The development of new engine types is proceeding very slowly. The Packard Diesel made a spectacular non-stop flight from Detroit to Langley Field in May, but since then has been kept well under cover. The Curtiss H-1640 (Chieftain) engine has not yet progressed beyond the development stage. The Wright V-1460, a twelve-cylinder inverted-vee air-cooled engine, is being installed experimentally in some Army Air Corps airplanes.

The Pratt and Whitney R-1340 (Wasp) has progressed to the Series C engine, which is slightly heavier than the series B, but has increased durability. The Pratt and Whitney Hornet has progressed from the R-1690 to an R-1860 (Hornet Series B) engine of 575 hp., which is already in service in both military and commercial airplanes.

The Wright Aeronautical Corporation has brought out the new J-6 (Whirlwind) engines, the R-540, R-760, and R-795. The J-5 has been withdrawn from production and the J-6 engines are being used extensively. The Wright R-1750 (Cyclone) has undergone various improvements. The Wright Company is bringing out an American edition of the De Havilland Gypsy.

The Curtiss Company has installed several of their water-cooled V-1570 (Conqueror) engines in commercial airplanes. The Curtiss R-600 (Challenger) in a Curtiss Robin airplane set up a world record for sustained flight of over 400 hours at Saint Louis. The Curtiss Company has recently produced a small 125-hp. inverted 6-in-line air-cooled Crusader engine.

One of the outstanding engine developments of the past year was the release, by both the Army Air Corps and the Navy Bureau of Aeronautics, of information regarding the work done on high-temperature cooling of liquid-cooled (hitherto called "water-cooled") engines. The most efficient cooling medium was found to be ethylene glycol (Prestone), which can be used with a jacket outlet temperature of 300 deg. fahr. It has the advantage over water cooling of permitting a 75 per cent reduction in radiator area, due to the greatly increased temperature difference between the cooling medium and the air.

Another outstanding power-plant development of the past year was the development of the venturi type of cowling for radial engines. The use of this cowling removes the greatest objection to the radial air-cooled type of engine—its excessive drag. In the free-for-all high-speed race at the National Air Races in Cleveland last August, radial air-cooled engines with venturi cowling placed one, two, three against the field.

An interesting trend in airplane power plants is the increasing use of geared engines, both direct-air-cooled and indirect-air-cooled (liquid-cooled), for the purpose of reducing propeller speeds to a point where the propeller can operate at its optimum efficiency. With the problems involved in the use of reduction gearing successfully solved, it seems logical to expect that engine speeds will increase to a point comparable with those of automobile engines, thus giving increased thrust horsepower for a given engine displacement and size.

Airplane Design and Construction[2]

In 1929 airplane design and construction made rapid advances, more so, perhaps, than in any of the immediately preceding years. Unlike the year before, a number of really new types were brought out and successfully proved. The decrease in plagiarism of designs and the increase of individual effort were especially noticeable. A number of new methods of construction were developed, and design with a view to mass production was vastly improved. As in the past few years, much attention was paid to improvements in details, both in the aerodynamical properties of airplanes and in their structure. Many new large airplanes were completed as well as many exceptionally small ones. The number of open-cockpit biplanes still predominated, as in the past, but did not increase as it had in the years past but rather decreased. On the other hand, much more attention was paid to the development of flying boats, seaplanes, and amphibians.

In design, the influence of the Aeronautics Branch of the Department of Commerce was shown by the considerable decrease in "fly-by-night radical and revolutionary designs," and as well in general improvement in all planes with respect to thoroughness in engineering and proper attention to details.

In the first half of 1929, 72 new approved-type certificates were awarded by the Department of Commerce as against 59 in the last half of 1928, an increase of 22 per cent. In the third quarter of the year 52 certificates were awarded as compared with 36 in each of the two previous quarters, an increase of 44.5 per cent. It should be remembered that these certificates signify

[2] Prepared by Richard M. Mock, Aeronautical Engineer, Bellanca Aircraft Corp (at the time of writing, on leave and with the Ernst Heinkel Flugzeugwerke, Warnemünde, Germany).

only the approval of new types for production and do not represent the quantity of planes of each design approved.

As to the detail design of airplanes produced in 1929, advance in aerodynamic "cleanness" is immediately apparent.

More than ever the tendency has been toward the monoplane rather than the biplane, and again toward the "clean" cantilever monoplane. Besides the efforts made to reduce resistance through the reduction of frontal area, much attention was paid in the past year to the elimination of induced drag caused by the mutual interference between the various exposed parts of the airplane. The efforts in this direction have resulted especially in cleaner landing gears, with more attention given to the relative location of the individual members. In some landing gears these members are completely eliminated by supporting the wheels by a cantilever beam. The landing gear of the Bellanca Pacemaker is an example of the truss type, much attention being paid to the mutual interference of the individual members. Many production designs now include as standard equipment fairings for wheels and tires, while on the Eaglerock Bullet the resistance of the wheels is almost practically eliminated by retracting the greater portion of them into the wing.

In the design of wings there has been a slight tendency toward increased aspect ratio to give better cruising performance. This has been more apparent in some European designs than in American ones. Little progress was made during the year with regard to the development of better profiles for wing sections. This was chiefly due to the dependence of commercial organizations upon government laboratories for information. However, at present many manufacturers are developing aerodynamical laboratories of their own, which should effectively advance the investigation of their individual problems.

Though the N.A.C.A. type of engine cowl was developed in 1928, it was not until the past year that it was really tried on a commercial scale. With the increased use of this cowl for radial air-cooled types and the development of clean air-cooled in-line engines, designers have paid a great deal more attention to cleanness in fuselage lines, resulting in somewhat rounded fuselages, many of which are oval in section. An excellent example of the result of good streamlining is the low-wing Travel Air monoplane of conventional American construction of welded steel-tube fuselage and wood wings, all fabric-covered. This plane attained a speed of 200 m.p.h. Also worthy of mention is the Eaglerock Bullet, a land plane with cantilever low wing and retractable landing gear.

Aerodynamically, most planes were quite conventional except for the Bellanca Tandem and the Furnic Ente. The Bellanca Tandem opens an entirely new field of development for multi-engined planes. The engine installation is new, while the wings are a further development of the Bellanca Roma or K-type brought out in 1928. The Furnic Ente is a twin-engine design differing from the usual Ente type in that it has two stabilizers, one in front and one behind.

From a structural point of view there has been an increasing use of duralumin, and especially of the corrosion-resisting alloy Alclad. In the United States there has been little or no work done with light-gage sheet steel, especially of the so-called stainless variety. This is used extensively in England and is being tried experimentally by Heinkel in Germany.

One of the most interesting developments in wing construction is the Barling monoplane of Nicholas-Beazley. Practically all American wings employ the two-spar construction, but one of the leading manufacturers uses three spars. In Europe there has been considerable development in single-spar metal construction, especially the English "mono-spar" and the German B.F.W. commercial planes.

More planes have been produced with dural fuselages than heretofore, and the number of dural tail surfaces has also increased quite rapidly.

From a production viewpoint there have been many advances. The development of the Consolidated Fleet Junior is the most outstanding example of a good production design. Also in this class is the new Great Lakes training plane.

Toward the close of the year there was evidence of an increased activity in the development of seaplanes and flying boats. This branch of aeronautical development has been somewhat neglected in the United States, except by Loening, Sikorsky, and Ireland. However, 1929 brought the development of the large Consolidated Commodore, the Hall, the Keystone-Loening Commuter, and the Great Lakes Amphibian, as well as a number of others that are not yet in production. Many European manufacturers have arranged for American production of their products. Savoia-Marchetti flying boats are already being built. Three German manufacturers are planning American production; Heinkel has developed an amphibian of medium size expressly for the American market, while Rohrbach has announced an American company presumably to produce the Roman and Rocco types. Dornier, too, has an American connection for fabrication of the Super Wal and perhaps the 12-engined giant DO-X, which last fall carried 169 people, establishing a world's record. Also planning American production under license are the English Blackburn and the French Schreck companies, both experienced organizations in flying-boat development.

In America the large passenger land transport plane has been receiving much attention. In 1929 the Curtiss plane Condor, the Fokker F-32, and the twin-engined Burnelli were developed, while production was increased on the Ford tri-motor, the Fokker tri-motor, and the Keystone Patrician. At the time of this writing the four-engined Fokker F-32 is the largest passenger land plane, carrying 32 people, and work is being rushed in Germany to complete the 50-passenger Junkers J-38, a design closely resembling the large Junkers G-31.

As regards cabin passenger planes, it is the writer's opinion that the German transports are much more comfortable, though great progress is being made in this direction in America.

All over the world there has been a tendency to increased power in airplanes, and in many cases, instead of being used to provide greater safety or better performance, it has been employed to overcome difficulties in design in what would otherwise be called exceptionally poor airplanes. The increased use of higher-powered engines, especially the Wasp, Hornet, and Cyclone, is noticeable, while in Europe builders have gone to even higher powers, employing 700–800-hp. and even 1000-hp. water-cooled engines on commercial airplanes.

Aerodynamics[1]

The past year has seen practical progress in the art of streamlining. Commercial designs have shown a tendency to imitate racer practice in reducing parasite resistance to a minimum. For example, commercial designers are using retractable landing gears (as in the Alexander Bullet) which have a resistance approximately 50 per cent of that of the fueslage. Monocoupe fuselages of nearly perfect streamline form are being built in both wood and metal. The filleting of wings into fuselages, and of struts into wings, is being considered as worthy of attention from a resistance point of view. Without evidence of systematic wind-tunnel experimentation, attempts are being made to decrease wheel resistance by providing wheels with fairings. The N.A.C.A. or venturi cowling has been successfully employed on a number of designs to reduce the head resistance and increase speed, although designers of single-engined planes are not adopt-

[1] Prepared by Alexander Klemin, Daniel Guggenheim School of Aeronautics, New York University. Assoc-Mem. A.S.M.E.

ing this type of cowling any too rapidly as it undoubtedly impedes vision. In England the Townsend ring, an annular surface placed round and at some distance from the cylinder heads, is apparently producing real aerodynamic improvement, and the device is of the simplest possible character.

In the design of airfoils, particularly in England and France, it is now more frequently the practice to design airfoils theoretically, and to employ airfoils with a constant center of pressure, partly with a view to increasing the stability of the airplane and partly with a view to decreasing the stresses on the spars. The successful employment of constant-center-of-pressure wings has also led designers to think more seriously of the single-spar cantilever monoplane. With a constant center of pressure achieved, single-spar construction offers decided possibilities. Designers are also giving much more attention to the careful aerodynamic design of cantilever monoplane wings. Besides taper in plan and thickness so as to provide both greater aerodynamic efficiency and greater strength at the root of the wing, it is now customary to give consideration to the center-of-pressure travel. By suitable design, and appropriate choice of sections along the span, it is apparently possible to produce tapered wings of real efficiency, high lift, and constant center of pressure. At the same time, by using constant-center-of-pressure sections at the tip, it is possible to minimize the dangers of flutter.

As regards control surfaces, a number of tendencies may be noted. Floating wing-tip ailerons, always in the line of wind, no matter what the angle of incidence of the main wing may be, have been tried out in a number of wind tunnels. The advantage of such ailerons lies in the fact that, even if the main wing is at or near the stall, the ailerons are always at zero near the wind, and therefore maintain effective rolling moment, while the adverse yawing moment either disappears or becomes negligible. In the Guggenheim Safe Aircraft Competition, the Curtiss Tanager is employing this type of control, whereas the Handley Page entry employs the so-called slotted aileron, in which the Handley Page automatic slot is placed at the leading edge of the wing and helps the lateral control at the stall. The so-called slot-and-flap aileron has been universally adopted on all machines used by the British Government.

The Handley Page Company has successfully developed a so-called "interceptor," in which the action of the ailerons working with a front slot may be still further strengthened. In this device the front slots may remain automatic, but the upgoing aileron raises a "spoiler," a flat plate normally lying flush with the wing. This spoiler still further decreases the lift on the side of the upgoing aileron, and also increases the drag on the side of the upgoing aileron.

The Safe Aircraft Competition has brought to light a series of interesting attempts to improve the airplane at the lower range of the scale. The special devices employed in wing design include: The automatic front slot working in conjunction with rear flaps, with which it is mechanically connected (Handley Page); the automatic front slot working in conjunction with a manually operated rear flap (Curtiss); variable camber and area (Burnelli); variable camber and incidence (Wentworth); and conversion of a monoplane into a biplane of very small gap (Cunningham-Hall).

The realm of aerodynamics, broadly speaking, may be considered to comprise the activity which has been shown in the design of variable-pitch propellers. Mechanical control, electrical control, and hydraulic control are now being supplemented by efforts at purely automatic control, with action dependent on the fine correlation of aerodynamic and dynamic forces.

The establishment of the Autogiro on American soil has led to increasing interest in this form of aircraft. One of the main difficulties previously experienced with this machine has been the slowness of starting of rotation of the main blades. By raising the tail surfaces in appropriate fashion so as to break the symmetry of flow, it is now possible to secure blade rotation with much greater rapidity.

The Isacco Helicogyre may perhaps be said to be a development of the Autogiro. It involves freely hinged blades as does the Autogiro, but the lifting blades are driven round not by windmill action alone, but by the placing of auxiliary engines near the tips, which actuate auxiliary propellers. It is hoped in this fashion to augment the admirable qualities of the Autogiro by increasing steepness of climb and rapidity of take-off.

Air Transport and Other Civil Flying[4]

Continuing the development described in the Progress Report for 1928, further extensions of air routes have been made in the United States. Perhaps the most outstanding feature in this connection has been the extension of the U. S. air lines to South America. This began with the extension of the Pan-American Airways route from Havana to Central America and thence through affiliated companies on the West Coast. At the same time a competitive group has obtained mail contracts from certain South American nations, has organized its personnel, and is just about to place into operation a competitive route running down the East Coast of South America to Rio de Janeiro and Buenos Aires. The traffic carried by practically all lines in the United States has undergone considerable increase, and this increase shows no signs of slacking up. While the air mail has had a very consistent growth, the outstanding feature on the traffic side has been the changed attitude of the public toward passenger services and the increased willingness of passengers to fly. As a result of this, passenger traffic, which was formerly lagging behind that of Europe, is now experiencing a very healthy growth and promises to become, within a short time, a most important source of revenue for the operators of air routes. Similar increase has been noted in the miscellaneous flying services and in the operation of flying schools. Because of its bearing upon transport operations, it is noted here that the increase in pilots is keeping up quite closely with the increase in airplanes. Thus it is evident that there will be no shortage of pilots as a whole, although for a time there may be some shortage of the very experienced types of pilots.

Among the elements of economic importance to the operators of air routes might be noted the recent tendency toward consolidation which has resulted in the merging of a considerable number of smaller operators into a lesser number of substantial groups controlling connecting routes. This development is somewhat comparable with the consolidations of the early days of railroading, and the air routes are becoming combined into well-organized systems somewhat similar to those which now exist in railroading. Incidental to this development, a considerable volume of additional capital has been drawn into the operating side. As this is being written, there is under consideration by the U. S. Post Office Department the possibility of some adjustment of air-mail contracts which may affect those operators holding contracts at the higher rates. The indications are, however, that the attitude of the Post Office Department will be quite reasonable and that no operator will be expected to accept a readjustment of rate which forces him to run at a loss, if this can possibly be avoided.

The movement toward the creation of private flying clubs, which began here within the past two years, is now producing some tangible results and is thus providing facilities which should give great encouragement to the private owner of airplanes and result in further increase in private flying.

[4] Prepared by Archibald Black, President and General Manager, Black & Bigelow, Inc., Air Transport Engineers, New York, N. Y. Mem. A.S.M.E.

Among the technical developments affecting air-transport operation might be noted the increase in size and horsepower of airplanes, of which the 32-passenger Fokker and the 50 passenger Dornier DO-X are recent examples. This is a very natural trend due to increased traffic and to the demand for still higher speed. As the traffic grows still further, similar further increases in size of airplanes may be expected until the equipment in use attains capacities very much greater than at present. The recently developed N.A.C.A. cowling is of most important economic advantage to the airway operator as it increases the speed of his airplanes without affecting the gasoline consumption. This is important from three viewpoints: First, it enables him to speed up his operations; second, it enables him to get more mileage with the same flying cost, or, conversely, a lower flying cost for the same mileage; third, it has a still further advantage in making it possible to get more miles per year with the same equipment. Recently, some experimental flights were made with the Opel rocket-propelled airplane. At present, however, this is purely a scientific toy.

TABLE 2 MILEAGE AND TRAFFIC STATISTICS FOR PRIVATELY OPERATED AIR-MAIL ROUTES WITHIN THE U.S.A., FOR YEAR ENDING JUNE 30, 1929[1]

Month (all routes)	Length of routes, miles	Miles of service actually flown	Total weight of mails dispatched, pounds	Amount paid to contractors
July, 1928	12,021	653,883	214,572	$445,238.41

[1] Compiled from Post Office Department figures by Black & Bigelow, Inc., New York, N. Y.

Within the past twelve months the Department of Commerce has made certain modifications in its regulations governing the licensing of pilots. These changes constitute a general tightening up of the previous regulations, so that a pilot who is licensed to fly a certain type of aircraft will hereafter be required to take an additional examination to fly a type very much larger than the one on which he obtained his license.

As this report is being written, the manufacturing side of the industry is undergoing a certain amount of readjustment, due to an increase of production at a greater rate than the increase in sales, combined with the seasonal drop in sales which usually occurs in the fall. This addition is most noted in the case of the smaller types of airplanes such as are sold to private owners. While this readjustment period will be a painful one for certain of the manufacturers, particularly those who are not very well financed, it is a passing phase, and the manufacturing side of the industry and should again be in sound condition when the seasonal increase in sales develops in the spring of 1930.

One of the interesting developments of the past year was the entrance of General Motors Corporation into the aviation field through the purchase of a substantial interest in the Fokker Company, and by close association with the Bendix Aviation Corporation through ownership of about twenty-five per cent of its stock.

Table 2 shows the continued growth of air-mail traffic and mileage development in the United States, while Table 3 shows the air-transport mileage of the world. It will be noted from this latter table that the lead which was attained by the United States between 1925 and 1926 has not only been held but has been very substantially increased in the past year.

The recent experiments of the Guggenheim Fund in connection with fog flying are being carefully watched by all operators and have been very promising up to date. Because of these experiments, the coming year may find the operator in a much better position to master the question of fog than he has been at any time heretofore. The use of radio in airways in the United States is becoming much more general, and several operators are now depending upon radio communication with airplanes in flight for the purposes of furnishing weather information and keeping in touch with pilots en route.

The railroads are now showing considerable interest in air-transport development, and in a few cases joint air-rail services have already been organized in which the railroad and airplane operations are coordinated and through tickets sold so that the passenger can make a through flight, using the train for part of the way and the air-service company for the remainder of the trip.

Progress of Naval Aviation[5]

Naval-aviation progress during the past year has continued to demonstrate the wisdom and soundness of the Navy's Five-Year Building Program as authorized by act of Congress approved June 24, 1926. Progress toward the accomplishment of this program is continuing satisfactorily, and it is important that this program be completed as authorized, on time and without material changes.

During the year, naval aviators flew a total of 205,421 hours. The average pilot flew about 216 hours, or about 19 per cent more than in the previous year. In the Fleet approximately 285 planes were being operated. Scouting, torpedo and bombing, observation, and fighting planes were carried on the *Lexington*, *Saratoga*, and *Langley;* and fighting and observation planes were operating from catapults on the battleships, while each light cruiser operated two observation planes.

The year opened with the Fleet's annual cruise in southern waters, participated in, this year, for the first time, by the two carriers, *Saratoga* and *Lexington*. Together with the battleship

[5] Prepared by Rear-Admiral Wm. A. Moffett, U. S. N., Chief of the Bureau of Aeronautics, Washington, D. C.

and cruiser planes, the carrier planes demonstrated every possible form of offense against surface craft and shore bases. Torpedo planes delivered attacks through smoke screens, fighting planes delivered attacks on surface vessels and shore stations, while radio-equipped observation planes kept the ships constantly informed of all phases of the "War." A night air raid sent out by one of the carriers while she was yet 150 miles off the coast of Panama, theoretically destroyed the locks. Two hundred forty-seven planes took part in the maneuvers and flew 4397 hours over nearly half a million miles, in every kind of weather and under varying conditions, without a single serious accident. The authorization of an additional aircraft carrier evidences Congress' realization not only of the need for, but of the expediency of, this type of tonnage in the Fleet. However, there is still an urgent need of additional carrier tonnage to provide for the expansion of the air arm in accordance with its proportionate

FIG. 1 NEW TYPE OF PURSUIT PLANE MANUFACTURED BY THE BOEING COMPANY AND POWERED WITH A PRATT & WHITNEY 420-HP. "WASP" ENGINE

(This type is known as the P-12 and is in use at the present time in certain service squadrons.)

relationship to the Fleet as a whole, and in order to provide the parity of aircraft-carrier tonnage allowed in the Washington Limitation of Armaments Treaty.

The Navy now has on hand or in production aircraft suitable for carrying out any mission which the forces afloat may be called on to accomplish. There are two new types of fighters being produced and a third type being experimented with; deliveries are being made on a large order for a modification of the present type of observation plane, while two new experimental types are under test; a modification of the standard torpedo and bombing plane is in production, and several experimental types are being tested; development of the patrol-type program, along both monoplane and biplane lines, is proceeding satisfactorily; of these, 55 airplanes have been contracted for on the basis of the development of the biplane PN-12, and a small production order placed for monoplane patrol boats similar to the XPY-1.

To provide all types of planes with suitable power plants, aircraft-engine development has been stressed particularly on the score of increased reliability along with further reduction in weight—factors which are mandatory in the design and construction of naval aircraft because of the limitation imposed by shipboard operating conditions. The air-cooled engine ranging in power from 200 to 600 hp. is standard in all types of Navy planes.

The two detachments of the naval air service which provided perhaps the most spectacular demonstration of successful aircraft operation during the year were the Marine Detachment in Nicaragua and the Naval Aerial Survey Detachment in Alaska. In Nicaragua, six tri-motored transport planes have been in daily use transporting personnel, food, ammunition, and other supplies through every sort of weather over rough, wild country. Ground units have been communicated with at least once daily from the air, and aerial escorts have been provided marching units. In Alaska, four amphibian planes continued the work of mapping which was so successfully initiated in 1926. The survey has proved to be of great value in the investigation of the mineral resources of Alaska, the location of forests, the discovery of new sources of water power, and in road and trail building through hitherto unpenetrated territory. The most outstanding single accomplishment of the expedition was the discovery of a 900-acre lake within three miles of the coast and at an elevation of over 2500 ft. The fall from the lake level to sea level is so abrupt that dam construction is unnecessary.

Progress on the Navy's lighter-than-air program is marked by the beginning of actual construction work on the first of the two dirigibles contracted for in 1928, and by the completion of the *ZMC-2* (metalclad) airship. Operations with the *Los Angeles* have included training flights and those on which tests of various apparatus have been made, principally the device for attaching airplanes to the airship, and mooring devices. A number of plane hook-ons have been successfully carried out.

Developments of the past year have conclusively shown the immense value of aircraft carriers, and it is considered that the most important requirement of naval aviation at the present time is to secure as soon as possible the additional carriers necessary to give the Navy the authorized carrier parity of tonnage allowed under the Washington Limitation of Armaments Treaty.

MILITARY AIRCRAFT PROGRESS IN 1929[6]

A more complete and general acceptance of aircraft as a most vital factor to any scheme of national defense coupled with steady increase in their performance and effectiveness, has marked the progress of military aeronautics during the past year. Keeping pace with the development of new and better equipment, those in charge of its employment have enlarged the field of aerial activities until hardly a tactical problem is now considered without giving much serious attention to the action of friendly and enemy air forces. Military aircraft should not be expected to displace

FIG. 2 EXPERIMENTAL THOMAS-MORSE PURSUIT AIRPLANE KNOWN AS THE "VIPER"

(This plane is interesting from two angles: construction—corrugated aluminum alloy; powered with a 650-hp. Curtiss "Chieftain" engine.)

any essential element in our present organization, such as the artillery, infantry, or the corps of engineers. A most important function is to cooperate with these various arms, increasing the efficiency of each as well as bringing a tremendous offensive machine into play against the enemy.

There are six general types of heavier-than-air craft in general

[6] Prepared by S. P. Mills, Matériel Division, Air Corps, U. S. A., Washington, D. C.

use by the United States Army today. They consist of training airplanes, observation, attack, pursuit, light bombardment, and cargo or transport airplanes. While there are many sound arguments against any considerable number of different types of airplanes in the service, yet it appears absolutely necessary to build many types in order to obtain airplanes of greatest effectiveness for the particular work which is required.

During the year the training planes in use were of the same general type as used the previous year. In place of the 180-hp. water-cooled Wright Hispano-type engine, we find a 9-cylinder air-cooled radial engine of the type which Colonel Lindbergh used in his famous transatlantic flight. The change represents an increase of approximately 45 hp., without an increase of overall weight, and was made due to the availability of the new engine and the desire to use the air-cooled type. A complete overhaul is given these engines after approximately 200 hours' training service. The air-cooled engines are now fitted with elaborate air filters attached to the carburetor air intake or air-intake pipes which conduct the air from the top and inside of the fuselage, schemes which eliminate a considerable portion of the usual cylinder wear due to operation upon dusty fields. It is predicted by many that much lighter and lower-powered airplanes will be used in the future, but the average Army pilot apparently favors a liberal amount of power, giving the airplane a maximum speed which is at least 40 m.p.h. above minimum. All Government training airplanes are now of the steel-tube-fuselage type, with a biplane structure of fabric-covered wooden wings. The steel-tubing structure has proved more satisfactory in every way, and appears to offer a surprising amount of protection to the crew in event of a crash. Training airplanes of this type have crashed into the ground from tail spins repeatedly without fatally injuring the occupants. The ability to stand abuse has been given a great deal of attention by engineers, a quality which has inspired the development of more rugged landing gears and wheels. The "Musselman" or "doughnut" type of wheel whose tire is very large in section and is mounted directly upon the hub, uses an air pressure of only 4 to 8 lb. per sq. in. This equipment give promise of cushioning the severe landings experienced while training students.

In the observation type of airplane the tendency to adopt the air-cooled engine is also present, although not so universally recognized yet as in the case of the training airplane. For several years the majority of the observation airplanes have been equipped with 410-hp. water-cooled Liberty engines. The wide use of the Liberty engine in recent years has been due to a surplus of such engines since the war period. Each year has added its improvements to the Liberty engine, until today many pilots still consider it a most dependable aircraft engine. The Government has definitely dropped the Liberty engine as equipment for any new-type airplanes. The use of radial air-cooled engines effects a saving of from 300 to 400 lb. installed weight in an observation airplane, a fact which greatly increases the rate of climb, and improves the take-off and all-around performance at higher altitudes. The maximum speed at the ground is apparently no greater, but increased performance along other lines appears to justify such installations.

There are three observation airplanes in use today: the Douglas series known as the O-2 (the O-2H being used in considerable numbers), the Curtiss series, and that manufactured by the Thomas-Morse Corporation. The Douglas O-2H airplane which is standard in the Air Corps this year is equipped with a water-cooled Liberty engine mounting a nose radiator and providing an exceptionally roomy cockpit for the gunner immediately to the rear of the pilot. It is of interest to note here that the Mexican Government has purchased nine new airplanes of the general O-2H type but equipped with Pratt & Whitney 525-hp. Hornet engines. The Mexicans report excellent performance from these airplanes, particularly under conditions where they are operated from the many very high-altitude landing fields throughout Mexico. The Curtiss series of observation airplanes mount either the water-cooled Liberty or the water-cooled Curtiss D-12 engine. Future plans for this series will use both air-cooled radial engines and liquid-cooled engines of higher horsepower. The Thomas-Morse observation airplanes will use radial air-cooled engines.

Three different types of fuselage construction are represented by three different makes of airplanes: the Douglas using a structure made of chrome-molybdenum steel tubing welded at the joints, the Curtiss, aluminum-alloy tubing riveted or bolted, and the Thomas-Morse, using a corrugated aluminum-alloy shell. Time alone will tell which type of construction will find the greatest favor in the service. Each type apparently offers the

FIG. 3 CURTISS PURSUIT P-1B EQUIPPED WITH CURTISS D-12 ENGINE AND ETHYLENE GLYCOL SYSTEM OF COOLING
(Note the very small radiator necessary to give the required cooling.)

crew of a plane a much greater protection in the event of a crash than the wood-wire construction. As judged from the experiences of the Air Corps during 1929, the tendency in observation practice appears to increase the performance by the addition of more horsepower and the material reduction of weight of the power plants. Another marked tendency is the increasing use of metal. It is not unlikely that in the future we shall see all-metal observation airplanes whose performance is very little behind that of the combat and pursuit class, some of which may use two or more engines and possibly carry a crew of more than two men.

In attack aviation the types generally used have been a sort of converted observation airplane powered by either an air- or water-cooled engine. The year has witnessed an increase in speed of attack airplanes and a great deal of additional experience on the part of attack personnel. Indications point toward the development of a specialized attack airplane whose forward speed at ground level will be considered the most important single feature, with maneuverability, vision, and machine-gun operation important additional considerations. It is possible that certain classes of attack airplanes may be provided with limited quantities of bullet-glancing armor plate placed around certain vital points of the cockpits and engines. Future attack airplanes may be equipped for doing much of their work under cover of darkness. The attack upon troops, and particularly upon supply trains, bridges, roads, and other small objects immediately in the rear of the scene of action will undoubtedly play a most important part in military campaigns.

The Curtiss and Boeing companies have provided the majority of service pursuit airplanes in present use. The past year has witnessed the equipping of certain squadrons with new pursuit airplanes powered with the radial air-cooled engines. As in the observation, the radial engines increase the all-around performance of pursuit airplanes. The speed due to the change of engines alone has not materially increased, but the airplanes themselves represent an advancement in this line. The new radial-engine-powered pursuit airplanes do not appear to have quite the diving properties of the water-cooled, but their rate of climb and performance at altitude are unquestionably better. A most interesting development during the year has been the substitution of ethylene glycol for water as a cooling medium in the radiators of pursuit airplanes. As a result of this scheme, the weight of a pursuit airplane is reduced about 100 lb., the size of the radiator is decreased 70 per cent, and the fuel economy for a given horsepower is considerably improved. Due to the high boiling point of this liquid (387 deg. fahr.), it is possible to operate the engines at an outlet temperature of 300 deg. with a loss of only two per cent in horsepower. Service tests of over 120 hours' satisfactory operation with this cooling system, indicate that the length of life of engines will not be materially decreased. Researches are now being conducted which will determine this more accurately. Should the new cooling system meet favor throughout the service, it is likely that it will be much used in the future by racing airplanes and certain classes of military aircraft.

Paralleling the development of ethylene glycol cooling has been the design and development of a series of cowls capable of entirely enclosing radial air-cooled engines. Speed increases of up to 17 m.p.h. have been recorded on pursuit planes using such equipment. In certain cases the cooling of an engine at full throttle has been somewhat impaired and the visibility of the pilot considerably reduced. While using a Matériel Division cowl on a P-12 pursuit airplane equipped with a supercharged Pratt & Whitney radial air-cooled engine, Captain R. G. Breene of Wright Field averaged 186 m.p.h. over a triangular course in the free-for-all race at Cleveland on September 2, 1929. The work of this development has been carried on by the Matériel Division of the Air Corps and also by the National Advisory Committee for Aeronautics. Although such cowls possess certain disadvantages, nevertheless any equipment which increases the speed of an airplane by 10 per cent must be reckoned with in future developments.

FIG. 4 NEW DOUGLAS ADVANCED TRAINING AIRPLANE
(Similar to the Douglas observation plane except that it is powered with a Pratt & Whitney "Wasp" engine instead of a Liberty engine.)

An effort to increase the speed of pursuit airplanes which is being followed closely is the use of a Curtiss Chieftain, a 12-cylinder double-bank radial air-cooled engine. Such an engine, while delivering in excess of 600 hp., has the same overall diameter as the Wright J-5 Whirlwind engine which delivers 230 hp. The Chieftain engine is still being experimented with in the laboratories of the Curtiss Company and the Matériel Division, and every effort is being made to develop this engine for pursuit and observation work. Possessing as it does its high horsepower and light installed weight characteristics of air-cooled engines, it has the further advantage of streamlining satisfactorily into a fuselage

and obstructing the vision of the pilot to a less extent than the single-bank radial of equal horsepower.

American pursuit airplanes are generally of the biplane type and constructed usually of welded steel tubing or of square duralumin tubing riveted and bolted together. As a result of observing the winners of the races of recent years, it would seem that the low-wing, all-metal monoplane will some time find its place as a combat and pursuit machine. It is likely that the retractable landing gear and increased horsepower with greatly reduced radiators will be the tendency in future pursuit development.

The development in bombardment aviation has been of a power plants. The year 1929 has witnessed the real beginning of the use of gearing in Air Corps bombing and observation airplanes. The twin-engine type of bomber appears to be still held in highest favor by the service as it gives a better distribution of defensive armament. The development of the Fokker F-32, a large transport monoplane powered with four 525-hp. engines, is being watched with much interest by various countries. This plane, with a reported maximum speed of 155 m.p.h., is likely to furnish some valuable ideas to the designers of bombardment airplanes. The construction of the modern bombing airplane follows much the same type as other classes: namely, the welded-steel-tube fuselage as used by Keystone Company and the bolted

FIG. 5 THOMAS-MORSE O-19 OBSERVATION AIRPLANE POWERED WITH A PRATT & WHITNEY "WASP" ENGINE
(Note the corrugated aluminum-alloy fuselage.)

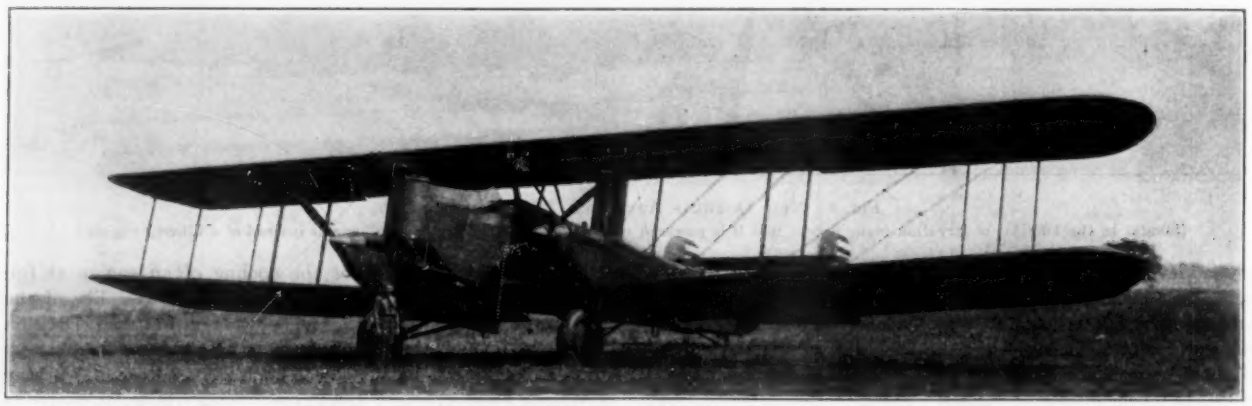

FIG. 6 CURTISS "CONDOR" BOMBER, POWERED WITH TWO 620-HP. CURTISS GEARED "CONQUEROR" ENGINES
(Note that a gunner is placed in the nacelle behind each engine.)

sound, consistent nature, resulting in a steady though not revolutionary increase in performance. The Liberty engines have gradually been displaced by Pratt & Whitney Hornet and Wright Cyclone engines of 525 hp. each, with a resulting conservative increare in speed and a considerable improvement in rate-of-climb and performance characteristics. The Keystone bombers thus equipped have shown speeds of over 120 m.p.h. coupled with satisfactory ability to handle big loads. The year has witnessed the supplying to the service of several Curtiss Condor bombing airplanes each equipped with two 625-hp. geared Curtiss Conqueror engines. The use of geared engines appears to give a material increase in propeller efficiency, and it is probable that the geared engine will be used to a greater and greater extent in future machines of this kind. The United States is probably a little behind certain other nations in the employment of geared and riveted duralumin fuselage as used by Curtiss Company. Again the tendency is toward a greater and greater percentage of metal construction and the addition of more horsepower.

Cargo and transport airplanes for the transportation of ammunition, supplies of all kinds, and even of troops, will undoubtedly be in great demand during the next emergency. In general it is expected their designs will follow that of a modified bomber with ability to carry tremendous loads from restricted fields, which means the probable employment of geared engines and controllable-pitch propellers. In all probability the speeds of bombers will be very much increased, using speed as a defensive measure rather than carrying so much weight in the defensive armament.

The year 1929 will be remembered in history of military aeronautics as the year during which the wartime Liberty engine was

finally discarded, being replaced largely by the new radial air-cooled engines. It will also be remembered for the attempted "come back" on the part of water-cooled engines through the employment of new cooling systems and the installation of several models of geared engines. Other developments too numerous to mention, such as the successful use of propellers which can be adjusted during flight, new high-altitude equipment, photographic equipment, parachutes with a more satisfactory operation, have all been pushed with much interest and painstaking care. Increasing use of metal construction and increased power have each contributed to increasing the performance of our military aircraft. It is imperative that this work of development be continued and that we learn all lessons possible from races, experiences of other countries, and commercial activities, in order that this important branch of the national defense shall be maintained at its highest point of efficiency.

Airships[7]

The circumnavigation of the world by the airship *Graf Zeppelin* in twenty-one days total time, or twelve days of actual flying time, was the outstanding aeronautical event of the year. In addition to the around-the-world flight, the *Graf Zeppelin* twice crossed the Atlantic between Lakehurst and Friedrichshafen. Notable flights were also made by this airship over Europe and Asia Minor. In May, the *Graf Zeppelin* made an unsuccessful attempt to cross the Atlantic, but because of engine failure was obliged to put into the French airport Cuers, near Toulon. This event caused some shaking of heads among the airship doubters, but an actual study of the course of events on this occasion showed the extraordinary ability of the airship to make port safely in spite of a must unusual accident. Four out of the five engines suffered broken crankshafts due to torsional vibrations induced by stiffening the couplings between the engines and propellers. With only one engine remaining in operation the *Graf Zeppelin* was able to make port in spite of strong adverse winds. The Zeppelin and Maybach companies, builders of the hull and engines, respectively, of the *Graf Zeppelin*, profited by this accident to study the subject of torsional vibration. The faulty couplings in the *Graf Zeppelin* were replaced by others which eliminated the disastrous periodicity in the power plant.

The two large British airships, *R-100* and *R-101*, of over 5,000,000 cu. ft. gas volume, have been completed and inflated with hydrogen. At the present writing they are practically ready for their trial flights. These airships are of a novel type, differing considerably from the Zeppelin pattern to which practically all previous rigid airships have closely conformed. The usual development troubles in a new type may be expected, but there is no reason for the prognostications of failure of these airships which have been broadcast by their opponents.

The small experimental metalclad airship *ZMC-2*, designed and constructed for the Navy Department by the Aircraft Development Corporation, of Detroit, Michigan, has successfully passed through its trials and been accepted by the Navy. Considering the extreme novelty of this airship, its trials were extraordinarily successful and free from troubles. On the other hand, it should be remembered that this ship has not yet been subject to the crucial tests of flying in rough weather, to continued exposure to the atmosphere, or to severe alternating stresses. A true estimate of the value of the metalclad construction for airships cannot be made until after the test of continued service.

The U. S. S. *Los Angeles* has been throughout the year in almost constant service, although no particularly long or spectacular flights have been made. Important work in the development of handling airships has been carried on with the *Los Angeles*. These developments include extended use of the stub mooring mast, and successful trials with a mobile mooring mast which can be towed in and out of the hangar with the bow of the airship attached to it.

A trapeze for carrying, releasing, and hooking on airplanes has been installed and successfully tested on the *Los Angeles*. Similar experiments have been carried out before with very light airplanes, but the installation on the *Los Angeles* is the first of its kind suitable for continued use, and adaptable to planes of real military value.

The Goodyear-Zeppelin Corporation at Akron has made good progress in the detailed design of the new 6,500,000-cu. ft. airships *ZRS-4* and *ZRS-5* for the U. S. Navy. Many of the girders for the first airship have been constructed, and assembly is now under way in the corporation's new huge airship factory and dock. A great deal of experiment and development work in connection with the details of these airships has been carried on during the year.

Airports[8]

A careful inspection of many of the nation's largest airports will probably disclose the fact that many of them are "white elephants." The financing of airports has frequently been of a sensational nature, and all too frequently the planning has been

TABLE 4 AIRPORTS AND LANDING FIELDS IN THE UNITED STATES ON JUNE 30, 1929

NOTE: The number of airports in column marked "Lighted" is included in the other columns and is not additional.

[7] Prepared by C. P. Burgess, Bureau of Aeronautics, Navy Department, Washington, D. C.

[8] Prepared by John Bonforte, Transcontinental Air Transport, Inc. Washington, D. C. Jun. A.S.M.E.

more of the kind to catch the eye of the investor rather than that of the flier.

However, much real constructive work has been done. Competent architects and better engineers are being employed for airport work. Plans are generally made with an eye to the future as well as to the immediate present. Airports have been laid out in many parts of the country. A list of airports and landing fields in the United States on June 30, 1929,[9] is given in Table 4.

It should be clearly understood that few of these airports and flying fields are beyond the preliminary stages of construction. Airports are like cities: they cannot be built in a day, a year, or even two or three years. It is probably true to say that airports, like many other progressive works of construction, are forever being built but are never completed.

Various trends noted in airport construction during the past year are indicated below.

Proximity and Accessibility of Airports to City. A strong present-day tendency is the location of airports closer and closer to the heart of the city. Close-in airport locations have probably been overemphasized, and the economic pressure of overhead costs will probably soon force airports out in the open country again.

The means of communication, the convenience of communication, and the time of travel from the business sections of cities to their airports are now given full consideration in the selection of an airport, and a general improvement in these features is readily noticed.

Building Construction. One extremely interesting construction this year has been the erection of the "hex-hangar" as a repair shop for the Western Air Express Company at Los Angeles. This innovation will undoubtedly be closely watched, and if the results prove successful, the widespread use of such a hangar as a repair depot is almost sure to follow.

Hangar doors have received special study. Practically all those used today are of the sliding, all-steel-construction type. Some hangar doors are of tubular construction, but the majority are of angle construction. The construction of hangar doors is also divided between the straight-rolling type and the round-the-corner type. The former is apparently in the majority. A recent hangar construction included the installation of motor-operated cantilever doors. The installation of this type of door is still too new for an opinion to be given regarding its general adoption by the aircraft industry.

Many airports now have comfortable waiting rooms and restaurants for passengers comparable to the best found in railroad stations. In addition, clubhouses, swimming pools, and other outdoor sports features are being installed at a few airports for club members.

Weather, Radio, and Communication Service. Reliable weather data are a feature of all the major airports. This has been made possible through the cooperation of the Department of Commerce. The use of radio and of the automatic telephone-typewriter system have also aided greatly in expediting the dissemination of weather data, as well as other pertinent information.

The telephone-typewriter has been found especially useful in the relaying of telegraph messages between the airport and the central telegraph office in the business section of the city.

Service Facilities. Improved service and repair facilities are noticeable at all airports. One of the major improvements is the underground electric fueling pits. The pumps used in conjunction with these electric fueling devices generally have a fueling capacity of 20 to 30 gal. per min.

Field service has also been greatly aided by the improved hangars and repair shops that have been built, where oil and water may be heated on cold days and general repairs on planes and engines conveniently made.

Drainage and Runways. These two parts of airport construction go together, for neither should be planned without fully considering the other.

The importance of adequate drainage at airports can hardly be overestimated, for it is truly the foundation of a good airport. Natural drainage is depended upon at some airports, but it is seldom adequate for all weather conditions. The increased use of hard-surfaced runways is making at least partial artificial drainage imperative. The tendency is, however, to tile the entire airport with pipe of such size that it will continue to function even after many years of silt filtration have partially clogged the pipes.

The trend in runway building is difficult to set down precisely. It varies with the climate, the materials available, the money available, and the uses of the airport. Concrete will probably never come into general use as a runway surface so long as its cost remains where it is at present, namely, between $2.50 and $3.00 per sq. yd. of 8-in. thickness.

The trend seems to be to surface the runway as cheaply as possible with oil, asphalt, or other bituminous material, and then to improve it from year to year as finances and requirements dictate.

Cinders, broken stone, and other loose materials have also been used as runway surfaces. While all these have many advantages, such as low cost, excellent drainage surface, etc., they also have such fundamental disadvantages as being very dusty in dry weather, and flying up and knicking the propellers of airplanes taxying across the field. These objections will undoubtedly limit the use of these loosely bound materials to the inferior airports.

Airport Lighting. Airport lighting has probably advanced least in point of efficiency of all the airport construction problems. The reasons for this slow advancement are:

1 Airport managers have only a meager knowledge of airport lighting

2 Few of the lighting companies understand the airport lighting problem. Consequently, they simply modify existing lighting equipment intended for railroad, marine, or airway use and market it for airport use.

In the future, adequate means of lighting runways distinctly will have to be developed. One or two firms are already marketing lighting products for such a purpose. Their efficacy and value are still undetermined.

Marking of Airports. The Department of Commerce is leading the way in the better marking of airports by installing and painting metal cones around each boundary light at intermediate fields, and placing a 6-ft.-diameter ground marker of white crushed stone at the base of each boundary light.

Another necessary marking at airports is the increased use of wind cones. In these days of mile-square airports, a single dirty wind cone flapping indistinguishably a mile away from the point of landing is of little value.

Landscaping of Airports. Airport landscaping is at present only the sketchy dreaming of architects. One finds it in drawings but not in actuality. However, as planning must precede achievement, it is certain that better- and better-looking airports will be built.

The Theory of the Autogiro

By JUAN DE LA CIERVA,[1] SPAIN

The author, realizing the fundamental limitations of the ordinary airplane, has worked for years to produce a new system of flying. Passing the helicopter and ornithopter stage, a machine was devised with articulating blades that could flap freely, the dissymmetry of the reactions on opposite blades being thereby overcome.

MOST persons know what the autogiro is, how it looks, and how it works, so that I am not going to enter into a detailed description of what the autogiro is. Instead I will try to convey briefly the philosophy of the autogiro, as an introduction to its theory.

I have been working for many years on the ordinary airplane. I am a great enthusiast of the airplane, and I think it is the most marvelous invention of modern times; but a long time ago I came to the conclusion that the plane had fundamental limitations due to its own nature, and I tried to produce a new system of flying free from those limitations. I thought that the airplane could be improved quantitatively in every direction, but my thought was and still is that no improvement can change the very nature of the airplane and its qualitative limitations.

After a certain amount of theoretical work I reached the conclusion that the only method for removing those fundamental limitations was to make the wings relatively independent of the frame or body of the machine, so as to make it possible to keep them going fast through the air while the machine could be going slowly or even be stationary. I saw the possibility of achieving this result without the introduction of mechanical complications such as those which inevitably will happen in the helicopter or ornithopter, or, generally speaking, in flying machines with driven wings, and I started then the study of a very primitive autogiro which only was related to the existing machine by the fundamental idea of freely rotating wings.

I am not going to explain in detail the long and painful experimental period through which the autogiro has passed to the present moment. I only point out to you that I did not achieve success at all until I had the idea of articulating the blades of the autogiro so as to let them flap freely, since there were too many mechanical and aerodynamical problems that could be solved only in that way.

The main problem I solved in this way was the dissymmetry of the reactions on opposite blades, since there is a single group of them rotating in the same direction. On one side of the machine the speed for a given point of the blade will be the addition of the general speed of advance of the machine and the peripheral speed, while on the opposite side there will be the difference.

To balance the lift in those two opposite planes by means of controls that would periodically change the incidence of the blade is a most difficult problem, and this solution of the articulation does it automatically and in a very simple way.

The aerodynamics of the autogiro is a very complicated problem, if one considers how difficult are the problems involved in the calculation of ordinary propellers and that the autogiro can be likened to a propeller with three or four more parameters. It is a propeller which is advancing through the air with a great obliquity and with blades which are free to flap. The speed and the incidence at every point of every blade at every moment are different. I cannot try to make a detailed analysis of the aerodynamical qualities of the autogiro and compare them with those of the ordinary airplane. Nevertheless, and in answer to an extended criticism to the autogiro, I want to point out that there is no fundamental reason why the autogiro should be aerodynamically inferior to the airplane. It has been said that, since the speed of the blades of the autogiro through the air is higher than the corresponding wings of the equivalent airplane, the energy expended will be greater. The autogiro because of its special qualities in landing is free from the necessity of having big wing surfaces, and in consequence it can utilize very high wing loadings, which means higher aerodynamical efficiency.

FIG. 1

The autogiro by its aerodynamical nature is not subject to any of the risk of stalling. The wings always move fast through the air, whatever the speed of displacement of the fuselage. It can be stopped in the air for a moment without losing completely its lift. If by a sudden maneuver, such as the pulling back of the stick, the machine is brought to a standstill in the air, the wings still continue for a moment to rotate under the action of their momentum, and they still give a certain amount of lift. This feature makes this machine fundamentally different from the airplane, which, when it is stalled, loses all grip on the air. As the movement of the blades continues even when the machine is not moving with any forward speed, the autogiro can become a parachute at the will of its pilot; and a most interesting aerodynamic problem can be pointed out in this connection. I had predicted as far back as 1921, by theoretical considerations, and since then I have confirmed them by experiments which have been checked by the officials of several governments, that the efficiency of the autogiro as a parachute is considerably higher than that of the ordinary parachute. As a fact it does not need discussion, and I should like to point out that the efficiency of this machine as a parachute is three times as high as that of an ordinary parachute formed by a disk of the same diameter as its rotor.

[1] United States representative: Pitcairn-Cierva Autogiro Company of America, Philadelphia, Pa.

Presented at the Great Lakes Aeronautic Meeting, Cleveland, Ohio, August 31, 1929, of the Aeronautic Division of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

The physical explanation of that phenomena is that, contrary to what most aerodynamists think, the mass of air influenced every second is much larger than that corresponding to the volume equal to the product of the surface of the rotor by the speed of descent. The ordinary parachute practically has an efficiency corresponding to the optimum in this assumption, and if there is considered the considerable amount of energy wasted in the complex vortices in its wake, it is obvious that a much greater efficiency can be achieved by a parachute like the autogiro in which the flow is much more smooth and regular. My theoretical results are that the optimum possible parachute would have an efficiency equal to six times that of the disk, and the present autogiro achieves about 50 per cent of that optimum.

Structurally the autogiro is based on a very different principle from that of the airplane. The wings of the airplane are constructed in such a way as to resist the stresses with rigidity, while the autogiro is a flexible structure. Sudden changes in incidence or speed do not increase the structural stresses in the same measure as they increase those of an airplane. The centrifugal force which keeps the blades approximately horizontal acts as a spring of long travel and gives the autogiro the quality of a much greater comfort. It has a smoothness in flight which is greatly different from the feeling that is produced in the flight of an airplane in bumpy weather. Many people ask whether the autogiro can fly in bumpy weather, and I can say that the autogiro is much less sensitive to bumps than is an ordinary airplane and that this is due to the flexible nature of its structure.

AER-52-3

The Problem of Catapulting Aircraft From Commercial Vessels

By LIEUT. WM. M. FELLERS, U. S. N.,[1] WASHINGTON, D. C.

After describing the catapult mechanism and the launching car, the author discusses the development of catapult launching by the U. S. Navy. Following this he outlines the several steps in launching a plane, stating the precautions which should be taken. In conclusion he discusses the possibilities of a ship-to-shore plane service, using catapults. It is his belief that the same mechanisms employed successfully in the Navy can be transferred almost intact to any commercial vessel, and that planes can be launched from shipboard with a degree of regularity and safety compatible with commercial operation.

THE unsolved part of the problem of catapulting aircraft from commercial vessels is largely an economic one. The technical part has been solved, as is demonstrated by more than seven years of service on the battleships and cruisers of the United States Navy. During this time experimentation and development have been continuous. Thousands of launchings have been made, and to date there has not been a single fatality or even serious injury to personnel as a result of catapulting.

It seems certain that the same mechanisms employed successfully in the Navy can be transferred intact to almost any commercial vessel, and that planes can be launched with a degree of regularity and safety compatible with commercial operation.

The Catapult

The catapult is a device to bring the airplane from a state of rest to one of minimum flight speed within the restricted space available aboard ships of conventional design. Catapults have been built through large ranges of length, and with various types of prime movers. In all cases it has been necessary to devise a prime mover capable of delivering a relatively large force for a comparatively short time, and the consideration of weight has been of major importance. Compressed-air and powder engines are both used in the service. A flywheel is used on one type to store up energy and deliver it during the launching interval. The author has been informed that a hydraulic catapult has been tried but abandoned. Probably it, as well as steam types, could be developed, although it is doubtful whether such catapults would be as serviceable as the ones now used.

To engineers accustomed to thinking in terms of accelerations and decelerations of trains, automobiles, and other vehicles used for passenger carrying, it will be interesting to know that accelerations of 90 ft. per sec. per sec. are regularly used during the launching period of airplanes. This is nearly three times the acceleration due to gravity. The car on which the airplane is held before and during the launching interval is brought to rest at the end of its launching stroke and returned to the starting point to launch the second plane. To conserve length of structure and to devote as much of it as possible to bringing the airplane up to speed, the stopping of the launching car is accomplished in as short a distance as practicable, and the deceleration is of the order of 100 times gravity.

[1] Bureau of Aeronautics, Navy Department.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

The Launching Car

The launching car is, to many, the most interesting part of the whole mechanism. It must hold the airplane in the proper attitude before and during launching, and must be strong enough to resist the forces acting on it during that time. In addition, it must resist a force of 100 times its weight during the deceleration or stopping process. If the car weighs 1000 lb., it must resist the action of 100,000 lb. during stopping. One engineer aptly said, "It lives in a little universe of 100 g, and lives!"

If a launching car were taken from its catapult and placed in a vertical position, and if a hundred other launching cars were placed on top of it in such a way that the upended one supported all that weight, the force acting on the bottom car would be the same as that acting during the deceleration period immediately following a full-speed launching.

Of course, the pilot and plane are not subjected to this deceleration. It is much beyond anything that could be endured by either. Instruments in planes have registered $12\,g$ during certain maneuvers. The pilot lived, but experienced a dislocation of his organs that put him in the hospital. A deceleration of $3\,g$ seems to be within the capacity of nearly all normal people to stand without discomfort. However, commercial passenger-despatching catapults will probably be made with slightly less acceleration, with either longer runs or slower end speeds.

The sensation of being launched is similar in degree to that experienced when an inapt automobile driver suddenly engages the clutch of a car with the gear in first and the engine racing. The only difference is that the catapult keeps on pushing, and the automobile engine either stalls completely or slows down in short order. The duration of a launching is from one to one and one-half seconds, depending on the run and end speed. This time is so short that it is not until after several launchings have been experienced that an individual learns to separate events into start, run, and release—it's just one grand push. Let the word "push" be emphasized; it is a push, not a blow.

Catapult Development in the Navy

One reason for the lack of casualties in connection with catapult development in the Navy has been careful design in the first place, followed by thorough proofing of each unit. Each report of malfunctioning has been studied, and whenever possible, even when the cause has obviously been due to lack of care in operating, simpler or better mechanism has been developed to replace the parts which gave trouble. It has been the ideal to furnish fool-proof mechanism. This ideal has not been reached, but progress has been made.

On the first catapults there were so many valves to be operated, each in its proper sequence, that operators needed long and careful training to make them proficient, and even with the best training many individuals were found who could not be depended upon to operate them properly. The control mechanism has now been simplified to the point where it is only necessary to pull a string or move a single lever to place the catapult in motion. As a result, reports of failures to complete an attempted launching satisfactorily have practically disappeared.

It is hoped that commercial development, when it comes, will follow along conservative lines and maintain the good record made so far.

Precautions Taken in Launching a Plane

Before the pilot climbs into his plane to be catapulted, the plane is inspected carefully and serviced. Particular care is taken to see that nothing is left adrift to fly back in his face or hit him in the solar plexus. Any freight to be carried must also be secured against motion aft, or it would all wind up in the extreme aft position, or possibly carry away completely and left behind.

The plane itself is then secured on its launching car so that it will not capsize due to a side wind, rotate forward due to the force acting through the propeller during the engine warming-up process, slide forward on the car due to the same force, or slide off backward during the accelerated run, or rear up in front. Whatever the means employed, it is imperative that the plane be released so that at the end of the accelerated run it is free to leave the car and will be in an attitude to start normal flight.

The loaded launching car is brought back to "battery" position and locked there. The pilot takes his place and the engine is started. As the engine becomes warm it is speeded up until finally it is running all out. This is done to test the engine and make sure that it is developing full power. The lock serves to hold the plane and car in the starting position during this test and also allows all slack to be taken out of the entire catapult system. Any slack would result in a jerky start, and sufficient slack would result in waves of force reaching the plane that might wreck it.

The plane is now slowed down to idling speed, and the signal to launch is awaited. In the fleet this signal comes from the flagship, and is made by first hoisting a series of flags, then pulling them down. The hoisting is the preparatory signal, the hauling down is the execution signal. On commercial vessels this signal would come from the bridge, and would be made when the ship had arrived at the desired point and had been maneuvered into a position that would enable the plane to be launched into the wind.

When the pilot receives the "execute" signal he waves his arm in a circular motion. The catapult crew make the last few preparations, such as putting in the powder or adjusting the air to the exact pressure required, and then the officer in charge of the launching replies to the pilot's signal with a similar circular motion of the arm.

The pilot then opens up his engine full out, and after satisfying himself that it is acting normally, settles himself in his seat, puts his feet on the rudder and one hand on the stick. He then holds out his arm. When he withdraws it, the officer conducting the launching counts, "One, two, three," waits until the middle of the next up-roll, and the plane is launched.

The actual signal to fire is not made by the aviator, but by an officer on the deck. This is done because the officer on deck can choose his position and can more easily see that nothing is in the line of flight. He can judge the phase of the ship's roll better, and thereby avoid launching the plane while the catapult is pointing down at the water. He can also hear the engine of the plane and can suspend the launching if it begins to slow down or if for other reasons it becomes desirable to hold up the launching.

If the engine should stop or slow down just as the plane started, no great harm would be done. The end speed attained would be only one or two miles per hour less than if the engine were running normally. The plane would have sufficient speed to make a safe landing without stalling or spinning, but would be in the sea, close to the ship, with her mission unfulfilled. Consequently every precaution is taken to see that the engine of the plane is running properly before the start, to insure its proper functioning when it is needed, which is immediately after launching is over.

The plane stays on the car throughout the accelerated run. It does not fly off at some indeterminate point when sufficient speed has been attained, but leaves the car as the car engages the brake at the forward end of the catapult track.

After the car has stopped it is brought back to loading position, and the next plane is put on it and prepared for launching.

During the actual launching, the pilot is only so much baggage. He may move his controls, if he so desires, but they have no effect on the plane, since it is held securely to the launching car. From the time he gives the signal to fire until his plane is flying off the end of the catapult, he is by no manner of means a free agent. At the end of the run he takes charge of the plane and can immediately control it, but not before.

Proposed Ship-to-Shore Service Using Catapults

In a paper delivered before the Metropolitan Section of the Society of Automotive Engineers, it was pointed out that the first step in the development of the combined use of aircraft and commercial ships should be a ship-to-shore service using a catapult. This conclusion was reached after giving consideration to the ships, aircraft, and machines now in existence, without discounting the future in any degree. It would be well to operate one or more planes from a single ship until all the special conditions surrounding such a service were experienced. Apparently desirable extensions of the service could then be given careful consideration in the light of experience gained. There is little doubt that new material could be evolved to meet any real need, provided profitable operation could be foreseen.

With material now available it is possible to shorten the time in transit of valuable mail and express both east and westbound across the North Atlantic. Planes could take off the morning before sighting land and in a few hours land in London or Paris on the eastbound trips, or in Boston, New York, or Norfolk on the westbound trips.

If planes took off 200 miles at sea, mail could be delivered or forwarded within three hours, while the ship would still be more than 100 miles out. This would result in a saving of from five to seven hours in New York. More time could be saved to Paris and London where stops and transfers are now necessary.

It is possible to build catapults of any capacity whatever. With larger catapults, planes with greater safe radii of action could be used and the time saved could be increased accordingly. With sufficiently long-range planes, passengers could be landed directly in inland cities or ones remote from the port used by the ship, and they could, in many cases, be landed at their remote destination while their fellow-passengers were descending the gangplank at the port, and sometimes sooner.

Places along the east and west coasts of the Americas that are now inaccessible because of being off main trade routes or because of having inadequate harbors, could be reached quickly by a plane flying from a ship whose regular route took her within a few hundred miles. Such a service might, in some instances, save weeks of delay.

Before any extensive plans are made, prolonged tests should be made in the North Atlantic. These tests should cover a period long enough to experience all the phases of weather, which will be worse there than on most trade routes. The equipment, including the catapult and planes, should be the best available. The pilots and operators should be experienced in operating from shipboard, and each problem encountered should be completely solved before attempting a more ambitious program. No attempt to operate under extreme conditions should be tolerated. Everything should be done to insure safety. Increase of range and load should be made by small increments. As in all transportation problems, the motto should be "Safety First."

To sum up, the problem of launching planes from commercial ships is one of procuring enough high-tariff traffic to offset the cost of operation, which will be high, even after every unnecessary expense has been eliminated. The physical problem of despatching an airplane from the deck of a ship has been solved.

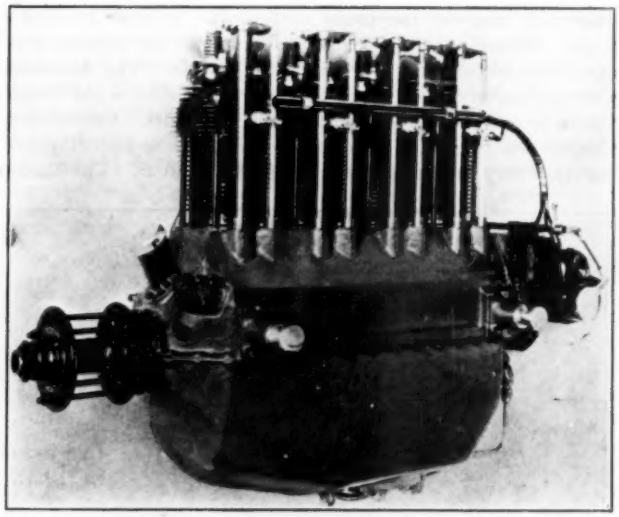

FIG. 2 WRIGHT GYPSY

Recent Developments in Aircraft Engines

BY JOHN H. GEISSE,[1] MADISON, WIS.

Improvements in engine design for airplanes during the year have been gradual. Production facilities now exceed the demand and developments should come more rapidly. There has been a trend during the year toward the "in-line" or air-cooled types of engines. However, the radial type still possesses a number of advantages. Manifolding in radial engines is quite a problem due to the impossibility of getting symmetry except in nine-cylinder types where three three-way manifolds may be used.

Cylinder construction with a steel sleeve having machined cooling fins and a cast-aluminum head is accepted quite generally, and there is a trend toward the use of heat-treated alloys for the crankcase. Many interesting developments in the Diesel types of airplane engines can be expected.

ABOUT one year ago the author prepared an article for *Aviation* on the development of aviation engines during the preceding 25 years. In that article he mentioned that the development was noteworthy in that there had been no radical or startling improvements made. The same statement holds true today. There has been no outstanding development in the last year or in the last 26 years. The most noteworthy event of the last year or two has been the number of new concerns that have entered or have become closely affiliated with this field and the tremendous expansion of production facilities on the part of the older companies. Outstanding among the new ones may be mentioned such well-known companies as the Continental Motors Corporation, Lycoming, E. W. Bliss Company, Le Blond, and the author's associates, the Gisholt Machine Company.

Before considering the products of these companies, it will be interesting to look into the possible market for their wares. A little over a year ago there was a definite shortage of engines. The stock of war-surplus engines was rapidly dwindling, and with the increased demand the production facilities of the country were not equal to meeting the situation. This curtailed the production of planes, and the market was quite definitely a sellers' market. Under this condition it was quite easy, and perhaps quite natural, for the plane manufacturers to make rather broad statements of the number of planes they could sell if only they could secure the engines. The existing engine manufacturers, and many others who were not then manufacturing, were influenced by these optimistic statements and immediately took steps to provide against another shortage this year. How admirably they succeeded is evidenced by the fact that present production facilities far exceed any possible demand. Whereas the year started with plane sales predicted to exceed 14,000, the latest estimates place the probable year's sales at less than one-half of this figure. The actual engine production for the first six months of this year as reported by the Aeronautical Chamber of Commerce was 3275, and it is doubted whether this figure will be greatly exceeded in the present period. If it is doubled in this period, it will mean a production rate of not over forty engines per day. In contrast to this it is very easy to total up claimed production facilities of over one hundred per day, and each day brings news of new enterprises, all planning on going into production, at the rate of ten per day.

It is not desired to paint a gloomy picture for the industry, but the author does want to impress the fact that there is no shortage in production facilities for the time being and that there is not likely to be another shortage in the immediate future. He confidently expects the industry to have a phenomenal growth and that the demand will catch up to production facilities, if the growth of the latter only will slow down to a saner rate.

This rush to get into production has, to a considerable extent, held back engine development during the last year. Now that production facilities exceed the demand, developments will come along more rapidly. Not only will the engineers have more time to concentrate on improvements in their products, but competition will demand them.

Reverting to the engine developments of the last year, one is

---

[1] Vice-President of Engineering, Comet Engine Corporation.

Contributed by the Aeronautic Division and presented at the Annual Meeting, New York, N. Y., December 2 to 6, 1929, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

impressed most by the trend toward the "in-line" air-cooled types. Whereas there were practically none in use here one year ago, there are now quite a few on the market. The American Cirrus Company has secured the American rights to the 95-hp. Cirrus four-cylinder-in-line engine, and the Wright Aeronautical Corporation has taken a license to build the 85-hp. "Gypsy" engine of very similiar construction (Figs. 1 and 2). The Michi-

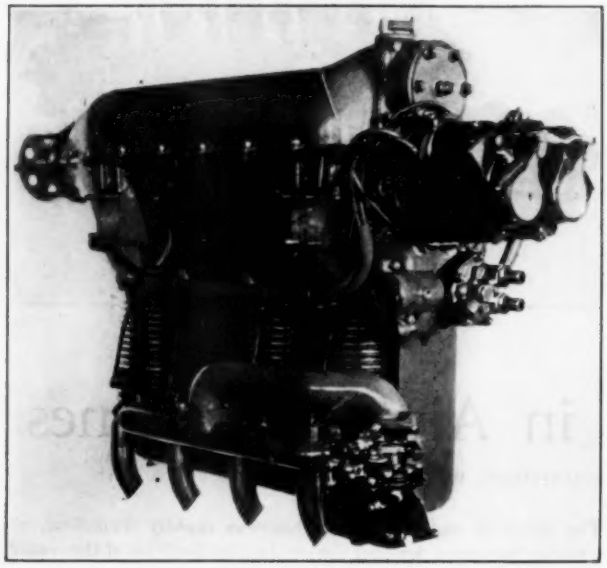

FIG. 3 MICHIGAN AERO ENGINE COMPANY ROVER

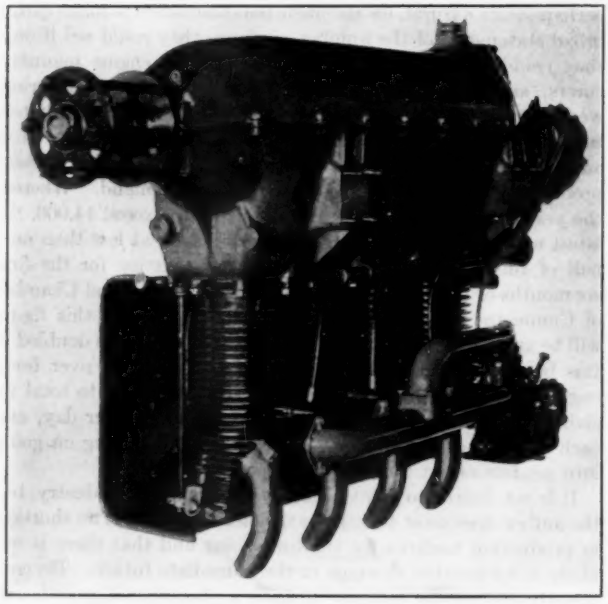

FIG. 4 MICHIGAN AERO ENGINE COMPANY ROVER

gan Aero Engine Company has brought out a 55-hp. inverted four-in-line known as the Rover (Figs. 3 and 4). The Dayton Airplane Engine Company manufactures a larger four-in-line developing 110 hp. (Fig. 5). The Curtiss Company has just added to its line of engines an inverted six-in-line of 125 hp. There are also several others in the development stage or about to be placed on the market.

Strange as it may seem, it is believed that the advent of cowling for the radial engines, which materially reduces their drag, has furthered the sentiment in favor of the in-line type. Until the airplane manufacturers had their attention called to the high resistance of the radial by cowls designed to reduce this resistance the radial was supreme. One manufacturer who had been using radial engines without cowling and without complaint made the remark that if the radial must have all of that cowling he no longer wanted to use it. However, jesting aside, the resistance of the radial, together with its interference with the pilot's vision, is a serious objection to the type and must be considered especially in the larger units and in planes designed for high speeds. The power required to drive a radial engine through the air at 100 miles per hour has been found to be as much as 20 per cent of the total power. At high speeds the percentage becomes greater, as the engine and other parasite resistance varies as the square of the speed, whereas the wing drag, being dependent only on the total load and the lift drag ratio of the aerofoil used, may increase or decrease with increase of speed.

However, the radial still has a number of advantages over the in-line type and undoubtedly will continue to be used by many

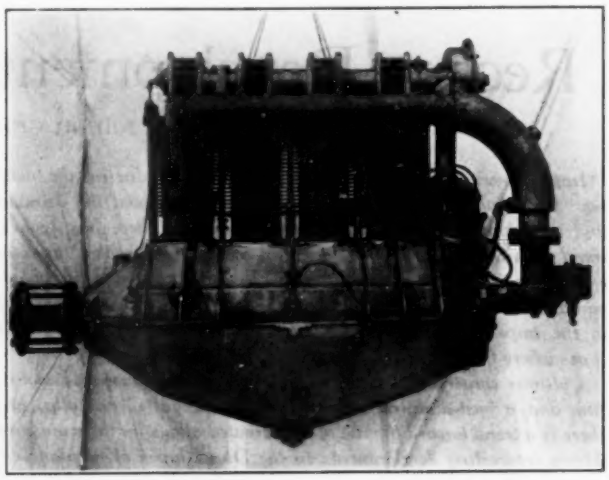

FIG. 5 DAYTON AIRPLANE ENGINE COMPANY BEAR

manufacturers. The radial offers no serious problem in securing uniform cylinder cooling, makes excellent use of crankcase and crankshaft material, and does not have crankshaft torsional vibration to contend with. The in-line air-cooled engines are inferior to both the radial air-cooled and the in-line water-cooled in these respects. Uniform cylinder cooling is not easy to attain and requires cowling to direct the air flow. Due to the finning of the cylinders and the necessity for providing sufficient spacing for air flow between cylinders, the cylinder spacing is comparatively large. This accentuates the poor utilization of crankcase and shaft material by making these parts longer than otherwise would be necessary, and by requiring a longer shaft introduces shaft-whipping problems. The increase in weight per horsepower over that of the radial, due to the poorer use of crankcase and shaft material, may be partly or entirely offset by utilization of higher speeds, made permissible by the lower crank pin loading with only one rod and piston per crankpin, and to the decrease in valve-gear reciprocating weight made possible by the use of an overhead camshaft.

There is one engine, the Curtiss Challenger (Fig. 6), that falls between the radial and the in-line engine so far as the crankshaft and crankpin loading is concerned. This engine, rated at 170 b-hp., has a two-throw crankshaft with three cylinders operating

from each crankpin. In addition to the reduction in crankpin-bearing loads, a reduction in weight of the counterweights is accomplished by this construction.

Another engine, the Comet, the product of the author's company (Fig. 7), has an intermediary position in so far as valve gear is concerned. It has a positive cam which relieves the valve springs of all inertia loads other than the valve itself. Since in all valve mechanisms the cam at some period of operation has to accelerate all of the parts in the gear as well as to overcome the valve-spring tension, it is apparent that this method of drive reduces the cam loading considerably.

The valve mechanism of the radial engine, when not compensated, has certain disadvantages which are not encountered in the in-line types. This refers to the very considerable change in tappet clearances with change in cylinder temperatures. It is not unusual for the tappet clearance to increase from 0.010 in. with a cold engine to 0.060 in. with the engine warmed up. Were

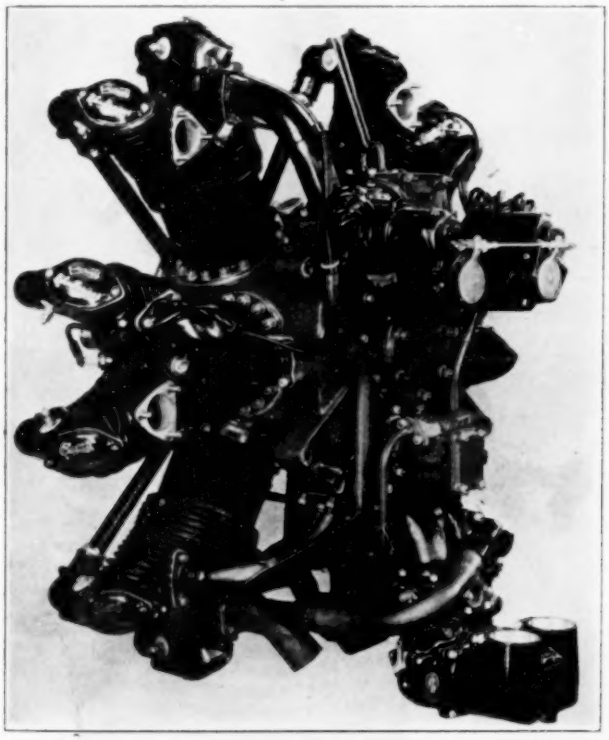

FIG. 6 CURTISS CHALLENGER

it not essential to limit the tappet velocity at the time of opening and closing of the valve and not have excessive accelerations, this would not be serious. However, with these limitations, this change in tappet clearance, even with careful cam design, causes a very appreciable difference in valve timing between a cold and a hot engine. Since the cam is designed to give the correct timing with the engine warm, the timing with the engine cold is very poor. In some engines the cold timing has as high as 50-deg. overlap and the intake valve does not close until 80 deg. after bottom center. This has a considerable detrimental effect on the starting and idling characteristics of the radial.

In the Bristol Jupiter engine a compensating arrangement is used. In this engine the rocker-arm fulcrum is not supported on the cylinder head, but is carried by a rod extending down to the crankcase. Since the supporting rod and the pushrods expand and contract together, very little change in tappet clearance occurs.

In the Wright J-5 engines (Fig. 8) a partial compensation was secured by supporting the rocker fulcrum on a lever, one end of which was fastened to the cylinder head and the other to the crankcase. The rocker box constituted the lever and the push-rod housing furnished the attachment to the crankcase.

In the Comet engine (Fig. 9) the intake valve is over-compensated and the exhaust valve has no compensation. The over-compensation of the intake valve is attained by the use of a

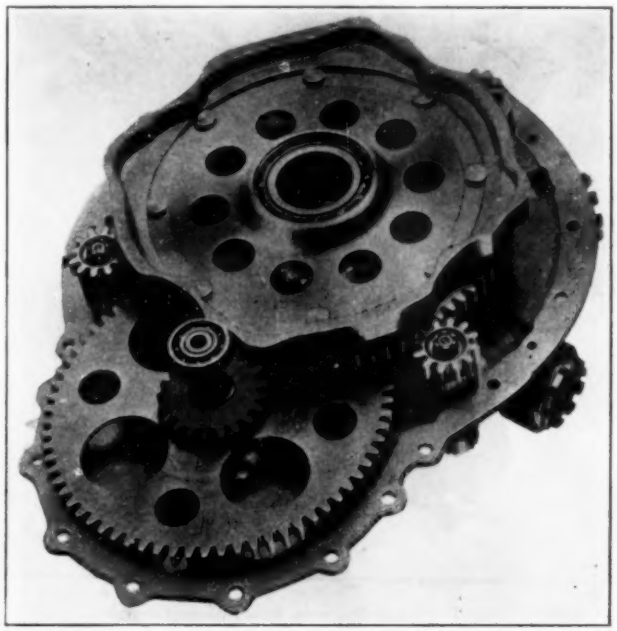

FIG. 7 COMET ENGINE CORPORATION ENGINE CAM

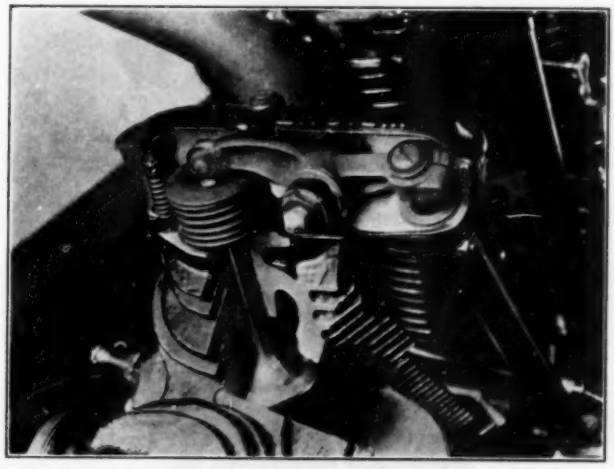

FIG. 8 WRIGHT J-5 VALVE GEAR

single rocker arm and push-and-pull rod, the intake valve being operated by pull on the rod. With this construction the tappet clearance is less with a hot engine than with a cold engine, and consequently the period of intake-valve opening is less with the engine cold. This greatly improves both idling and starting characteristics.

Manifolding is also somewhat of a problem in a radial engine due to the impossibility of getting symmetry, except in the nine-cylinder types, where three three-way manifolds may be

used. There has been a trend this year toward the use of diffusers or superchargers with the object of improving distribution and also, in some cases, of increasing the volumetric efficiency.

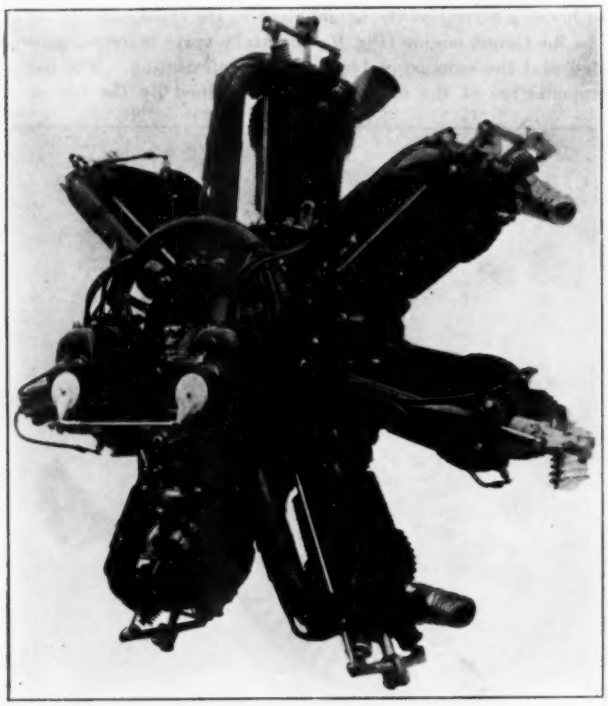

FIG. 9 COMET ROCKER-ARM CONSTRUCTION

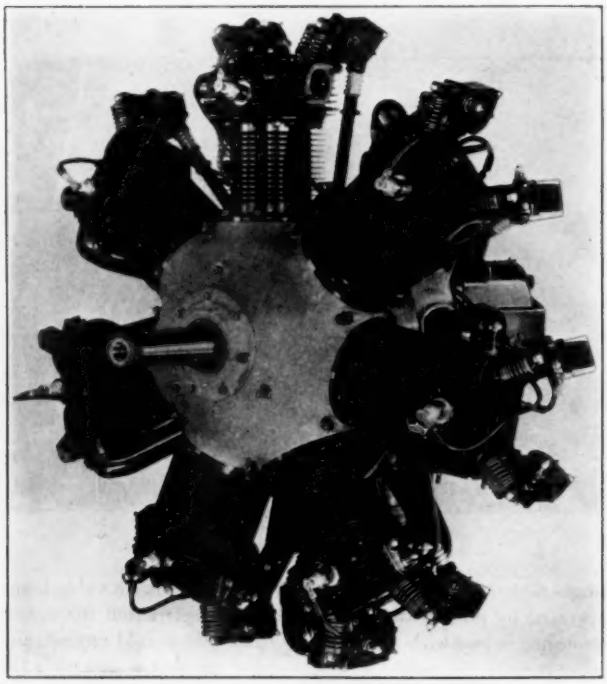

FIG. 10 WARNER SCARAB

Whether this device will be the ultimate solution of the problem is somewhat questionable. In one test of three engines of the same power rating, the engine without a diffuser gave better fuel economy than the two so equipped. However, in this case, all engines had nine cylinders, and the one without the diffuser had symmetrical three-way manifolds. It is possible that, were the comparison made of the best seven-cylinder manifold without diffuser and a seven-cylinder with diffuser, the results would be reversed.

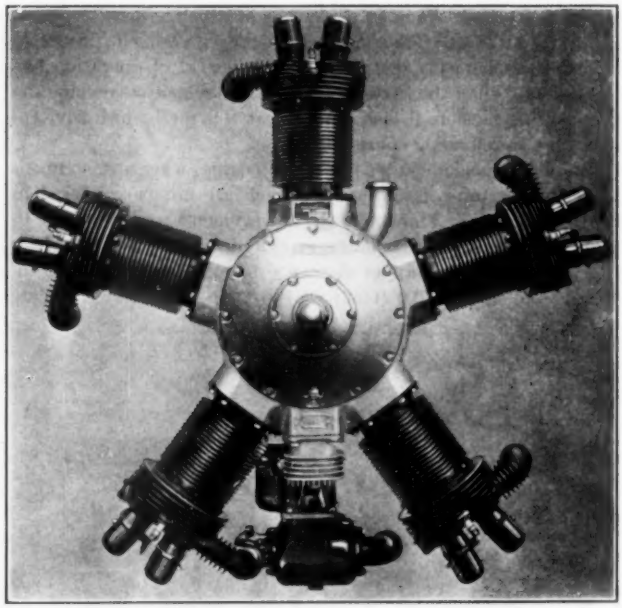

FIG. 11 KINNER, WITH BOLTED-ON HEAD

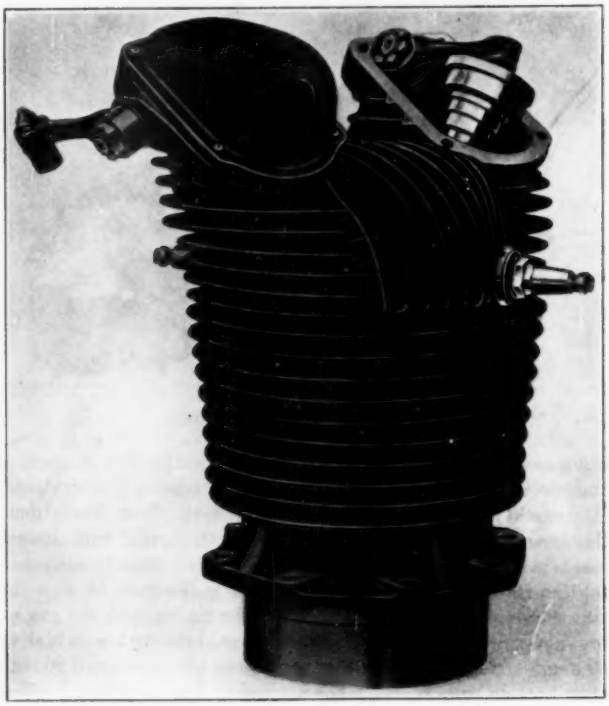

FIG. 12 LE BLOND CYLINDER

The advantage of increasing the volumetric efficiency with geared-up diffusers, or superchargers as they should be termed, is also subject to argument. Assuming a certain grade of fuel, it

is of course necessary to use a lower compression ratio with the supercharged engine than with one not so equipped. This means a reduction in thermal efficiency and an increase in fuel consumption. In addition, supercharging increases cylinder, valve, and piston-cooling problems.

There has been an almost general acceptance of the cylinder construction comprising a steel sleeve having machined cooling fins and a cast-aluminum head screwed and shrunk on the sleeve. Exceptions to this practice are noted in the Warner Scarab (Fig. 10), which has a bolted-on head which is not intended to be removable, in the Kinner (Fig. 11), which has a bolted-on head that is removable, and the Le Blond (Fig. 12), which uses a one-piece cast-iron cylinder. In most cases the heads are cast in "Y"-alloy which retains a relatively high strength at elevated tempera-

tures, giving about 26,000 lb. per sq. in. at 500 deg. fahr. The cylinders are generally machined from a 1050 S.A.E. heat-treated forging. A new development of this year is the elimination of

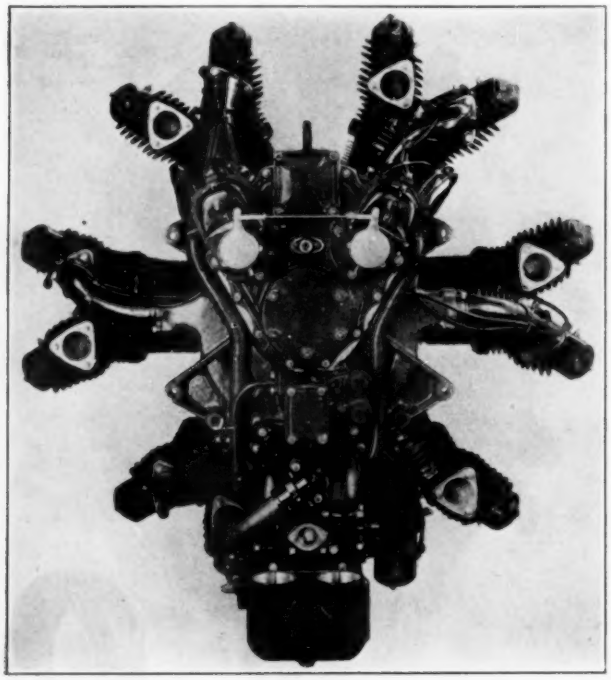

FIG. 18 CURTISS CHALLENGER

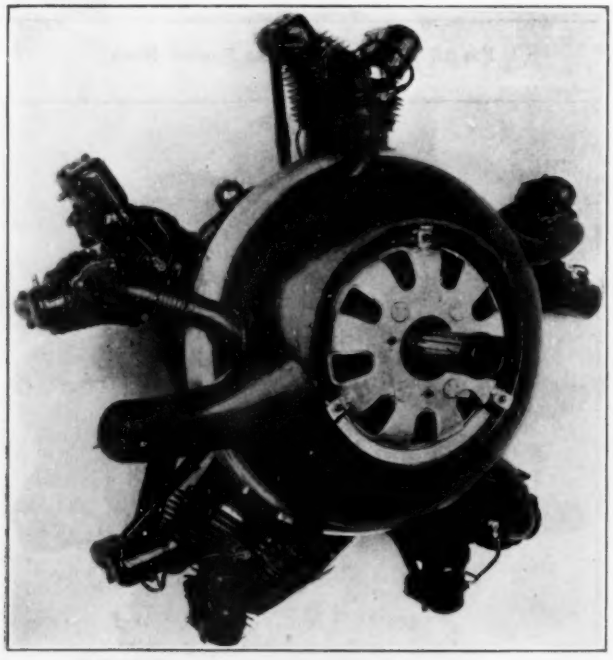

FIG. 19 WRIGHT J-6

normalizing, and the reheat-treating of cylinder forgings. One prominent manufacturer is now securing his cylinder forgings with one heat treatment, which gives the desired Brinell hardness, but leaves a very coarse grain structure. The saving in heat-treatment cost is not particularly great, but the material in this condition is very much easier to machine than when normalized and reheat-treated to give the same Brinell hardness.

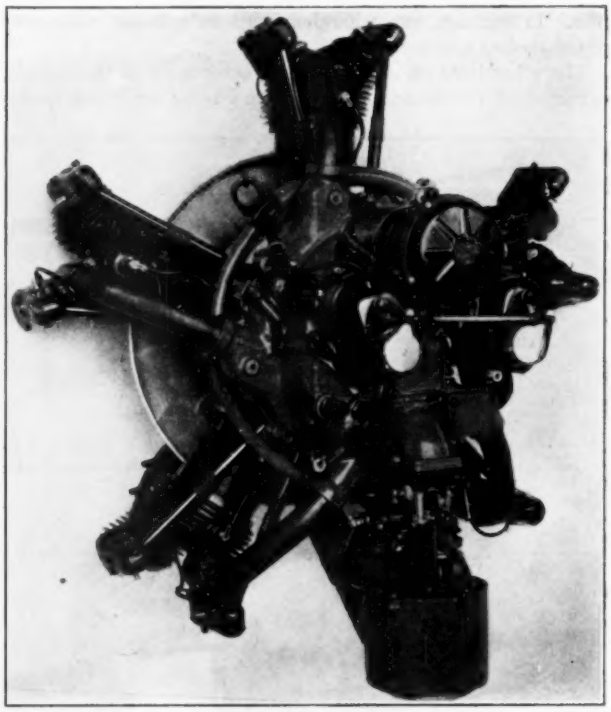

FIG. 20 WRIGHT J-6

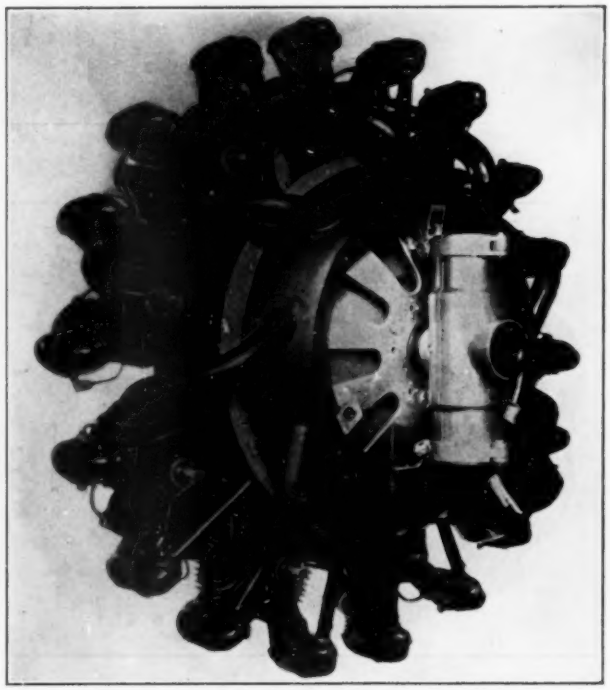

FIG. 21 LYCOMING

Split crankshafts permitting the use of solid master rods also have gained adherents during the last year. Two methods of joining the halves are in use. One is used by Pratt & Whitney

(Fig. 13) and consists of a maneton on the rear half fitting into the crankpin of the front half. The other, of which the Wright J-6 is a typical example (Fig. 14), consists of clamping the rear cheek to an extension of the crankpin. In some of the latter

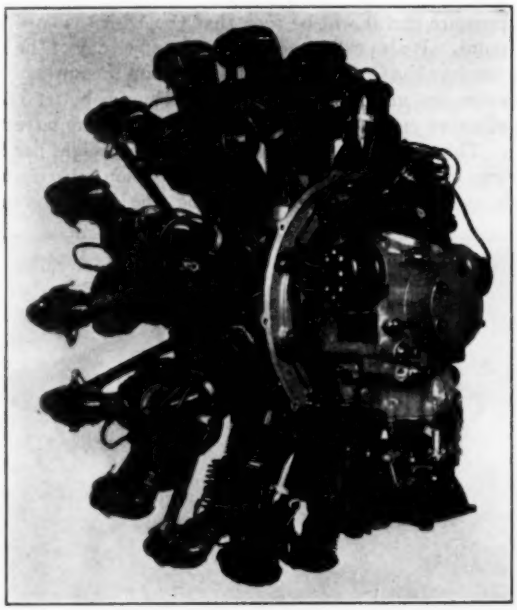

FIG. 22 LYCOMING

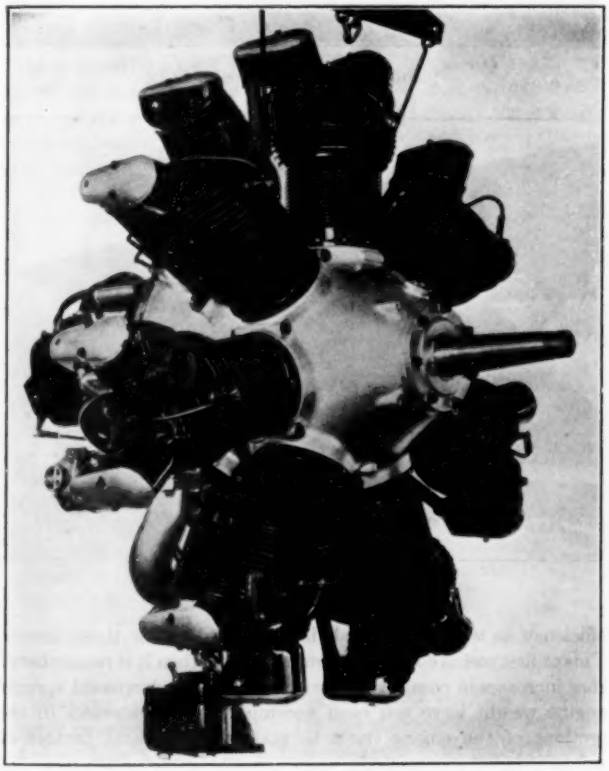

FIG. 23 CONTINENTAL

adaptations a key is used to resist torsional stress in the joint, and in others the friction of the surface is relied upon to prevent slipping.

There has been a general trend toward the use of heat-treated alloys for the crankcase. These alloys have a tensile strength of 30,000 to 40,000 lb. per sq. in. in the heat-treated condition in contrast to the approximately 20,000 lb. per sq. in. obtained from the more common No. 12 alloy. Due to the limitations imposed

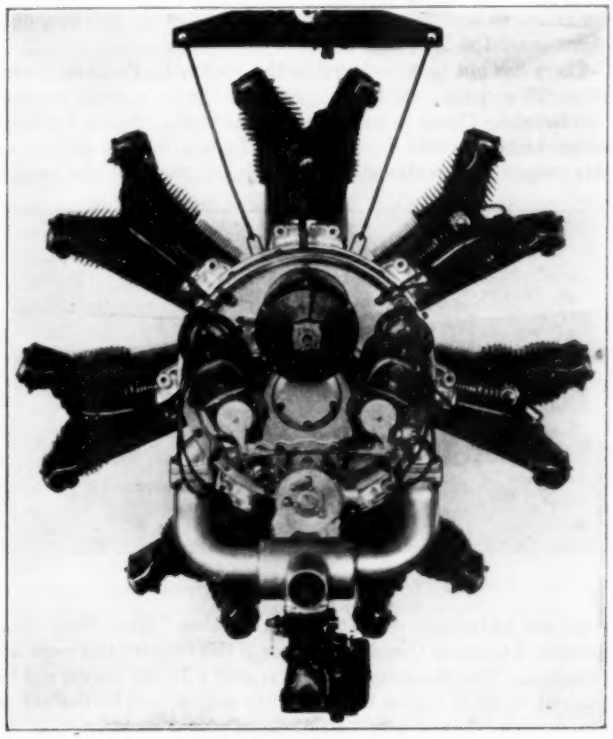

FIG. 24 CONTINENTAL

FIG. 25 PACKARD DIESEL

by casting difficulties on minimum wall thickness and to the variations in wall thickness in the usual castings which may adversely affect the heat treatment, all of this gain in strength cannot be utilized for weight reduction. These considerations, along with the higher price of the castings, make the use of these alloys questionable in many cases. The use of forged crankcases is

still limited, it is believed, to Pratt and Whitney (Figs. 15 and 16). Curtiss is using some magnesium castings, which permit a considerable saving in weight where strength is not required, but which are quite expensive.

Of the new engines, those drawing the greatest interest are the Curtiss 150-hp. Challenger (Figs. 17 and 18), Wright 165-hp. J-6 (Figs. 19 and 20), Lycoming 150-hp. (Figs. 21 and 22), and Continental 150-hp. (Figs. 23 and 24.)

There has not been included in this group the Packard Diesel (Figs. 25 and 26), which of course does create a great amount of interest in Diesel power plants for aircraft. Before Packard stepped into this field it was rather difficult to interest any one in this project. The almost general opinion was that the weight

FIG. 26 PACKARD DIESEL

could not be brought down to a usable value. Now there are a number of aviation Diesel enterprises in this country and more are expected. It is the author's opinion that a Diesel engine will be evolved which is lighter than the Otto engine, and he has yet to find any one who can give a good reason why it should not be.

To secure such an engine, three things will be necessary. First, it must be a two-stroke-cycle-engine—not at all as difficult a problem with Diesel engines as with Otto engines. Second, it must be operated at speeds common to Otto practice. Third, it

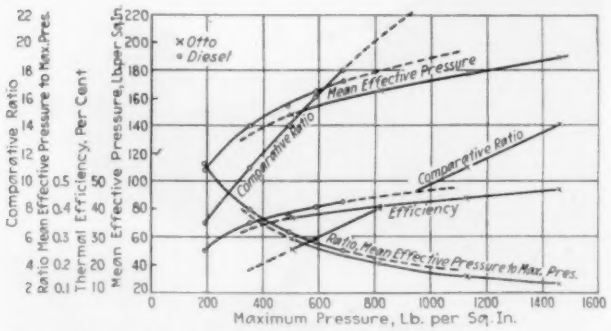

FIG. 27 COMPARISON OF DIESEL AND OTTO CYCLES AND THERMODYNAMIC CHARACTERISTICS

must burn the fuel at substantially constant pressure. This is where the difficulty comes in. Many will say that it cannot be done. It would be better to say that it has not been done, at least generally. The National Advisory Committee claims to have operated a Diesel on such a cycle at 1700 r.p.m. But regardless of this, is there any fundamental reason why it cannot be accomplished? It is not believed so. It is even possible now to operate an Otto engine with almost constant-pressure combustion by use of special fuels. How much has been done on developing fuels for the Diesel engine with this same purpose in view? Nothing that is known.

With reference to the curves of Fig. 27, the author will explain why he contends that the Diesel engine will be lighter than the Otto. The relative weights of the two types will be roughly proportional to the ratio of brake mean effective pressure to maximum pressure. These ratios are plotted against maximum cylinder pressure and it will be seen that the Diesel is superior at every point. It also will be noted that the efficiency of the Diesel is greater than the Otto for identical maximum pressures. These curves also are interesting in that they show a better ratio of mean effective pressure to maximum pressure as the latter is reduced. This means that in the Otto engine the weight per horsepower can be made lower with a low compression ratio than with a high compression ratio, maintaining the same volumetric

FIG. 28 WATER-COOLED D-12

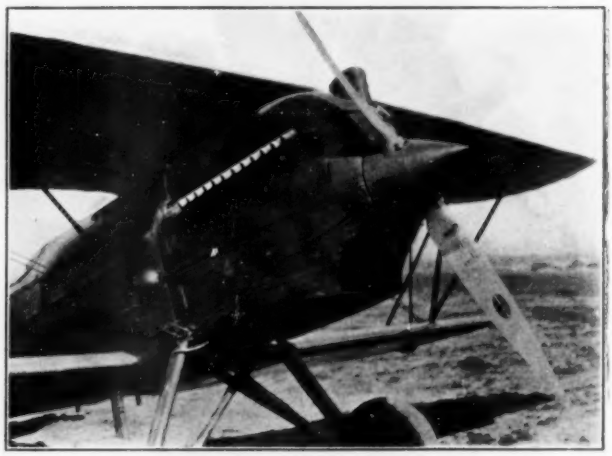

FIG. 29 PRESTONE-COOLED D-12

efficiency as was done in calculating the data for these curves. This at first seems contrary to practice, but when it is remembered that increases in compression ratio which have decreased specific engine weight have not been accompanied by increases in the sections of the engine parts to maintain the same factors of safety it is not inconsistent.

The author's belief is that for transport work in the not too distant future the Diesel engine will reign supreme. The advantages of the Diesel are well known to all and need only be itemized here. They are dependability, reduced fire hazard, better fuel economy, and lack of radio interference. The Diesel of the future, it is

expected, will be Prestone-cooled, and that brings up the development which is considered to be the most interesting of the year.

At the Cleveland S.A.E. meeting, Mr. Frank, of the Army Experimental Station, Wright Field, presented the first paper on the subject of high-temperature liquid cooling. Both the Army and the Navy have been working on this development for a number of years, but have not made public the results of this work. The Army has been concerned with the reduction in radiator size which can be attained by the operation of the radiator at temperatures greater than water permits. Ethylene glycol, sold under the trade name of Prestone, was found to be a suitable liquid for this purpose, having a boiling point of about 380 deg. fahr. and a low freezing point. Tests were made in the Curtiss D-12 and Curtiss V-1540 engines, and the results were entirely satisfactory. Only minor changes in these engines were required to adapt them to the use of high jacket temperatures. The reduction in radiator size accomplished is well shown by Figs. 28 and 29. Fig. 28 shows a plane with a radiator for water cooling. Fig. 29 shows the same plane with the same engine, but with the radiator required for Prestone cooling.

But interesting as this may be, the goal of the Navy Department is still a step farther. The Navy also started out with the goal of reduced radiator size due to higher radiator-surface temperature, but about three years ago the author became convinced that the radiator could be eliminated entirely. Up to that time all had been overlooking the reduction in radiator size which was being accomplished by increasing the heat dissipated from the cylinder jackets themselves. A few calculations showed that, with the temperatures permissible with Prestone, sufficient finning could be provided on the cylinder-jacket surface to dissipate all of the heat.

There was some delay in getting started on this phase of the development due to rush of other work and the lack of an engine which would lend itself to the modifications necessary. However, a Wright E-4 engine without any modifications was successfully run without a radiator on a relatively cold day in the course of tests to determine the effect of the higher jacket temperatures on detonation.

This development appears to offer the solution of most of the present problems. In-line engines are in demand due to their better visibility and lower head resistance. As pointed out earlier in this paper, they have some objectionable features in the direct air-cooled type. The difficulty of obtaining uniform cylinder cooling, the necessity of the use of cowling, and the relatively large cylinder spacing resulting in increased weight and more flexible shaft were mentioned. None of these applies to the Prestone-cooled engine; and furthermore, the most serious objection to water-cooled engines, i.e., trouble with the so-called plumbing system, also does not apply, since no plumbing system will be required. It is even quite possible that the circulation pump can be dispensed with and dependence placed on thermosyphon circulation in the jackets.

In closing, the author wishes to express his thanks to the engineers of the various engine companies who so kindly supplied him with data and photographs.

Discussion

ROBERT INSLEY.[2] As the author points out, the old controversy between the radial and the line engine seems to be in grave danger of settlement by actual comparison of the types in service. It is unfortunate that the majority of the line-engine experiments have been undertaken in a power field where the radial engine has such outstanding advantages. The relative advantages of the line engine become more attractive as the size of the power plant increases. The inherently superior features of this type (smoothness, low frontal area, small obstruction of vision) are rather insignificant in the smaller sizes (roughly 200 hp. or less), and such disadvantages as weight and cost are magnified in contrast with similar radial engines. From that point of view it seems regrettable that the first direct comparison should be made in this field. But this much is certain: if the results of this comparison should favor the line engine at all, its superiority in the larger sizes is fairly well assured. It would seem to be a fair guess, however, that the radial engine will hold its own in the smaller sizes and that the line engine will appear attractive in the larger horsepower classes. One sentence of the paper in this connection seems to deserve comment. With reference to the line engine the author remarks that "uniform cylinder cooling is not easy to attain and requires cowling to direct the air flow." That is perfectly true, but it is doubtful if the amount of cowling required by the line engine is much greater than seems to be necessary for satisfactory operation of large radial engines.

The comments concerning the usefulness of the so-called "diffusers" are particularly interesting in the light of recent comparative performances with and without this method of induction. The behavior of some later models of unsupercharged radial engines with respect to distribution, acceleration, and ease of starting suggests that perhaps our expectations in the way of supercharged performance have been too optimistic. It cannot be denied that the supercharger affords a means of developing more horsepower per cubic inch of displacement; but have not some of our recent unfortunate experiences with such superperformance engines indicated that the unsupercharged engine with reasonable compression ratio will develop as high volumetric efficiency as is desirable for general commercial service? The author's doubts on this subject seem well justified.

The paper cites a new development in "the elimination of normalizing and the reheat-treatment of cylinder-barrel forgings," but makes no comment on the effect of this process on physical properties. Unquestionably this shortened process saves a few cents per forging, but it also definitely reduces the strength and wear resistance of the material. One is tempted to inquire whether in the normal course of development a reversal of this process would not be considered a step in advance.

The author questions the advisability of using heat-treated aluminum castings for crankcases. It is true that in unstressed wall sections the minimum thickness required for good casting properties affords sufficient strength in non-heat-treated castings. In the highly stressed parts, however, such as mounting bolt lugs, cylinder flanges, and bearing webs, the saving in weight possible in the heat-treated castings will well repay the slight additional cost. In discussing the use of magnesium-alloy castings in parts where strength is not required, the author apparently has iforgotten that the strength of the cast magnesium alloy is distinctly better than common aluminum casting alloys, approximately the same as "Y"-alloy, and that the elongation is nearly twice that of the best aluminum alloy in use for aircraft-engine parts. The cost, piece for piece, is approximately 25 per cent higher than aluminum, which, together with its susceptibility to corrosion, has restricted the general use of this material.

In the midst of the widespread enthusiasm for the Prestone-cooled engines the author's comments on this subject are particularly interesting. His suggestion that total elimination of the radiator is not at all out of reason is very alluring; but, after all, it may be asked if some of the chief advantages of the liquid-cooled engine are not the possibility of placing the radiator where it will do the most good and the least harm, the "buttoning up" the engine inside the cowling where it is protected from the elements and from violent temperature changes, and the possibility

[2] Vice-President, Continental Aircraft Engine Company, Detroit, Mich.

of direct control of the engine temperature—all of which would be impossible if the engine were exposed to the direct air blast without the benefit of streamlined cowling. Is there not a possibility that by this semi-direct cooling there may be sacrificed some of the benefits of the compactness and low head resistance of the line engine and thus combine some of the disadvantages of both types? If not, the possibilities of weight and cost reduction are very attractive.

C. Fayette Taylor.[3] The author is to be congratulated for his truthful statements about the condition of the aircraft industry. The industry has suffered considerably from overoptimism and from failure to face the facts.

The author makes the statement that a radial engine does not have crankshaft torsional vibration to contend with. Recent experiments have indicated that this is not the case, but that torsional vibration in radial engines is a serious problem. It has been found that, when radial engines are run at or near the torsional critical speed of the crankshaft, failure always occurs within a comparatively short time.

In his discussion of Prestone cooling the author mentions the possibility of using thermosyphon circulation. The writer does not believe that this will be possible, because in order to take advantage of the high temperature of the Prestone, it will be necessary to hold the surface of the radiator or cooling fins at approximately the temperature of the liquid. This would be impossible without an extremely high rate of liquid circulation. In other words, when we extract heat from the cooling surface at an extremely high rate, we must also make sure that there is an equally high rate of heat transfer from the liquid to the cooling surface. Without this, the temperature of the cooling surface will fall and the rate of heat dissipation will be correspondingly reduced. This may prove to be an important factor to contend with in Prestone cooling systems.

P. B. Taylor.[4] The paper points to the excessive drag and obstruction to vision of the radial type, but does not refer to the sight developments which aim to eliminate these disadvantages in large-displacement engines.

The in-line engine accomplishes this result for small engines, but is limited to six or possibly eight cylinders by a practical consideration of length available for the power plant. The largest air-cooled cylinders at present displace in the neighborhood of 215 cu. in. This size is not likely to be increased greatly in the near future as the experience of engine builders has demonstrated a limiting law; engine trouble varies as the square of the displacement of one cylinder.

Using the largest air-cooled cylinders developed, the in-line type is limited to 1290 cu. in. for a six and to 1720 cu. in. for an eight. Both the six and eight will be extremely long because of the large cylinder bore. The maximum rotative speed also will be limited by the weight of reciprocating and rotating parts for the large cylinders.

The twelve-cylinder inverted air-cooled V-engine is suggested as one solution to this problem. This arrangement has excellent balance and presents the possibility of doubling the displacement of an in-line six without interfering with vision or adding more than 30 per cent to the frontal area, considering both engines as equipped with cowl, without which neither will operate.

The displacement per cylinder for the twelve-cylinder engine when compared with a similar single-row radial or in-line engine is necessarily considerably less. The twelve-cylinder engine can therefore be constructed with small-displacement cylinders which permit of high rotative speed. The necessary spacing of cylinders to allow air to flow between the barrels leaves room for adequate bearings for the high-speed operation.

The bottom and side cowlings are simple pieces of sheet metal which can be designed by the engine manufacturer for engine cooling without reference to structural considerations on the individual airplane. The cowl forms a streamline over the cylinder block and adds little or nothing to the drag. Cooling of this engine as observed from block and flight tests is somewhat better than of the radial engine due to the efficient utilization of the air entering the V in passing over all sides of the cylinders.

The engine can be constructed with overhead cams and full-lubricated valve gear, thus eliminating the maintenance wear and high inertia forces of the push-rod construction and again permitting high operating speeds. The weight, while somewhat greater than the radial, is less than the water-cooled V-type due to the elimination of water, radiator, and plumbing. Since no counterweights are necessary, this feature compensates to some extent for the increase of crankcase, crankshaft, and connecting-rod weight over that of the radial engine.

The possibilities of the air-cooled V-engine are shown by the characteristics of the Wright V-1560, which is under development by the Wright Company for the U. S. Army. These are as follows:

Model	V-1560
Type (inverted air-cooled)	60° V
Number of cylinders	12
Bore, in.	5
Stroke, in.	$6^{5}/_{8}$
Piston displacement, cu. in.	1560
Normal r.p.m.	2400
Maximum designed r.p.m.	2700
Normal b.m.e.p., lb. per sq. in.	$128^{1}/_{2}$
Normal b. hp.	600
Weight bare, lb.	825
Weight with reduction gear, lb.	900
Overall length, in.	$70^{7}/_{16}$
Additional length of reduction gear, in.	$6^{11}/_{16}$
Overall height, in.	$35^{1}/_{4}$
Overall width, in.	$32^{1}/_{4}$

(A supercharger is incorporated for sea level pressure at 12,000 ft. altitude.)

It will undoubtedly be possible to increase both the r.p.m. and the b.m.e.p. after sufficient experimental work. A rating of 140 b.m.e.p. for military work at 2600 r.p.m. is within the realm of immediate possibility, giving a horsepower rating of 715 and a weight rating of 1.15 lb. per hp. Since the frontal area of this engine is no greater than a small fuselage, this type should help to fill the present demand for greater performance.

Sanford A. Moss.[5] The author gives scant attention to superchargers, although the centrifugal supercharger is in use on the majority of aircraft engines now being sold. Doubling the A.C.C. figure of 3275 would give approximately 6550 engines sold for 1929. About 5000 superchargers will be sold, nearly all of which have been used on American engines. Superchargers are therefore used on a very large proportion of all engines sold in 1929.

It would be desirable if the author could give some truly comparative data regarding fuel consumption. It is to be noted that the true comparison would have to be between two engines delivering the same power at maximum efficiency. In this event the cylinder displacement of the supercharged engine would be 10 to 20 per cent less than that of the unsupercharged engine, so that the friction and radiation loss would be less.

The power for compression in the supercharger of course relieves the engine cylinder of this duty.

[3] Consulting Mechanical Engineer, Massachusetts Institute of Technology, Cambridge, Mass.

[4] Wright Aeronautical Corporation, Paterson, N. J.

[5] Engineer of Supercharger Department, General Electric Company, West Lynn, Mass. Mem. A.S.M.E.

The meager data which exist indicate that there is at least no loss in efficiency with a supercharger. There is certainly a decrease in weight and cost of engine for a given power and a marked improvement in smoothness of operation, due to better vaporization.

It is sometimes assumed that, when an improvement is made in utilization of materials so that a greater amount of service is secured with a given weight of parts, there is necessarily a loss in durability. This of course is not true, and supercharged engines are as durable in service as the non-supercharged engines. The matter of durability is entirely one of detailed design of the individual parts, and this may be done well or poorly, entirely independent of the use of superchargers. A manufacturer who does not use a supercharger, and thereby necessarily has a greater weight of engine for a given power, cannot make merit of this fact alone and claim that because it is heavier his engine is more durable. In other words, it does not necessarily follow that a heavy engine is a good engine. The criterion for durability is not a matter of weight for a given power at all or a matter of the use or omission of a supercharger, but is a matter of detailed design of the engine.

Author's Closure

Mr. Taylor is perfectly correct in stating that radial aircraft engine crankshafts are subject to torsional vibration. However, the recent experiments to which he probably referred indicated that the radial engine could be run for long periods at its critical speed without resulting in crankshaft failure. Mr. Taylor is also perfectly correct in his statements relative to the use of a thermosyphon circulation system. It undoubtedly does require greater cooling area than would be required with a forced circulation. However, the simplicity of the thermosyphon system makes it very attractive, and it is quite possible that the increase in weight which would be required in the heat-dissipating elements would be more than offset by the saving in weight due to the elimination of the circulating pump.

Dr. Moss requests some comparative data regarding fuel consumption, which I am sorry to say I do not have. He states that the comparison should be between two engines delivering the same power, but to be at all conclusive the data really should be on one engine, both with and without supercharging. I would like to refer Dr. Moss to a test which was made a long time ago on a Liberty engine which I believe will give him the information he desires.

This test was made by the Navy Department so as to determine the best combination of compression ratios and carbureter choke sizes for the engines used in the NC-4 boats which were the first to cross the Atlantic. These tests indicated that the best performance was obtained with the higher compression ratio and smaller carbureter chokes.

I take exception to Dr. Moss's statement in which he indirectly accuses me of claiming durability goes with a high weight per horsepower. I make no such claim, but do claim that the use of low mean effective pressures has a very great tendency to increase durability.

Due to the fact that Dr. Moss's statement is almost a direct challenge to the company I represent, I would like to call his attention to the fact that though our engine has a low mean effective pressure, its weight per horsepower compares very favorably with some engines using a General Electric supercharger.

The Aircraft Diesel Engine

By LEIGH M. GRIFFITH[1] and EDWARD T. VINCENT,[2] BELL, CAL.

In this paper the authors present information to show that the Diesel or fuel-injection engine in some of its modified forms is well adapted to the requirements of airplane and airship propulsion. They believe that its first and most important commercial application will be in relatively large units on large aircraft and that increased fuel economy, both as to weight and cost, will be an important factor in the progress of commercial air transportation. They consider that the greatly reduced fire hazard will be an important factor in the development of quantity air transport of passengers and that the absence of radio interference will greatly simplify the problems of navigation and communication. The potential advantages of two-stroke cycle operation will be realized in the Diesel engine. In large airplanes from one to three engines of large size will be used, and these will be mounted and enclosed so as to allow of attendance during flight. Such engines will be fluid-cooled, either by liquid circulation or evaporation. The service reliability of the Diesel, they believe, will exceed that of the carbureted, air-cooled engines inaccessibly mounted, and the problems of weight and cost are less serious than are generally supposed, and will soon be solved commercially.

DURING the past few years there have been many published discussions regarding the possibilities of the Diesel engine as a power plant for aircraft propulsion. While the detailed opinions of the various writers have differed greatly, there has been an underlying agreement that the Diesel engine will have a large field of application in aeronautics, when and if the weight per horsepower is reduced to a value sufficiently low to compete with the standard carbureted type of aircraft engine. Most Diesel engineers have taken a pessimistic attitude. The flight of the Packard-Dornier engine a few months ago probably provided the first real jolt of evidence to American engineers that the aircraft Diesel was no longer a mere dream, although the Beardmore airship Diesel had yielded comparable results some time previously, and tests at the N.A.C.A. research laboratory had long shown the entire feasibility of Diesel operation with engine structures of acceptable weight. The recent flight of the Junkers 600–700 hp. Diesel has provided a further demonstration.

The problems connected with the development of Diesel engines of low weight and possessing operating characteristics satisfactory for this service are most interesting and have attracted the careful consideration of engineers connected with both the aeronautic-engine industry and the Diesel-engine industry. It is proposed in the present paper to discuss the general considerations involved, to make an attempt to evaluate quantitatively the possibilities of the Diesel engine as compared to the present carbureted engines, to analyze briefly the technical problems involved, to note the magnitude of recent advances and accomplishments pertinent to this application, and to discuss the probable type of airplane most suitable for Diesel application.

The merits of the Diesel engine as an aeronautic power plant have been frequently pointed out, but may well be again enumerated for the purpose of the present discussion. They include:

(1) Decreased cost of fuel
(2) Decreased fire hazard
(3) Non-interference with radio communication
(4) Increased radius of operation
(5) Special adaptability to two-stroke cycle
(6) Special adaptability to large units.

The disadvantages usually cited against the Diesel as an aircraft engine are:

(*A*) Increased specific weight
(*B*) Increased first cost
(*C*) Increased difficulty of maintenance
(*D*) Fuel less cleanly
(*E*) Fuel not generally available.

In order to establish a basis for analysis of the subject let us consider the comparative merits of the two forms of engine from the standpoint of installations at the opposite ends of the

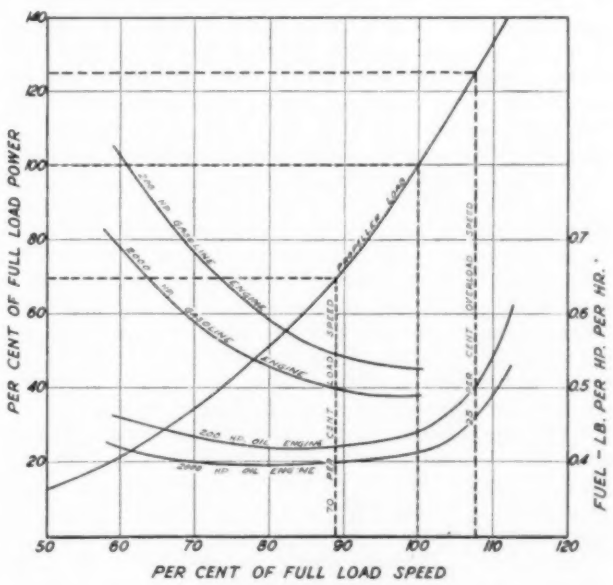

FIG. 1 FUEL CONSUMPTION OF GASOLINE AND OIL ENGINES AT VARYING LOADS

TABLE 1 COMPARISON OF TWO FORMS OF ENGINE INSTALLED IN TWO TYPES OF AIRCRAFT

	Sporting	Transport
Type of service

size scale, such as a 200-hp. airplane used largely for sporting purposes and a 2000-hp. airplane employed in regular commercial-transport service. Consider also that these four aircraft

[1] Vice-Pres. and Gen. Mgr., Emsco Aero Engine Company.
[2] Fuel Systems Engineer, Emsco Aero Engine Company.

Presented at the Third National Meeting of the A.S.M.E. Aeronautic Division, St. Louis, Mo., May 27 to 30, 1929.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

are powered with a single engine each and that all cruise at 120 m.p.h. on three-quarters power. Table 1 gives data for these units as based on factors believed to be reasonable.

The cost of gasoline is relatively unimportant for the small airplane, being less than 2½ cents per mile, while for the large unit it approximates 21 cents per mile. The use of a fuel costing one-fourth as much as aviation gasoline would mean a saving of only 2 cents per mile or $2.30 per hour for the 200-hp. unit, but would approximate 17 cents per mile or $21 per hour for the large unit. The $2.30 saving would have little effect on the total operating costs of the small airplane, even though flown frequently, but the $21 saving would be an important item in the operating costs of the large airplane used continuously in regular transport service. Decreased operating costs of the large unit due to lowered fuel costs alone would approximate the fare of two passengers, and this saving certainly would be a material aid in putting air transport on a paying basis.

The probable decrease of fire hazard realizable by the use of the less-inflammable fuel is difficult to evaluate. Certainly it must be admitted that Diesel fuel with its flash point at not less than 150 deg. fahr. is far less likely than aviation gasoline, or even automobile gasoline, to ignite as the result of a fuel leak or a crash. There can be no question of this if the source of potential ignition be a spark or flame. There is a difference of opinion, however, when the potential ignition cause is a hot surface. Laboratory experiments with hot plates indicate that, under some conditions of limited temperature and air flow, some fuel oils will ignite from a hot plate more readily than will aviation gasoline, thus leading to a limited conclusion that the fuel oil was no safer. However, the experience to date with aeronautic and automotive Diesels, as well as the extensive experience with land and marine Diesels, tends to show that the hot-surface ignition risk is in reality practically non-existent. This opinion has been confirmed by several personal experiences in which fuel oil was sprayed from burst fuel lines or spilled over exhaust pipes or other hot surfaces during tests, but in no case did inflammation result. Even when the fuel oil is ignited, the spread of the flame is relatively slow, and there is therefore a much greater opportunity for extinguishing or rescuing.

While the passenger in the small airplane would probably appreciate the lessened fire hazard as much as those in the large plane, it appears that the pilot of the smaller aircraft usually keeps closer to landing fields, and has a relatively much better opportunity to make a prompt landing in case of actual or threatened fire. The large airplane on a transport route is usually not as free to make immediate landings, and the larger passenger capacity makes the risk responsibility much greater, so that it appears that the large airplane, especially when used for passenger transport, is most in need of the fire-hazard reduction offered by the Diesel engine.

Elimination of the high-tension ignition system made possible by the Diesel greatly simplifies the problem of radio communication with the airplane. The standard ignition system can be shielded so as to nearly eliminate interference with radio signals, but the resulting complication increases both the first and maintenance costs, and has the serious disadvantage of reducing the reliability of this most important element of the carburetted engine. For the present comparison it may be said that only a very small percentage of the smaller airplanes will be equipped with radio, either for communication or direction-finding purposes, so that this advantage of the Diesel is of small importance in that case. The large airplane will most certainly be equipped for two-way communication as well as direction finding, and no interference with good radio reception or transmission can be tolerated. The inherent advantage of the Diesel in this respect is therefore of most value in the large aircraft.

For reasons similar to those governing in the item of fuel costs, the small airplane derives little real advantage from the increased radius of operation made possible by the Diesel. The cruising-load fuel consumption of the 200-hp. unit may be taken at 0.55 lb. per hp-hr. for the standard gasoline engine and 0.42 lb. per hp-hr. for the Diesel, as shown in Table 1. This increased radius of around 30 per cent is not of very great value to an airplane which ordinarily makes only short flights. The reduction of fuel load is also unimportant, even for flights of two or three hours' duration.

The case is very much different, however, for the 2000-hp. unit in transportation service. The specific consumption of such an engine at cruising load would be about 0.50 lb. per hp-hr. for the gasoline engine and 0.40 lb. per hp-hr. for the Diesel. The increased radius of 25 per cent would be an important item in this large unit, as the resulting increase of pay-load capacity would yield immediate returns of economic importance. For a four-hour trip the actual increase of pay load would approximate 600 lb., the equivalent of three or four passengers.

The foregoing comparative figures are based upon more or less ideal conditions, and it is probable that the comparison of actual service results would be somewhat more favorable to the Diesel engine. The modern carbureted aircraft engine can be made to show excellent fuel economy on the test stand, but it is difficult if not impossible to realize such economies under actual service conditions.

Considerations of reliability operate to compel the use of mixture ratios in service which are considerably richer than those accompanying the low fuel consumption under test conditions. Easy starting, prompt warming up, smooth idling and running, cool operation, snappy acceleration, decreased fire risk from backfire, and other desirable attributes are accentuated by operating with a mixture ratio richer than that which gives maximum fuel economy. The carbureted engine which can be made to show a specific consumption of 0.45 lb. per hp-hr. on the test stand probably has an actual service consumption rate between 0.55 and 0.60 lb. per hp-hr. The limited experience accumulated to date with high-speed Diesels coming within the general requirements of the aeronautic type tends to show that the fuel consumption of the Diesel will show very little increase under service conditions. It is believed that the aeronautic Diesel which will yield a consumption of 0.35 lb. per hp-hr. on the test stand will give a normal service consumption rate not exceeding 0.40 lb. per hp-hr.

The preceding discussion serves merely to indicate the order of the fuel-economy advantages offered by the Diesel in air-transport service. Considered from the economic standpoint only, the prospect of carrying three or four additional passengers on a four-hour trip, and at a saving in fuel cost more than equivalent to the fare of still another passenger, can hardly fail to interest the large commercial organization faced with the problem of creating or increasing operating profits.

The power output of any given engine at a given speed being a function of the product of the b.m.e.p. and the frequency of power strokes, it is apparent that the power may be increased by doubling the number of power strokes, even though a lower b.m.e.p. is incurred in so doing. This advantage of two-stroke cycle operation has long attracted the efforts of the aircraft- and automotive-engine designer, but the complication and reduced efficiency accompanying all solutions so far proposed in connection with the carbureted engine have prevented the realization of the anticipated advantages. The case is quite different with the fuel-injection engine, however, and the two-stroke Diesel offers a definite means of realizing this increase of power output.

The effective stroke of the two-stroke Diesel piston is less than that of the four-stroke piston by some fraction of the height of

the ports, the i.m.e.p. is slightly lower by reason of the lower combustion efficiency resulting from the less effective scavenging, and the mechanical efficiency is lowered to the extent of the approximate difference between the energy required to move the scavenge air in the two-stroke engine, and the energy to drive the four-stroke engine during the exhaust and suction strokes, so that the two-stroke engine cannot be expected to equal the b.m.e.p. of the four-stroke engine. For any specific application, the factors involved may be so adjusted that the most favorable combination of the b.m.e.p. and specific fuel consumption is obtained. The performance of modern Diesel engines in land and marine service shows that as low a specific fuel consumption can be expected from the two-stroke engine as from the four-stroke type, if a reduction of about 10 per cent in b.m.e.p. is accepted. This loss may possibly be doubled for the higher operating speeds required of aeronautical Diesels.

Experience in the laboratory and with actual production high-speed automotive four-cycle Diesels shows that at the present time there can be secured and maintained in ordinary practice a full load b.m.e.p. of 100 lb. per sq. in., with a fuel consumption of 0.40 lb. per hp-hr. and an overload b.m.e.p. of 120 lb. per sq. in. at 0.48 lb. per hp-hr. at reasonable maximum pressures. Those figures would be reduced to perhaps 80 and 95 lb. per sq. in. for the two-cycle engine at the same fuel-consumption rates, so that the power output per cylinder would be increased by about 60 per cent. This increased power will be obtained at a cost of perhaps as much as 25 per cent increase in engine weight, represented mainly by the scavenge blower, so that the weight per horsepower should be reduced by about 20 per cent. As the space occupied by the engine is reduced by a greater percentage, the advantageous possibilities of the two-stroke aeronautical Diesel are most interesting.

This favorable comparison does not hold for most of the two-stroke Diesel mechanisms now in use, however, as many of these are inefficient in their scavenging or combustion functions or involve too high friction losses in complicated mechanisms. High-percentage scavenging must be secured with a minimum volume of air supplied at a minimum pressure. Exhaust ports must be of minimum height consistent with good scavenging, in order that the effective expansion stroke may not be unduly shortened. The fuel spray must be of correct characteristics and form. The combustion-chamber shape must suit the fuel spray form, and effective turbulence must be secured. The scavenge air pump must be efficient, and the engine structure itself must be of simple design involving those features making for high mechanical efficiency.

Our consideration of the merits of the Diesel as an aircraft engine having confirmed the original statement that this engine is of particular advantage for large units, let us now take up the disadvantages cited. It has been frequently stated that the Diesel must be much heavier than the carburetted engine because of the inherent limitations imposed by the lower b.m.e.p. and the much higher combustion pressure. Frequent repetition of this opinion has caused it to be generally accepted, notwithstanding the disproving accomplishments of Beardmore, Maybach, Junkers, and several other organizations. Since weight of engine structure is roughly proportional to the magnitude of the maximum forces handled, and power output is proportional to b.m.e.p., the realization of a light engine is dependent upon a low ratio of maximum to mean cylinder pressure. This is equivalent to saying that the material of the engine structure must be usefully worked at stresses as uniform and high as possible. The exhaust and inlet strokes of the four-cycle engine are direct violations of this requirement, since only useless inertia loads are incurred. An extension of this reasoning leads to the conclusion that double-acting two-stroke cylinders would be ideal from this standpoint of engine-structure weight utilization, although the gain from this last step would be limited by material fatigue induced by the reversed high stresses.

A few writers have contended that the attainment of acceptable b.m.e.p. and fuel economy in high-speed Diesels depends upon such an early injection as to insure combustion of all or nearly all of the fuel under constant-volume conditions. The sharp-topped or Otto cycle card resulting in that case has a very high maximum pressure value of the order of 1200 lb. per sq. in., and this high pressure involves the serious disadvantage of a correspondingly heavy engine structure. The constant-volume combustion-requirement theory has been disproved by laboratory and development tests of sufficient number to be conclusive, so that advanced workers in this field know that it is not unduly difficult to secure a reasonably high b.m.e.p. combined with a low fuel consumption at maximum pressures as low as 600 lb. per sq. in. That this accomplishment is not particularly new is indicated by data in Proc. I.A.E., Vol. XXII, 1927–28, showing that the R.A.E. 20T experimental Diesel engine had some time previously yielded 107 lb. per sq. in. b.m.e.p. at 1200 r.p.m. on a fuel consumption of 0.443 lb. per hp-hr. with a maximum pressure of 650 lb. per sq. in. The main requirement is to control the injection so that the combustion follows the desired dual cycle, part at constant volume and the rest at constant pressure. A maximum pressure of 600 lb. per sq. in. is not much higher than is regularly encountered in the carburetted aircraft engine, so that an engine structure of similar dimensions should suffice.

The best modern four-stroke carburetted aeronautic engines regularly yield a maximum b.m.e.p. of 140 lb. per sq. in. as compared to the stated value of 120 lb. per sq. in. for the high-speed four-stroke Diesel, but the two-stroke Diesel may show an equivalent value of $2 \times 95 = 190$ lb. per sq. in. On this basis, the weight of the two-stroke Diesel could be some 35 per cent greater than that of the four-stroke carburetted engine for the same cylinder displacement, and this would take care of such slightly higher maximum pressures as would be experienced with proper combustion control. It is to be expected, however, that more difficulty will be experienced in securing a satisfactory weight per horsepower in small units than in large ones, so that here again the Diesel is of most interest for large-powered units.

Owing mainly to the extra high quality of materials and workmanship required in the construction of fuel pumps and injection nozzles, the Diesel engine is more expensive to build than the carburetted engine for an equal number of cylinders. For this reason it is desirable to limit the number of cylinders and to use the two-stroke cycle. This urge toward the use of fewer and larger cylinders operates to advantage in large Diesel engines and tends to equalize their cost as compared with carburetted engines of the same power. It is believed that the continual normal development and simplification of fuel-injection systems will soon reduce the cost of this part of the Diesel engine to such an extent that the two-stroke Diesel in large powers will cost no more than the carburetted engine of equal power and torque uniformity. In the meantime, any extra cost of the Diesel must be amortized from the fuel-cost saving which it makes possible.

As the 200-hp. Diesel must have not less than five four-stroke cylinders or three two-stroke cylinders in order to give an acceptable balance and torque uniformity, the use of large cylinders is prohibited. Not less than three to five injection-system units are therefore required for this small engine. The 2000-hp. Diesel on the other hand may have as few as five large two-stroke cylinders requiring only five injection units, so that the large engine is here again seen to be the most promising field for the aircraft Diesel.

Maintenance of the Diesel has been stated to be more difficult and expensive than that of the carburetted engine. This is

probably true for engines using complicated and delicate fuel-injection systems which require frequent inspection, cleaning, and adjustment. The more advanced types of fuel pumps and injection nozzles, however, will show a surprising ruggedness and long life, so that there is every reason to believe that these seemingly delicate mechanisms may soon be normally expected to be at least as free from need of attention as is the modern carburetor or magneto. Perhaps the best available data bearing upon this point is the record of the Beardmore rail-car engines in regular operation on the Canadian National Railway, where an average of 1200 hr. of operation is secured from the fuel pumps without service attention, while the injection nozzles require only that the carbon be removed from the nozzle tip every 250 hr. or so of operation. In any event, whatever attention is required is more readily assured to the large engine in transport service than to the small engine with its necessarily more casual care, again pointing to the large unit as the legitimate field for the aircraft Diesel.

No one will deny that Diesel fuel oil is less cleanly than aviation gasoline. The fuel oil has a distinctly disagreeable odor, and serves as a medium for the accumulation of a dirty deposit when spilled and not wiped clean. The clean evaporation of aviation gasoline is in sharp contrast, and is a point against the use of fuel oil in the small engines used for sport flying. Special cleanliness provisions are not difficult to secure, however, in the case of large engines in regular commercial-transport service. The further fact that fuel oil is not generally obtainable would be a real difficulty for the small sporting plane which may frequently refuel at other than its home field. The large airplane in commercial-transport service covers a definite route, and private fueling facilities are usually provided at the terminals by the operating company. Emergency supplies of fuel oil may readily be stored at important intermediate fields, the storage deterioration loss being naturally very small with this fuel. The use of fuel oil therefore appears to present no difficulties to the operator of the 2000-hp. Diesel.

It is true, or nearly so, that airplanes are not at present large enough to require power plants as large as the 2000-hp. Diesel. This depends upon what may be considered the best power-plant arrangement for large commercial aircraft. We have been frequently told that the airplane with only a single engine is a poor risk, because, having only one engine to fail, failure meant an immediate forced landing. Proponents of this argument have assured us that the three-engine airplane represented the acme of safety, on the basis that failure of an engine merely necessitates that the airplane land at the next convenient field on its route. This supposed safety might be realized if any two of the engines would sustain the airplane in level flight in ordinary weather and still permit adequate control and maneuverability. In many of the three-engine airplanes so far offered this performance is not realized, so that a failure of one engine generally necessitates an immediate landing. The public has been so thoroughly sold on the supposed supersafety of the three-engine airplane by interests engaged in its exploitation that it will pass by as unsafe a modern overpowered single-engine airplane, and then unhesitatingly climb into any sort of airplane that may be equipped with three engines. The number of recent serious crashes of three-engine airplanes of reputable make, however, has had the effect of weakening the public confidence in this type of safety. Many engineers in the industry believe that the three-engine airplane which will not give a reasonable performance on any two of its engines is really only one-third as safe from the standpoint of power-plant failure as the properly powered single-engine airplane. In many cases the correct ratio is more nearly one-fourth or one-fifth, since each of the three small engines cannot well be as perfect in construction, installation, and maintenance as the single large engine, so that the risk of individual failure is therefore very much greater than for the single large engine.

Moreover, the general practice followed in this country of hanging two of the engines below the wings of a monoplane results in an aerodynamically inefficient monstrosity. The wings interfere with the flow of air through the propellers, while the propellers and engines ruin the smooth flow of air past the wing at that point. This is proved by the fact that two-thirds of the total power of the three-engine combination will yield a superior performance when concentrated in one properly mounted engine. This means that a single engine of power equal to the sum of the three will give the same maximum performance when throttled to two-thirds full power, with resulting increased reliability and fuel economy. The single-engine installation will inherently be considerably lighter, so that its reliability may be still further increased by the strengthening of structural elements, by the addition of duplicate or standby accessories, or by other means of compensating for the failure of those elements in which experience has shown the greatest weakness to lie. If reasonably full advantage is taken of the possibilities of this opportunity, the single-engine airplane will prove more reliable than even the three-engine machine which will really fly on any two of its engines.

As airplanes increase in size, the problems of satisfactory power-plant installation become more serious. Looking forward to the really large commercial aircraft of, say, 100-passenger capacity, one is struck with the obvious conclusion that the power-plant solution is not to be reached by mere multiplication of engine units of sizes now available. Present reports of the new Dornier X seaplane now under construction state that it will be powered with 12 Jupiter engines. This hanging of engines all over a large airplane is assuredly most undesirable from the standpoint of control and accessibility, however valuable it may appear to the airplane designer as a means of minimizing the structural stresses by distribution of weight and thrust. The larger the commercial airplane, and the more importance is attached to reliability, the more certain it is that the power plants will be few in number and so placed that they will be under constant observation and care while in flight. There seems to be no fundamental justification from the load- and thrust-distribution standpoint for using more than four engines on even the largest airplanes now proposed.

Designers are now providing from 60 to 90 hp. per person for the better class of two-engine and three-engine transports. The 100-passenger high-speed transport may therefore require about 6000 hp., and this is given by three 2000-hp. Diesels. As a matter of interest, the Dornier X (also designated "100 Passenger Boat") with its 12 Jupiter engines has a rated total power of just that amount. On the same basis, the 50-passenger transport which may be said to be just around the corner might be powered with two 2000-hp. Diesels or one 3000-hp. unit. The authors believe that the logical development of such large airplanes cannot be expected until engines of correspondingly large size become available.

The modern aeronautic engine is a remarkably reliable power plant. The majority of such failures as do occur originate in the accessories rather than in the structural parts of the engine itself. Of course, crankshafts, connecting rods, valves, and other major parts do break occasionally, but failures of this kind are generally looked upon as evidence of faulty construction, and will soon be considered as inexcusable. The minor elements have not, however, reached as high a state of perfection, the so-called plumbing of the power plant being perhaps the greatest source of weakness. The rise of the air-cooled engine has eliminated the weaknesses of the water-cooling system, but the fuel and oil systems still remain to plague us. The ignition system is perhaps of the same

order of weakness, with the carburetion system close behind.

The comparative reliability of the Diesel in respect to these several features may be at least roughly estimated. The main structural parts may evidently be made just as reliable as for the carburetted engine by adhering to similar stresses, load factors, and temperature gradients. The two-stroke Diesel makes possible the elimination of failures of valves and their operating gear. The fuel supply system up to the engine may be of the same general character for both oil and gasoline engines, but the higher viscosity of the fuel oil reduces the loss through small leaks, while the relatively slight inflammability eliminates the necessity of immediate landing because of fire hazard. The lubricating-oil system would be quite similar, so that the reliability of this element might be said to be unaffected by the engine type. As the Diesel has no ignition system, all failures due to this source are eliminated. The carburetion system is replaced by a number of fuel-injection pumps and spray nozzles, both the total number of parts, and the apparent complication being thereby increased. While this at first glance would seem to increase the chances of failure, there is reason to believe that the comparative ruggedness of the moving parts and the large forces available to operate them will tend to make this system as reliable as the carburetor. Furthermore, failure of an injection pump or nozzle need affect only the one cylinder served thereby, so that the remaining cylinders could continue to function normally, an advantage which could be secured with the carburetted engine only by having a separate carburetor for each cylinder. The scavenge and supercharge blower required for the two-stroke Diesel will offset and be of the same order of reliability as the geared centrifugal-mixture distributor and supercharger now incorporated in many of the carburetted engines. Taking all these points into consideration, and remembering that the two-stroke Diesel need have only one-half as many cylinders or pistons as the four-stroke carburetor engine to secure the same torque uniformity, it is concluded that the two-stroke Diesel especially offers a wide margin of advantage from the standpoint of service reliability.

Failure of important structural members of modern aircraft engines is very rare, and is being further diminished to the vanishing point by constant improvements in design and material. Most power-plant failures arise from causes which in themselves are relatively minor, and which in the majority of cases could have been easily corrected or temporarily repaired if it had been possible to work on the engine during flight. The bulk of future air transportation will be carried in large airplanes or airships for the same reasons that the bulk of ocean transportation is carried by large ships and not by motor boats. To place the engines of such aircraft in an inaccessible position is as fundamentally unwise as it would be to lock the engine-room crew of an ocean liner out of the engine room during the whole voyage. This fact is recognized in airship design, and the engine eggs or nacelles are made large enough to permit a mechanic to work on the engine at any time. As the airplane is more dependent upon the regular operation of its engines than the airship, it is rather peculiar that the large-airplane designers have so seldom made provision for this attendance. A partial explanation applying at least to conditions in this country may be based on the perfection and popularity of air-cooled engines of excellent reliability.

The air-cooled engine can be placed in an engine compartment or nacelle only with the greatest difficulty, and even then the necessary air ducts or shields would prevent effective detail attention by a mechanic. The water- or steam-cooled engine on the other hand can be readily enclosed and made generally accessible. Attendance on such enclosed water- or steam-cooled engines is certainly no more difficult or disagreeable than in the case of the submarine or the destroyer. The use of surface condensers and cabin-heating radiators of small size takes care of the final heat disposal by condensing the steam, thus allowing the greatest latitude in placing the engines.

The difficulty of dissipating the heat from the air-cooled cylinder increases with the cylinder size, probably about in proportion to the increase of the ratio of volume to surface (or directly as the diameter) so that there is some indefinite limit beyond which it is not practical to increase the air-cooled cylinder size. Large engines of that type will therefore involve a large number of cylinders, with resulting great increase of complication and risk of failure. The liquid-cooled cylinder can, on the other hand, be satisfactorily operated in large sizes, so that a large power output can be secured with a relatively simple engine involving the minimum number of cylinders necessary to secure satisfactorily smooth operation. The use of a cooling fluid having a much higher boiling point than water, such as ethylene glycol with which the Army Air Corps has been experimenting, will undoubtedly operate to still further reduce any apparent advantages offered by direct air cooling.

Despite the important advances made in the development of the high-speed oil engine in the last few years there still remains a great deal to be learned. It may be of interest to consider the various problems that need solution before the engine can be considered to be in a position to displace the gasoline engine. These include (*a*) efficiency (thermodynamic and combustion), (*b*) power output, and (*c*) reduction of engine weight.

Thermodynamic Efficiency. Despite the fact that the Diesel cycle is the most efficient one at present in use, it is considered that a great improvement in the thermodynamic efficiency has yet to be made in order to secure the maximum power output that the cycle is capable of delivering. Since so much has been written under this heading in the last year or so, it is not proposed to discuss this in great detail, but rather to set out the divergence of the actual cycle from theory, and consider its effect upon the design, power output, etc.

Experience with the high-speed oil engine has shown that for an efficient unit it is necessary to depart from the Diesel cycle, where combustion occurs at a constant pressure equal to that of the compression pressure, and operate on what is known as the dual cycle where heat addition occurs at both constant volume and constant pressure. This cycle is practically generally used now, whatever the engine speed, but the amount of heat addition at constant volume has been increased considerably in high-speed work. This of necessity involves increase in the maximum cylinder pressure, and the engine design must therefore be modified to take care of the resultant stresses. This increase in the amount of constant-volume combustion results in a more efficient cycle, and therefore a greater power output for a given fuel supply. The maximum efficiency would be reached if all the fuel was burned at constant volume, this cycle being that of the gasoline engine, but possessing a higher efficiency due to the greater expansion ratio possible. In practice it is not possible to utilize constant-volume combustion only, as it is at present considered that the resultant cylinder pressures would be higher than can be handled safely for long periods. The efficiency of the actual dual cycle used falls short of this maximum value, but is still much higher than that of the gasoline engine, which means that the oil engine will deliver more work than the gasoline engine for a constant air charge and given heat supply if combustion is completed. Theoretical reasons thus indicate that the output of an oil engine should exceed that of the gasoline engine by 10 to 15 per cent.

In practice the use of partial combustion at constant volume results in a greater gain in economy than simple theory indicates, since the higher temperatures involved, coupled with the slightly increased time available for combustion, result in a very substantial reduction in the fuel consumption. There is, however,

a limit to the amount of the constant-volume portion of the cycle, and this depends to some extent upon the engine speed. It is estimated that at 800 r.p.m. there is little gain in exceeding 950 lb. per sq. in. maximum pressure, while at 1000 r.p.m. 1100 to 1200 lb. per sq. in. represents approximately the most economical figure. For still higher speeds the limit has yet to be determined, the authors having used 1500 lb. per sq. in. without any sign of the limit being reached. These higher figures are outside the range that can be recommended for present practice, but fortunately the economies obtainable at lower pressures are such that the high-speed oil engine ranks as the most efficient prime mover yet constructed. So far as the authors' experience is concerned the following figures represent closely the most suitable maximum pressures at which excellent all-around economy and reliability can be obtained:

Speed, r.p.m.	Maximum pressure, lb. per sq. in.
600	700
800	750
1000	800
1400	900

Further gains result in actual practice, principally due to the fact that it is not necessary to operate the engine on a constant-mixture strength. At reduced loads a full air charge is still drawn into the engine cylinder, the power output being regulated by the quantity of fuel injected into this air at the end of the compression stroke resulting in low mean-cyclic temperatures and therefore reduced heat losses. In the gasoline engine the mixture strength must be maintained within very narrow limits, and the maximum temperatures of the cycle vary but little with the power, resulting in proportionally increased heat losses at reduced throttle openings. In the case of aircraft full power is ordinarily required for only a very short portion of the time that the engine is in operation. The average output is of the order of 70 per cent of full power at about 85 per cent of normal full speed, and it is at such loads and speeds that any comparison should properly be made. Fig. 1 shows the usual form of power curve for a propeller load, which applies equally well to Diesel and carburetted engines. Propeller-load fuel-consumption curves for both types of engines in two sizes also are shown, the data having been taken from the best available information. Note that the full load specific consumption of 0.41 lb. per hp-hr. for the 2000-hp. Diesel is 16 per cent better than the corresponding value of 0.49 lb. per hp-hr. for the carburetted engine, but that at 70 per cent load the Diesel advantage has increased to 20 per cent. The Diesel advantage is considerably greater in the small 200-hp. engine. Note also that the Diesel will carry a 25 per cent overload on considerably less fuel than the carburetted engine will carry its normal load.

Efficiency of Combustion. The previous paragraphs indicate the possibilities of the oil engine from a theoretical standpoint. In actual practice, it has not yet been possible to run these engines at a mean pressure approaching the theoretical limit. The maximum mean pressure is a function of the efficiency with which the combustion process is carried out. It is here that present knowledge is deficient. Until improvements are made in injection and combustion control, the maximum power output will be much less than that theoretically possible. The gasoline engine runs at approximately correct-mixture strength, and due to the intimate mixture of the fuel with the air, the combustion process is nearly 100 per cent efficient. The whole of the oxygen available in the air charge takes part in the combustion process, and the indicated efficiency approaches very closely to the theoretical limit. The efficiency of combustion is to a certain extent outside the control of the designer of the gasoline engine, so that a definite result is quite certain if the combustion-chamber shape, position of spark plugs, etc., fulfil the necessary conditions for efficiency. But in the case of the oil engine, even though the chamber shape and position of atomizer be ideal, the results obtained will depend upon the manner in which the injection process is carried out. Seemingly slight changes in the sprayer or pumping system often produce a great variation in the combustion process.

If continued progress is to be made, it will be necessary to determine the laws controlling the combustion, to the end that the whole of the oxygen available in the charge can be made to take part in the oxidation process. The fuel has to be sprayed into and distributed throughout the combustion chamber during the firing period, and at present it has been found impracticable to utilize the whole of the air available for the combustion process, an excess of something like 30 per cent usually existing in the exhaust. By the addition of extra fuel it is possible to cause some of this extra air to take part in the combustion process, but only at the expense of a rather rapid increase in fuel consumption, say from 0.38 to 0.48 lb. per hp-hr. for an increase of b.m.e.p. from 100 to 120 lb. per sq. in. This additional consumption is not in itself of great importance since the fuel used is still less than that of the gasoline engine, the greatest objection being the black smoke that is emitted from the exhaust. Provided that this can be tolerated there is no reason why, in the case of an airplane, this maximum output could not be used for the take-off. This smoke is obviously due to imperfect distribution and combustion.

How well this problem of air utilization is to be solved is not easy to say, but the result of years of experience in the testing of all types of oil engines has indicated that at least a partial solution is at hand in the present engine. It is necessary to give very careful attention to the combustion chamber, spray valve, and injection system, analyze their functions, and determine the correct relationship of one to the other in order to secure increased efficiency of combustion. Very low fuel consumptions have been obtained at different times, and when an engine is operating under such conditions (say 0.35 lb. per hp-hr. at 100 lb. per sq. in. b.m.e.p.) the maximum output is of the order of 130 lb. per sq. in. b.m.e.p. This begins to compare favorably with a gasoline engine, but is considered to be capable of material improvement. The attention that is now being given this type of engine should result in such mean pressures being easily available at an early date on four-stroke engines, with a maximum of say 110 lb. per sq. in. b.m.e.p. in the case of two-stroke engines.

Power Output. In judging the relative merits of various prime movers it is necessary not only to consider the thermodynamic efficiency, but also the power output per unit of air consumed, weight of material involved, and the relative costs of construction. It is not proposed to consider the item of costs, since so much depends upon the number of engines under construction. Most gasoline engines are manufactured on a production basis which is conducive to low costs, while the high-speed oil engine is being constructed only in very small numbers at present. Undoubtedly the oil engine will be slightly more expensive to manufacture, due principally to the high-class workmanship required for fuel pumps and atomizers.

Of the technical difficulties that have to be overcome in the development of the Diesel engine, the question of its power output is the most important, and at present it is necessary to install a slightly larger engine for a given horsepower. The usual rating of the four-cycle oil engine is of the order of 100 lb. per sq. in. b.m.e.p. against an average of say 130 to 140 lb. per sq. in. for a gasoline engine. It must be remembered that the latter engine is usually rated at practically its maximum output for any given speed, increased power being obtained only by increase in the speed of revolution, while in the case of the fuel-oil engine the rated output is usually that at which a reasonable fuel economy

and clear exhaust are obtained. The oil engine thus rated has a capacity of at least 10 to 20 per cent greater power for long periods while even 25 per cent could be carried for, say, 15 min. with perfect safety, much depending upon the injection system. The actual maximum power therefore is quite near that of the gasoline engine. However, the best interests of the industry will be served by keeping the maximum output of the four-stroke oil engine within, say, 110 lb. per sq. in. until greater experience is obtained, which means that the oil engine will be rated at 85 to 90 per cent of the power of the corresponding gasoline engine running at the same speed. The maximum output of the two-stroke oil engine should be limited to 100 lb. per sq. in.

The power output from any internal-combustion engine is limited by the following: (*a*) The air drawn in per stroke, (*b*) the efficiency of the cycle, (*c*) the efficiency of combustion, (*d*) mechanical losses, (*e*) speed of revolution, and (*f*) cycle of operations. Since (*b*) and (*c*) have already been considered, attention will be concentrated on the other items.

Air Supply. Little need be said on this point other than to distinguish the differences existing in the two types of engine. The fuel and air are drawn into the gasoline engine cylinder together, and the evaporation of the fuel causes a reduction of air temperature, and results in a higher volumetric efficiency than would otherwise exist. This action does not occur in the oil engine, resulting in a slightly lower volumetric efficiency. Against this has to be set the fact that the exhaust gases left in the clearance space of the gasoline engine are at a higher temperature, and roughly $2^1/_2$ times the volume of that of the oil engine, thus reducing slightly the advantage due to the cooling action of the fuel. On the whole, the volumetric efficiency of the oil engine is slightly less than that of the vapor engine, which, other things being equal, will result in reduced output.

Mechanical Losses. The mechanical losses of an engine determine how much of the work developed in the engine cylinder is actually delivered for useful purposes. These losses depend chiefly upon design, and are affected but little by the cycle employed, and hence the engine losses do not depend upon whether gasoline or fuel oil is used as fuel. Due to the fact that the pressures of the oil-engine cycle exceed those of the gasoline engine, there is possibly a slightly higher piston friction in the former. There is also the loss of power due to the fact that the high-pressure injection pump absorbs more power than the magnetos of the gasoline engine. This effect is very small, however, as the total power absorbed by the fuel pump is little over 1 per cent of the engine output.

Engines of the high-speed mechanical-injection type, with plain white-metal bearings throughout, have shown a mechanical efficiency of 85 per cent. This value is very little different from that of a gasoline engine of similar design, so that differences of mechanical efficiency are of slight importance when considering the relative merits of the two prime movers.

Speed of Revolution. Not many years ago the oil engine was considered to be essentially a slow-speed engine and its application to automotive and aircraft purposes almost an impossibility. With the increasing knowledge that has become available on the injection and combustion of liquid fuels, piston speeds have increased to figures which compare very favorably with the gasoline engine, and excellent test results have been secured at the same time. So far as the authors' experience is concerned there appears to be no limit to the speed of rotation that can be employed, the limiting speed of combustion being far from reached.

It has been stated that the time lag of combustion remains constant, and that therefore satisfactory results can be secured only by using the constant-volume combustion cycle. If this was the case the high-speed engine would be an impossibility. There is a lag of something like 15 deg. of crank angle between injection and combustion, no matter what the speed may be. Consider the case of an engine running at 300 r.p.m. Tests have shown that the lag is of the order given, and this represents a time interval of $^1/_{120}$ sec. Now in the case of an engine running at 1800 r.p.m., the engine rotates through 90 deg. in this same time interval, so that, if no change occurred in the time lag, injection would have to begin something like 100 deg. before top dead center in order to secure ignition at the desired point. Under such conditions detonation would be very severe. Actual measurements have shown that the beginning of injection when operating at 1400 r.p.m. is something like 15 to 20 deg. before ignition occurs, which shows that time lag is not a constant quantity, but depends upon the degree of atomization, compression pressure, etc. There seems to be no reason why the oil engine should not run at any speed that may be necessary. Test results of engines at various speeds have shown that the economy is unaffected by high speed, and therefore there appears to be no factor in the combustion process which will limit the operating speed of the Diesel engine.

Cycle of Operations. Present practice in the aeronautic Diesel engine is solely in the direction of four-stroke engines, but there seems to be no reason why this type of engine should not put the two-stroke principle upon a satisfactory basis due to the use of air only for scavenging purposes, thus eliminating the loss of fuel that occurs in the gasoline type, together with the other objections resulting from the employment of an air-fuel mixture for scavenging.

A two-stroke Diesel engine of the opposed-piston type, experimented with by the authors, developed indicated mean-effective pressures of the order of 135 lb. per sq. in. with a fuel consumption of 0.32 lb. per i.hp-hr. and maximum pressure of 650 lb. per sq. in. when running at 500 r.p.m. Now if this performance can be obtained in an aeronautic engine with a mechanical efficiency of 80 per cent, a maximum output of 108 lb. per sq. in. b.m.e.p. at 0.40 lb. per b.hp-hr. will be possible, and this is equivalent to 216 lb. per sq. in. b.m.e.p. in a four-stroke engine. Even allowing for the higher engine weight mainly due to scavenge blower, there would still be a considerable drop in weight per horsepower over a corresponding type of four-stroke engine.

A four-stroke oil engine weighs approximately 10 per cent more than a gasoline engine of the same type and size, and it should be possible to design a two-stroke engine for a further addition of, say, 10 per cent to the weight. Now if such an engine was conservatively rated at an equivalent output of 170 lb. per sq. in. on a four-stroke basis, the resultant weight per horsepower would be of the order of that of the gasoline type, and the Diesel is at once placed upon a new footing altogether. It is considered that the two-stroke principle when correctly applied presents the best possible power output for a given engine weight, and therefore should be the logical prime mover for aircraft.

Reduction of Engine Weight. It has already been stated that the oil engine weighs approximately 10 per cent more than a corresponding gasoline engine. This additional weight is due to the fact that higher combustion pressures are encountered with this type of engine, and at present there seems little chance of reducing this weight without sacrificing fuel economy to such an extent that the additional fuel required for a long flight will more than offset the reduced engine weight. The research work now in progress may result in lower maximum pressures than those used at present, under 800 lb. per sq. in. being possible, but as aeronautic work requires maximum power and economy consistent with satisfactory service a material reduction of maximum pressure is very doubtful.

Test Results. There are so many variables in engine testing that it is almost impossible to vary them one by one, so that it becomes necessary for very complete data to be available when

tests results from various engines are being compared. The suppression of one or more facts that might appear unimportant may result in very different conclusions being reached. This is so well known that further stressing of this point is unnecessary, and it has been mentioned only because of the new variables that are encountered in considering the compression-ignition engine for aircraft. The essential conditions of engine testing for the gasoline engine and fuel-oil engine are similar, but there is one point that is very important in the case of the latter, and which does not enter into the case of the gasoline engine. This is the maximum pressure of combustion.

The maximum pressure of the gasoline engine is determined by the compression ratio employed, the mixture strength, spark advance, etc., and for engines of the same compression ratio the maximum pressure varies but little when correctly tuned up.

This does not apply in the case of the oil engine, the maximum pressure being one of the most important figures to be included in the test results. If this figure is omitted, as is frequently the case, the power output and fuel consumption are valueless for comparative purposes. The reason for this is the fact that, unlike the vapor engine, the whole fuel supply is not in the cylinder at the moment of ignition, and therefore considerable control of the combustion process is possible. If all the fuel is injected as rapidly as possible, the cycle approaches the well-known constant-volume type, while by distributing the injection period over a considerable crank angle the constant-pressure cycle of the slow-speed Diesel engine is approached. In the first case the maximum combustion pressure will be of the order of 1500 lb. per sq. in. while in the latter the pressure approaches that of compression, say 500 lb. per sq. in. for air-injection and 400 lb. per sq. in. for mechanical-injection engines. By adjustment of the injection device all intermediate conditions can be obtained, i.e., there will be some definite proportion of the fuel burned at constant volume, while the remainder will be burned at approximately constant pressure. This cycle is known as the dual cycle, and it can be shown theoretically that this cycle is more efficient than the constant-pressure cycle, and that the efficiency gradually increases until the constant-volume condition is reached, though due to variable specific heats of the gases of combustion the increase in efficiency gradually reduces.

It is therefore seen that the normal Diesel cycle is the most inefficient type of combustion considered and that the good fuel economy achieved with this type of engine is due to the high expansion ratio employed. Increased economy is obtained by burning some of the fuel at constant volume, but incurs the disadvantage of an increase of maximum pressures. In the case of the slow-speed engine of, say, 100 to 200 r.p.m. the amount of constant-volume combustion possible is strictly limited because of the fact that combustion proceeds very slowly, mainly due to the low value of turbulence. If the speed of injection be increased in an attempt to accelerate combustion, detonation results. Experience with engines ranging in speed from 100 to 1400 r.p.m. has proved that the degree of constant-volume combustion that can be usefully employed is a function of engine speed, increasing as the speed of rotation is increased, until at something like 1800 r.p.m. it is thought that the whole of the combustion process can be carried out at constant volume with advantage despite the resulting high maximum pressures. By this means maximum economy is possible, provided that the engine will withstand the stresses involved. The present state of the art is such that it is considered inadvisable to go to this extreme.

Extended experience with engines of all sizes and speeds has amply demonstrated that when the high-speed engine is under consideration, the maximum pressure is of vital importance. The following representative test figures will illustrate this: When operating at 1000 r.p.m. an increase in full-load maximum-combustion pressure from 750 lb. per sq. in. to 1100 lb. per sq. in. resulted in the fuel consumption being reduced from 0.40 lb. per hp-hr. to 0.355 lb. per hp-hr. while the maximum engine output was increased. Many other similar instances can be quoted to illustrate this, so that a statement of fuel consumption alone without its corresponding maximum pressure is of no use for strictly comparative purposes. Very few of the available test reports include this fundamental information, hence the relative merits of the different injection and combustion systems cannot be ascertained with any degree of accuracy.

TABLE 2 PERFORMANCE OF VARIOUS TYPES OF HIGH-SPEED OIL ENGINES

Engine	No. of cyls.	Bore and stroke, inches	Speed, r.p.m.	B.hp.	B.m.e.p., lb. sq. in.	Max. pres., lb. sq. in.	Fuel cons., lb. b.hp-hr.	Weight, lb. b.hp.
Beardmore.....	6	8.25 × 12	1400	700	103.0	850	0.43	3.36
Beardmore.....	6	8.25 × 12	1007	424	92.0	900	0.365	4

McLaren-Benz .	6	5.32 × 7.87	800	90	84.7	...	0.42	42.3

Table 2 records the performance of various types of high-speed oil engines at their rated outputs. Examination of these results reveal some very excellent performances, and the figures serve to bring out why the type of engine under discussion will be a very serious rival to the gasoline engine as used at present. The maximum pressures are recorded where available. It is seen in lines 2 and 4 that the abnormally high maximum pressures as used in the Packard engine are not essential for high efficiency, since the Beardmore engine has an economy far superior to the Packard engine while only utilizing a maximum pressure of 800 to 900 lb. per sq. in. against 1200 lb. per sq. in. in the latter. It is reported that the Packard engine has given a fuel consumption of 0.35 lb. per sq. in. at approximately 55 per cent propeller load, the maximum pressure being still 1200 lb. per sq. in. (See *S.A.E. Journal*, vol. XXIV, Feb., 1929.) The Beardmore engine also shows lower fuel consumptions if operated at reduced loads. The impression exists in certain quarters that high maximums are essential for success. It is seen that this is not the case, high efficiency being secured with normal maximums. In case it is necessary to obtain maximum economy and power output, the use of higher pressures can still be resorted to.

There is little information available regarding the results of two-stroke engines operating at high speed. The Junkers engine is the only example in Table 2, but its performance ranks among the best. This is attributed to the excellent scavenging of this type of engine, the opposed piston arrangement having the advantage of unidirectional gas flow, and resulting in very complete sweeping of the cylinder free of exhaust gases. The engine also operates at a comparatively high m.e.p. for a two-stroke engine, again due to its excellent scavenging. Results from the slow-speed engines of this type confirm these views. The employment of this system should make the aircraft two-stroke engine a practical proposition.

It is seen that only two of the high-speed engines shown can be considered to be of the aeronautic type, viz., the Packard and Beardmore, each of which weighs approximately 3 lb. per hp. Now some qualification of the weight per horsepower is necessary when considering the oil engine, since, unlike the gasoline engine, a maximum power up to 20 per cent greater than the rated load is possible, if the engine is an efficient one, and therefore the load assumed in calculating the specific weight must be stated. In the *S.A.E. Journal* already referred to, the Packard engine is given as weighing under 3 lb. per hp., but no mention is made as

to whether this applies to its rated load or overload capacity. The Beardmore engine weight is based upon the rated load, and therefore this figure represents what the engine will weigh for each horsepower of continuous output. The specific weight would be decreased considerably if computed for the temporary maximum load.

Detonation. The most important factor controlling the output of the gasoline engine is the limit imposed on the useful compression ratio due to the occurrence of detonation. The phenomenon of detonation is also encountered in the Diesel engine, but is so seldom met with in practice that little is known of the laws governing it. It was not until the high-duty engine appeared that this characteristic was observed at all. The conditions of compression, speed of injection, etc. usually encountered in the slow-speed engine are such that true detonation does not occur. The metallic ring identified with detonation in the gasoline engine is not met with in the Diesel, so far as the authors' experience is concerned, until loads and speeds far in excess of normal practice are attempted.

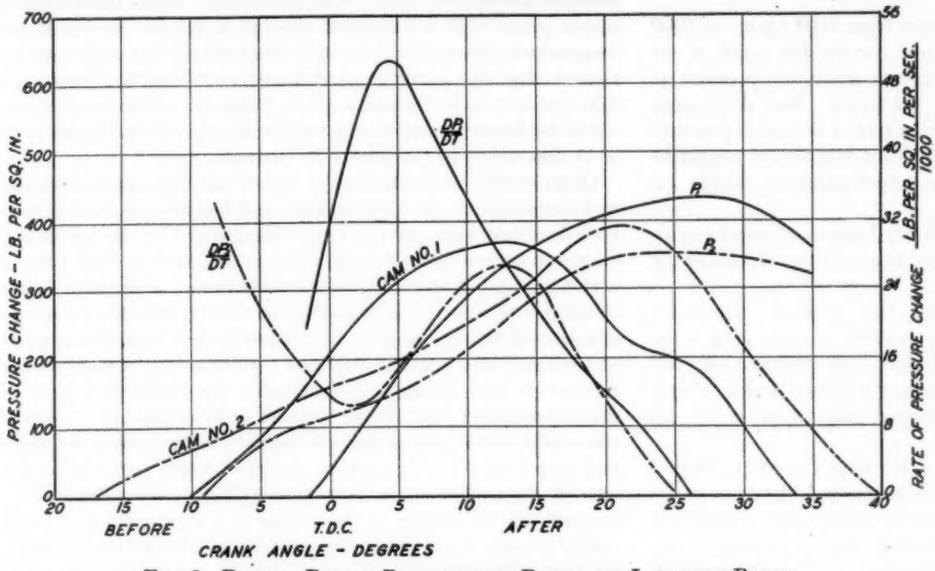

FIG. 2 RATE OF RISE OF PRESSURE FOR DIFFERENT INJECTION RATES

The effects of detonation upon the operation of a Diesel engine were first encountered by the authors while experimenting on a high-speed Doxford opposed-piston engine in which high b.m.e.p. was carried, and what appeared as excessively heavy explosions were encountered, though the indicator diagrams failed to show abnormal maximum pressures. These observations resulted in a close watch being kept on the combustion process while various changes were made in the factors controlling the combustion. A numerical value was given to each set of conditions to indicate the intensity of the resulting detonation as judged by the ear alone. This of course was only a rough estimate, but it served to give some sort of order of comparison.

The indicator diagrams obtained from the engine during this series of experiments were analyzed in the following manner. Combustion diagrams were plotted on a time base, and on the same base a compression and re-expansion curve for no fuel addition was added. The difference in pressure between these two curves represents, therefore, the heat addition due to combustion. This is not strictly true, because work is being done on the piston, but in the early stages of combustion with which this phenomenon is associated the piston is practically stationary and little work is being done compared to the heat added.

The indicator cards suggested that the rate of rise of this pressure increased as the detonation increased, the maximum pressures reached being maintained the same in all cases by adjustment of the time of injection. To examine this characteristic, the ordinates between the curves were plotted on a time base and differentiated, resulting in a curve showing the rate of rise of pressure. Then by plotting the maximum rate of rise of pressure against the detonation number assigned to the test, it was seen that these were related, which indicated that detonation was a function of speed of combustion, and not maximum pressure.

One series of such curves for the Doxford engine is shown in Fig. 2, the fuel cam shape, change of pressure, and rate of change of pressure curves being recorded. Comparison of a large number of such curves indicated that the change of pressure or heat addition follows very closely the cam shape, while the rate of change of pressure increased with the detonation. The results indicate that the rate of injection, other things remaining constant, has considerable influence upon detonation. Further tests with varying compression pressures and rates of injection showed the effect of each of these changes upon the resulting rate of change of pressure, and it was firmly established that detonation is eliminated in the injection engine by increasing the compression pressure, instead of reducing it as with the gasoline engine; also, that a reduced rate of injection eliminated detonation, if the compression was maintained at a constant figure.

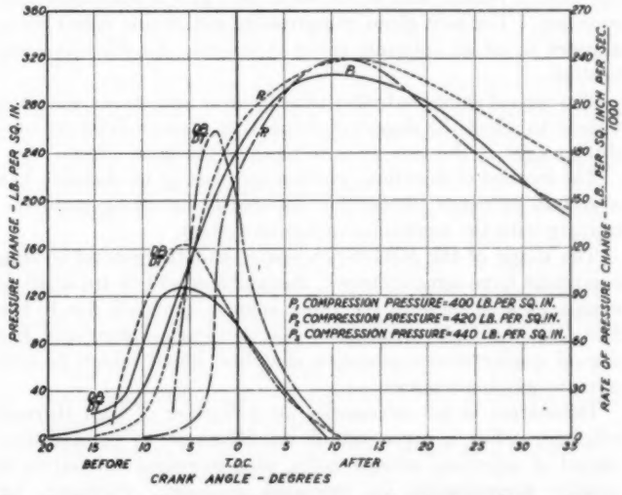

FIG. 3 RATE OF RISE OF PRESSURE FOR DIFFERENT COMPRESSION PRESSURES

These conclusions have been confirmed in subsequent work on engines of various makes and at speeds up to 1400 r.p.m. Fig. 3 indicates the effect of compression pressure upon rate of change of pressure in a high-speed mechanical-injection engine, there being slight detonation with a compression pressure of 400 lb. per sq. in., while there was none in either of the other cases. The only change made during these tests was in compression pressure, the rate of injection and the maximum pressure being

kept constant. It is seen that a slight change in compression is all that is necessary to eliminate detonation, in this case 20 lb. per sq. in. reducing the rate of change of pressure from 193,000 lb. per sec. with 400 lb. per sq. in. to 124,000 lb. per sec. with 420 lb. per sq. in. in compression, and eliminating all traces of detonation. This figure was further reduced to 97,000 lb. per sec. by an additional increase in compression to 440 lb. per sq. in.

The effect of change in engine speed from 1000 r.p.m. to 1300 r.p.m. is shown by the following test results, the point of injection only being altered so as to secure maximum pressure at approximately the same point in the cycle. Bad detonation was occurring at the lower speed with a rate of change of pressure of 270,000 lb. per sec., while the detonation was almost negligible at the higher speed, although the rate-of-pressure change increased to 410,000 lb. per sec.

Considering the results of both air-blast and mechanical-injection engines together, detonation depends upon the following variables:

Compression Pressure. Increasing this pressure eliminates detonation in the injection engine, instead of producing it as with the petrol engine. This result has been observed on two-stroke and four-stroke engines with both air-blast and mechanical-injection systems, and is considered characteristic for all engines of this type.

Speed of Injection. For economical working, the charge should be injected at the maximum possible rate which does not cause detonation or an undesirably high maximum pressure. Injection at a slower rate may give inferior results, but not necessarily so.

Engine Speed. Detonation is a function of the engine speed, the two being related in some inverse manner.

These are the three leading facts, and they work together to a certain extent. Detonation may be eliminated by increasing the compression, by reducing the rate of injection, or by increasing the engine speed. A point is reached, however, with low-compression pressures where no value of injection rate will produce the desired results, and at the same time give a reasonable fuel economy. For any given compression and engine speed there appears to be an optimum speed of injection for efficient combustion.

The type of engine, whether two-stroke or four-stroke, does not appear to affect the degree of detonation, though different conditions exist in the two types to produce the same effect.

The method of injection, whether air-blast or mechanical, has a certain influence, detonation apparently occurring more frequently with the mechanical-injection system.

The shape of the combustion space, and the general cooling conditions have some influence, though these effects are small as compared with those in the vapor engine; probably due to the fact that the high-performance injection engine invariably has a good symmetrical combustion chamber, which cannot be said of many gasoline engines.

Detonation is not necessarily an indication of high thermal efficiency. For a given set of conditions as to compression, period of injection, sprayer holes, etc., increased detonation is usually accompanied by increased economy. However, by changing one or the other of these variables, severe detonation can be produced coupled with a decreased efficiency, and usually with increased maximum and mean temperatures.

It is difficult to say at present whether detonation of the type under review is dependent upon pressure and temperature. The following facts have, however, been observed: Detonation is increased by advancing the injection. Both pressure and temperature are thereby increased, but only so to any marked degree near maximum pressure, which seems to have little effect on the speed of combustion. The correct interpretation of these observed results appears to be that it is the initial stages of combustion that determine whether the charge will detonate or not. By advancing the ignition, the fuel is injected into the combustion chamber earlier in the cycle, and therefore the initial stages of combustion are controlled by a lower compression pressure and temperature. Advancing the point of ignition by 5 deg. means that the first portion of the injected fuel encounters a compression pressure lowered by about 45 lb. per sq. in. Since the diagrams shown prove that a reduction of even 20 lb. per sq. in. in the compression pressure will produce detonation, it is reasonable to assume that the lower compression encountered by the earlier injection will have the same effect, hence the detonation is produced by lower pressures and temperatures, and not higher ones as at first might be thought to be the case.

Observations of the manner in which this phenomenon occurs, and examination of all the results and factors influencing it at both low and high speeds, has confirmed the above reasoning. It is well known that ignition is not instantaneous, that there is a certain lag between injection and ignition. During this time interval fuel is being continually fed to the cylinder at a rate determined by the pump and injection system as a whole, while at the same time vaporization and the formation of combustible mixture is proceeding, and eventually the initial fuel injected ignites and produces a rise in pressure and temperature. Now if the rate of fuel supply during this period has been too rapid, there will be a localized rich mixture produced which under the influence of the conditions in the engine cylinder may detonate in a manner exactly similar to the charge of a vapor engine. If the rate of supply of fuel exceeds some limiting value set by the rate of ignition, detonation may occur due to spontaneous ignition throughout the whole mixture supply. A detonation wave may also be set up in the following manner. The fuel first injected is vaporized and ignited. While this flame is traveling across the combustion space, fuel is being continually supplied, and the combustion chamber behind the flame could, if the supply is sufficiently rapid, be filled with a rich but unvaporized mixture which under certain circumstances could be partially vaporized so that the rise of temperature and pressure due to the combustion of the first fuel sprayed might cause a detonation wave to form in this mixture. This is supported to a certain extent by the observation that detonation usually occurs when a considerable time lag takes place in the engine, due, say, to inefficient atomization.

The effect of injection period and compression pressure are easily explained. Increasing the period of injection reduces the rate of fuel inflow, and prevents the formation of a mixture strong enough for combustion before ignition has occurred, while increasing the compression pressure causes the vaporization and combustion of the initial fuel injected to be accelerated, and rich pockets are again prevented.

It has also been observed that heating the fuel supply produces detonation. This seems to be opposed to the foregoing theory, since it would be presumed that ignition would occur earlier, and reduce the amount of combustible mixture formed. The actual sequence of events is thought to be as follows. The fuel being heated vaporizes very readily, and much of it is converted to a gas soon after entering the combustion chambers, in which state all penetration is lost, so that instead of traveling across the cylinder, the fuel is concentrated near the spraying device, and thus forms a rich mixture in a shorter time interval. This conclusion receives support from the fact that reduced combustion efficiency accompanies heating of the fuel, showing that either the distribution has been upset or penetration is lacking. Since the distribution remains unaltered, so far as it is affected by the direction determined by the nozzle and the turbulence is concerned, there is left only lack of penetration to account for the increase in fuel

consumption, which would also help detonation, and blackening of the exhaust.

This discussion is not intended to convey the impression that detonation is considered a serious problem in the development of the high-specific-power Diesel. The power output and maximum combustion pressure are almost unaffected by detonation, while the fuel consumption may be slightly decreased when the detonation is slight, but will be increased if excessive detonation occurs. The principal objections to detonation in the Diesel arise from the noisier operation and the destructive shock loads on bearings and structural elements due to the greatly increased rate of gas-pressure rise. The importance of detonation as a problem will be further decreased as the operating speeds continue to increase, but may again assume some importance if means are developed for utilizing the whole of the oxygen in the air charge, in which case the mean pressures will be considerably increased.

As the result of his own work and that conducted by the Royal Aircraft Establishment during the past few years, the eminent British research engineer Harry R. Ricardo recently expressed the opinion that the speed of the Diesel or compression-ignition engine is not limited by the combustion processes, that the pumping and metering of the fuel present no serious difficulties at speeds under 2000 r.p.m., that the high efficiency is little diminished by unskilled handling in service, and that the two-stroke Diesel can be built about 10 per cent lighter than the carburetted engine.

Conclusions

In conclusion, we may summarize our views in the following terms. The Diesel or fuel-injection engine in some of its forms is well adapted to the requirements of airplane and airship propulsion. Its first and most important commercial application will be in relatively large units on large aircraft. The increased fuel economy, in both weight and cost, will be an important factor in the progress of commercial air transport. The greatly reduced fire hazard will accelerate the growth of passenger business. The absence of radio interference will simplify the problems of navigation and communication. The potential advantages of two-stroke operation will at last be realized. In the large airplanes, from one to three engines of large power will be used, and these will be so mounted and enclosed as to allow of attendance during flight. Such engines will be fluid cooled, either by circulation or evaporation. The service reliability will greatly exceed that of carburetted air-cooled engines inaccessibly mounted. The present problems of weight and cost are less serious than generally supposed and will very soon reach commercial solution.

Discussion

C. R. Alden.[3] The authors state that the trend of the fuel-injection system owing to the high cost per cylinder of fuel pumps is toward fewer and larger engine cylinders for the Diesel engine as compared with the carburetted engine. Judged by present standards it is granted that this statement is true with at least two additional influences contributing to its truth:

1 For fuel pumps of contemporary design it may be even more difficult and expensive to build a satisfactory fuel pump for small cylinder sizes than for larger cylinder sizes. Engines of the smaller cylinder sizes are called upon to perform at higher rotational speeds introducing the necessity for still further refinements in the design and construction of the fuel-injection system

2 Each increase in the number of engine cylinders increases not only the number of pumps required, but the number of adjustments required to divide properly the load between cylinders, with attendant increase in maintenance costs.

Operating against the logic of decreased numbers of cylinders and increased cylinder sizes, there is the tendency toward increased specific engine weight due to the decreased rotational speed obtainable from engines of larger cylinder sizes, often with attendant increase in engine vibration.

However, the fact that two well-known systems of airless fuel injection have held the center of the stage since the idea of airless fuel injection was first conceived (at least 25 years ago) is not sufficient reason for being tied to the limitations of these two systems forever.

To some who have given much thought to the application of specialized equipment, to the production of precision fuel-injection details, not to mention the possibilities of accomplishing the fuel-injection objective by methods differing widely from the commonly accepted practice of the present day, there remains a confidence that the first cost, weight, and freedom from delicate adjustments of the fuel-injection system can be brought down at least to a level comparable to the present respective attributes of the carburetors, and magnetos eliminated from the aircraft engine by the use of the compression-ignition cycle. This conviction holds without regard to the number of cylinders or size of cylinders likely to be chosen by the aircraft-engine designer.

Philip Lane Scott.[4] There is reasonable ground for saying that the aircraft Diesel engine, the injection engine, will equal or exceed the four-stroke cycle carbureting engine in b.m.e.p., and that a two-stroke cycle injection engine can be built of nearly the same weight as the four-stroke engine of same bore, stroke, and r.p.m. The Diesel will have about twice the power for equal size, and will be simpler and more reliable. Work comparable to that spent in developing the beautifully functioning valve mechanism, and the astonishing ignition and carbureting system of the four-cycle engine will be done in developing the scavenging and fuel-injection systems of the two-cycle injection engine, and the scavenging and fuel systems are inherently simpler elements than their counterparts in the present engines.

Use of the two-stroke cycle may well be emphasized as one of the two major reasons for the development of the injection engine. Why has four-stroke cycle been used almost exclusively? Because feeding a pre-mixed charge and driving out burnt gases with it meant, inherently, serious losses.

Four-stroke cycle engines can be charged with two major breaches of sound design. Such an engine acts only as a low-pressure air pump during two complete strokes, but the parts are designed to carry loads 4000 per cent or more in magnitude. A single low-pressure light-weight unit serving a multiplicity of cylinders would do just as well. The four-cycle engine has a multiplicity of valves and driving mechanism. A few holes in the cylinder wall would suffice if some loss of the scavenging and recharging medium were permissible.

The injection engine at once permits the use of a two-stroke cycle since air alone is used for scavenging and recharging, and a little loss is permissible. Ports in the cylinder wall are substitued for the valves and their drive. A low-pressure air blower replaces the engine itself as an air pump. In many cases four-cycle engines now have air blowers for pressure carburetion and for altitude work, though still compelled to keep the entire valve system.

Aircraft-engine designers have become so wedded to the four-cycle engine that the inertia against change is enormous. When as much effort is spent on the simpler mechanism of the two-cycle

[3] Ex-Cell-O Tool and Mfg. Co., Detroit, Mich. Mem. A.S.M.E.

[4] Consulting Engineer, San Mateo, Cal.

engine as has been on the four-cycle engine a type will result which will work full time, not half time, and in which the extra weight of the air blower may not greatly exceed the weight of the valve mechanism discarded.

The authors, conservatively, place limits unfavorable to the two-cycle engine in the matter of combustion for the present, and also make the point that injection is at present substantially behind carburetion in b.m.e.p. produced even with four-cycle operation.

For equally good combustion the working pressures in a two-cycle engine as against a four-cycle engine depend solely on the amount of oxygen in the cylinder. An opposed piston two-cycle engine (Junkers type) has shown 95 per cent fresh charge. The four-cycle engine has always a clearance volume, some 10 per cent or more of burnt gas to mix with the fresh charge. The two-cycle engine always charges above atmosphere, and the four-cycle below unless it uses pressure carburetion in which case the disadvantage of the extra weight of the air blower on the two-cycle engine is cancelled, for the four-cycle engine must have the same device. A two-cycle engine charging at two pounds above atmosphere as against a four-cycle engine charging at one pound below has a 22 per cent advantage in amount of oxygen, potential power output. This is a power factor of 244 against 100 on a basis of power strokes per minute.

The authors show that the working pressures with fuel injection are some 20 per cent to 40 per cent lower than with carburetion on a basis of rated load for injection, and about maximum for carburetion. The maximums of the two methods are about the same. It is interesting to remember in this connection that many oil engines have been successful commercially with powers based on 30 lb. b.m.e.p., and some as low as 20 lb. Not so long ago a 75 lb. b.m.e.p. was considered good for a gasoline engine. The war development has brought the 140-lb. pressures which injection must strive to exceed.

Combustion with injection of fuel is the phase of the matter about which least is known. The high effective pressures must be obtained without excessive maximum pressure or the familiar black smoke so common at "overload." There are several kinds of undesirable burning found in the case of fuel injection which are not present when a pre-mixed charge is fired though the burn of a pre-mixed charge has its special bad tricks also. A group of several series of indicator cards taken over a wide range of pressure and temperature variation showed quite clearly detonation and rough burning occurring at several distinct places in the runs. Gasoline is made by subjecting the rather unstable molecules of the heavier-oil fractions to various pressure and temperature combinations. It is reasonable to think that the same sort of thing may occur in the engine cylinder in a detrimental way. The physical chemistry of oil should prove a valuable source of information, and aid in avoiding the undesirable combinations. The matter of bringing all the oxygen in the cylinder in contact with the fuel is strictly a test of the skill of the designer in dealing with the spray nozzle and combustion chamber.

The great advantage that injection of fuel has over carburetion and electric ignition is that combustion is substantially under control by the rate of injection, while the flame once started in a pre-mixed charge does pretty much as it pleases. With the carburetor-electric ignition system engineers have learned to prepare and distribute an elastic material, and to handle an almost intangible substance at some 15,000-volts pressure. With fuel injection an inelastic material and only one is dealt with which can be more easily metered and controlled.

A. L. PARKER.[5] The authors assume for the Diesel engine certain probabilities of development for comparison with carburetted aircraft engines of present-day development, with the supposition that the latter has reached its ultimate efficiency, whereas the Diesel engine only has potential possibilities. With this supposition the writer does not agree.

Citations of actual performance of Diesel engines in aircraft service are limited, and there is scant performance data other than pertaining to fuel economy, the first advantage claimed for the Diesel engine.

The authors fail specifically to classify Diesel fuel. Their statement that Diesel fuel costs one-quarter as much as aeronautical gasoline indicates the usual low-grade fuel oil used for stationary Diesel engines. In the aircraft carburetted engine it has been considered advisable to use a fuel more costly than the fuel ordinarily used in carburetted engines, the expensive fuel being desirable because of improved acceleration, reliability, and reduction in service requirements, as well as for the increased mileage obtained. High-test fuel has contributed materially to the performance of aircraft carburetted engines, and it seems likewise probable that development in Diesel fuel may contribute to the performance of the aeronautical Diesel engine in a like manner. Improved vaporization and distribution with extension of the limits imposed by the occurrence of detonation may result from the use of a higher grade fuel, and it seems quite logical to assume that such improvements will be made. Data indicating the effect on performance of Diesel fuels of various degrees of volatility, density, and viscosity would be of interest. Apparently the high-speed Diesel aircraft engines are identical with the stationary commercial engines of this type except that by careful design, weight has been eliminated, and maximum working pressures have been reduced to some extent by departure from the constant-volume cycle with the extension of the injection period over a considerable crank angle.

The crank-angle limits for injection of fuel are of course irrevocably established so that the design problem hinges about control of maximum internal pressures, within the limits imposed by structural strength, and the improvement of fuel distribution in the combustion chamber. Increased maximum pressures necessarily demand increased weight; therefore, attainment in this direction has its limitations. Although injection nozzles with suitable turbulence created may be designed for a fixed speed of any particular engine, it will be necessary to vary the injected charge for different speeds, and the control of the injection conditions to coordinate with varying speeds will probably constitute a serious problem. Speed changes, acceleration, and retardation will be accomplished only by control of fuel rather than by control of fuel-air mixtures. This control of fuel with as simple facilities as characterize the carburetted engine controls seems unlikely as an injection nozzle setting is so exceedingly sensitive, as reflected in the shape and character of the spray, that manipulation will be difficult to accomplish with efficiency and simple means. Change of fuel injected by change of injection-line pressure will always result in varying spray and fuel distribution with partial combustion resulting at variable speeds.

This inherent difficulty of efficiently controlling Diesel-engine speeds is reflected in the general opinion that the Diesel engine is primarily a constant-speed unit. A variable-pitch propeller may, if properly developed, be the answer for the Diesel aircraft motor, as such a propeller may be operated with efficient results without unusually wide range of motor speed. One outstanding advantage of injection engines is their ability to carry increased load without increased speed. The variable-pitch propeller seems to be essential fully to capitalize this valuable Diesel characteristic in air service.

Improvement in distribution of fuel in the combustion chamber is dependent upon refinement of injection nozzles. Although combustion chambers may be designed to create sufficient turbu-

[5] The Parker Appliance Co., Cleveland, Ohio

lence for thorough vaporization and distribution of fuel, no doubt the greatest problem confronting the designer of high-speed aircraft Diesel engines is the construction of a reliable and efficient injection nozzle.

Experiments with injection nozzles seem to indicate that super-accuracy is required, and dimensional limits are so very close that the slightest corrosion or clogging due to carbon or soot is very apt to disrupt performance and decrease efficiency. Efficient injection nozzles will, no doubt, require so accurate design and adjustment to attain the desired fuel spray and distribution throughout the combustion chamber during the limited firing period imposed by high speeds that exceedingly delicate adjustment will be unavoidable. Wear or distortion of these delicate adjustments will require so accurate service that it will be impractical for the average mechanic to service parts of this character. It is doubtful if turbulence alone can promote satisfactory fuel atomization and distribution throughout the charge with a simple rugged nozzle construction.

If, in commercial low-speed Diesel engines, such as are in operation on the Canadian National Railway, it is necessary to remove nozzle tips for the removal of carbon every 250 hours or so of operation, it is quite natural to assume that in aircraft motors of high speed and efficiency with more delicately adjusted injection nozzles, this operation will have to be performed more often. Greater service attention will thus be needed than in the carburetted gasoline engine.

Efficient spray injection without great turbulence is, no doubt, a function of nozzle design, and suitable penetration and distribution of the sprayed fuel will require unusually high injection pressures for high-speed engines with accordingly difficult fuel-distribution problems.

Manufacturers of industrial Diesel engines experience considerable difficulty with fuel-injection lines. Such lines must invariably be of exceptionally heavy construction to withstand possible backfire which occasionally occurs in these engines. These lines must also withstand a severe fluid hammer or vibratory effect as fuel is injected at rapid intervals into the cylinder. As the speed of Diesel engines is increased, and the fuel injected at a higher rate of speed, this vibratory or fluid hammer effect will, no doubt, be materially increased. This will require careful and strong construction of fuel-injection lines.

If the spring-loaded injection nozzle is used, a very small air bubble will quickly disrupt the performance of the motor, which, in aircraft service, would be most undesirable.

Excessive air accumulation in the fuel-injection lines may cause backfire. With the open type of injection nozzle, it is questionable whether fuel pressures could build up rapidly enough to give the desired spray and distribution of fuel. It has been found that an efficient spray requires very high injection pressures, and the trend of design in the Diesel engine is to increase fuel-injection pressure to the very high limits of 4000 to 5000 lb. per sq. in. To carry from 800 to 1500 lb. fluid pressure in any conduit, particularly with rapid periodic impositions of these pressures, creates a plumbing risk far in excess of any plumbing risk to be found in the gasoline-powered ship of today. Should pressures of from 3000 to 4000 lb. per sq. in. be found necessary for really efficient fuel spray and distribution, this plumbing problem is correspondingly complicated.

The authors classify so-called plumbing of the power plant as "one of the minor elements." No part of an airship should be classified as a minor element, and surely such an important part as fuel-distribution equipment may not be so classified. A casualty accruing from plumbing is just as deplorable as one from engine failure, and plumbing is as important a part of the engine as is the crankshaft, piston, or other unit. Tendency on the part of both power-plant and aircraft designers to classify aircraft plumbing as a minor element and to give too little attention to the design and installation of this important part of aircraft construction is responsible for many failures, both in power plants and in ships. Fuel-distribution plumbing is vitally important, and a most essential portion of a ship. It must of necessity spread throughout the ship whether carburetted gasoline or Diesel engine is used, and upon the plumbing is dependent the safe and efficient distribution of fuel for both gasoline or Diesel engines. The plumbing of the Diesel engine is subjected to far greater strains than the gasoline engine, and therefore it is safe to assume that with the adoption of high-speed, high-pressure Diesel engines, the power-plant plumbing must be given the same care and design as is given to fuel pumps, distribution nozzles, and other vital and important units of the Diesel engine.

These plumbing problems may be solved in the same way that aircraft gasoline-plumbing problems have been and are being solved. Exception is taken to the statement that aircraft power-plant plumbing has not reached the state of perfection comparable with the perfection of other aircraft units comprising a ship. It is true that many ships in service are deficient in structural detail (plumbing included), but performance records indicate that during the past several years there has been a most marked and indisputable improvement in aircraft plumbing, quite comparable to improvements in other aircraft structural units.

The one great problem confronting the aircraft industry today is reliability and safety. Safety exceeds cruising range, carrying capacity, comfort, economy, or any other factor. Complete public confidence awaits safety, and is to be acquired only from demonstrated safety. Absolutely dependable power plants that nothing can stop but the pilot is the basic problem of the industry. The place of the high-speed Diesel engine for aircraft service rests upon proof of inherent reliability characterized in air service rather than upon economy. It is true that there is a popular opinion that the Diesel engine is far more reliable than the gasoline engine, but has this been satisfactorily demonstrated for the high-speed light-weight engine? Stable performance of the industrial Diesel engine of heavy construction in uniform temperatures, protected from the weather, with constant attendance may not be considered proof of superior reliability in the air.

The carburetted gasoline engine has been established upon a very elaborate production schedule. Service is established throughout the world, and unless the high-speed Diesel engines have unusual stability and reliability, it seems questionable if a change from present practice will be warranted purely on the grounds of improvement in economy and cruising range. The Diesel engine, no doubt, requires far higher standards of production than the carburetted engine. Fuel injection and pump parts must be machined with an accuracy seldom required in commercial production. Although great improvement in performance may be anticipated, it is quite possible that limitations are inherent, and that such perfection in fuel injection and distribution, as anticipated, may be unattainable just as in the gasoline engine inherent characteristics have prevented attainments anticipated years ago.

The Diesel engine is, no doubt, more adaptable to the construction of large units in comparison to the air-cooled radial engine. With our present knowledge of propeller design, and with available materials, it seems that propeller sizes and tip speeds have reached a maximum for efficient performance. New developments in propeller construction and design are, no doubt, required for the efficient absorption of 2000 hp. in a single propeller.

If huge slow-moving propellers are to be used with power units of this capacity, gear reduction of some kind will be required, with a corresponding decrease in efficiency. It may be that the future will develop means for transmitting power from a single large

power-plant unit into several propellers disposed about the ship. In view of recent developments in hydraulic power transmission, it may be that hydraulic or other fluid power-transmission mechanisms may serve this purpose, but some means for distribution of this large power output from a single unit will be necessary.

The authors have made no reference to such motor characteristics as starting quality, acceleration, pickup, effect of temperature and climatic condition on performance, and similar characteristics which affect the performance of a ship. Military ships require the best of acceleration or pickup qualities. It is true that for the most part flying is accomplished with comparatively uniform motor speed, but as air lanes become crowded, pickup and acceleration will be most important motor characteristics.

Judging from the fuel curve shown by the authors the imposition of overload on the motor brings a sharp rise in fuel consumption with soot and smoke development, so that it is logical to assume that, at least for the time being, no appreciable output above the rated capacity should be counted upon for high-speed Diesel engines, as operation under overload conditions for any considerable length of time or at frequent intervals would probably create deposits in sufficient quantities to be detrimental to fuel injection and require frequent overhauling and servicing.

The decreased fire risk claimed for the Diesel engine seems to be disputable. The text indicates that this advantage is of a limited extent, and that Diesel fuel apparently has at least a tendency to ignite from a hot surface more readily than gasoline, as proved by laboratory experiment. Inasmuch as it is and probably will be compulsory to equip ships with suitable fire-extinguishing facilities, no doubt the slight advantage accredited to the Diesel type of engine will not be of material consequence as fire-extinguisher equipment will still be necessary. As stated, Diesel fuel is unquestionably less cleanly than gasoline, and due to the fact that it will not evaporate as readily as gasoline, it may be in some instances a greater fire risk than gasoline, so at least the two types of engines seem to be about of a parity in this respect. In view of progress in the efficient shielding of high-tension ignition in the system from radio interference, it is quite possible that an entirely efficient and satisfactory shield equipment may be established in the course of further development of the gasoline engine inasmuch as such shielding equipment is quite as new as the high-speed Diesel engine, and it may be that the development of such equipment will provide valuable protection for the ignition system, and contribute to more dependability rather than to detract from its efficiency.

Two-cycle high-speed engines are a problem of the future in both carburetted and Diesel style. The Diesel cycle offers the advantage of intake of pure air as compared with a fuel-air mixture. Scavenging pumps are, however, a requisite of both carburetted and Diesel two-cycle engines. Superchargers as developed to date can hardly be termed dependable for two-cycle high-speed service capacities. The question of ample and proper scavenging of two-cycle engines will be the problem for designers to solve before success is assured. With proper scavenging equipment available, engines of intermediate type may develop; that is, a two-cycle engine burning a volatile fuel such as gasoline with injection of fuel over a wide crank angle with low maximum pressures, and with electrical ignition maintained for combustion. In such an engine fuel distribution throughout the charge could be obtained readily with low-pressure fuel-injection piping, comparatively simple injection nozzle, rugged and inexpensive lightweight fuel pump, and with performance comparable with two-cycle high-pressure Diesel performance in the same ratio as the four-cycle engines now compare.

In the advantages claimed for cruising range, consideration of the 10 per cent greater weight of the Diesel engines seems to have been ignored. This 10 per cent additional weight for a large unit (fuel costing 21 cents per mile) will approximate the weight of one passenger, which would, in turn, offset the double fare gain, due to fuel economy as cited in the text.

Is not the advantage of working on an engine in flight overestimated? Particularly if dependence is placed entirely upon a single prime-mover. So little can be accomplished in the way of servicing a running engine in flight that it is highly improbable that any but the most minor adjustment could be accomplished unless multi-power plants are so disposed as to permit quite extensive shutdowns during flight. Claims for Diesel aircraft engine superiority are well taken, but performance data to date are too meager to warrant final confirmation of such superiority.

HAROLD C. GERRISH.[6] It is gratifying to note the interest that is being shown in the development of the high-speed oil engine for aircraft use. As pointed out by the authors, the "dual cycle," a combination of both the Otto and Diesel cycle, is the cycle commonly used as the operating cycle for high-speed oil engines. It not only reduces the theoretical weight per horsepower and increases the reliability in comparison with the Otto cycle for the same power output, but is especially adapted to the oil-injection engine.

Several valuable contributions on the ideal cycle efficiency of internal-combustion engines made during the past ten years have not been brought out definitely by the authors, as follows: T. B. Morley (1)[7] developed an approximate chart for both constant-volume and constant-pressure combustion cycles and found in many cases "that the chart gives results for efficiency and mean effective pressure within three per cent of the correct values;" R. W. Bailey (2) derived algebraic relations and presented graphs and tables necessary for the graphical and arithmetical method of solution; W. J. Walker (3) obtained a general expression for the efficiency of the "dual cycle," a combination of constant-volume and constant-pressure combustion; G. A. Goodenough and J. B. Baker (4) analyzed two leading cycles of internal-combustion engines, giving the ideal efficiencies under various conditions, while using several fuels; F. O. Ellenwood, F. C. Evans, and C. T. Chwang (5) considered the working fluid to be actual cylinder gases, and gave results of calculations for ideal efficiencies for the Otto and Diesel cycles in the form of curves and tables; A. E. Hershey (6), using the method developed by G. A. Goodenough for calculating internal-combustion-engine efficiencies and temperatures, showed the effect of compression ratio on the maximum temperature of combustion, the temperature of exhaust for the Otto and Diesel cycles, and the thermal efficiency for various amounts of excess air.

Two of the main factors which must be decided upon in the design of high-speed oil-injection engines suitable for aircraft are compression ratio and maximum cylinder pressure. The effect of these factors on the performance of an oil engine is impossible to obtain accurately by actual experiment, because of the influence of several factors difficult to control, such as penetration and atomization of the fuel spray, chemical composition of the mixture, and the rate of combustion.

The National Advisory Committee for Aeronautics, Langley Field, Va., has therefore, during the past two years, conducted an investigation to determine the effect of compression ratio, maximum cylinder pressure, and excess air on the cycle efficiency, indicated mean effective pressure, and fuel consumption of oil-injection engines working on the "dual cycle." This investigation covered a range of compression ratios from 8 to 18, maximum cylinder pressures from 700 to 1200 lb. per sq. in., and excess air from 0 to 244 per cent. The working fluid was considered to

[6] Assistant Mechanical Engineer, National Advisory Committee for Aeronautics, Langley Field, Va.

[7] Numbers refer to bibliography at end of discussion.

be actual cylinder gases, the mixture to vary at different points on the "dual cycle," the specific heats of the gases to vary with the temperature involved and the complete combustion of the fuel. A complete report of this work is soon to be published and will include a sample calculation of the method employed.

W. L. Dempsey.[8] The authors have given a complete picture of the development of the aeronautical Diesel engine up to date. The state of the art has been clearly recorded and will be of historical value in the future. However, the term "aeronautical Diesel engine" has not been defined. It is assumed that it means an engine adapted to meet the requirements of aviation and has about the following characteristics:

(1) An engine capable of burning the heavier hydrocarbons, ranging from 30 deg. Baumé downward.

(2) Since the r.p.m. is the function of the stroke or crankarm, to meet satisfactorily the requirements of an aviation engine, it should have a piston velocity at three-fourths maximum speed of not less than 1500 ft. per min.

(3) It will have the Diesel characteristic of autoignition.

(4) It will have variable speed characteristics over a wide range.

If this be a correct definition of an aeronautical Diesel engine, I fear that it is but another noble and costly experiment, another rosy dream at twilight that becomes a fading fallacy at dawn.

Every natural process under the sun functions on a fixed and immutable time schedule. In spite of learned theses and abstract and subtle mathematics dealing with the relativity of time and space, the physicist is still keenly conscious of the existence of both time and space, and each is infinitely beyond the puny power of man to affect.

The electronic beams of light and energy pouring forth from the sun travel on an exact and unchangeable time schedule, first arriving at Mercury, then Venus, Earth, Neptune, and the infinite wastes beyond the Polar Star, arriving at each with such precisely timed exactness that, if we but knew the curvature of this grand cycle, we could determine the exact second when they would return again to rekindle the fire of a perhaps slowly waning sun. Even at the terrific velocity of 186,000 ft. per sec., we can calculate to the second the return of a comet that departed from our skies centuries ago.

It will be as easy for the genius of man to accelerate or decelerate the flight of a comet through stellar space as it will be for him to change the time schedule for the burning of the molecules of the homologous petroleum series. Methane (CH_4) will always burn in a shorter length of time than pentane (C_5H_{12}); therefore, if only the heavier molecules are to be utilized as fuel, the piston velocity will inevitably be determined by the size and boiling point of the molecules of the fuel used. Piston velocity is necessarily controlled by the time schedule of the burning fuel, and this fixed and immutable law of nature stands between the high-speed aeronautical Diesel engine and success. The Diesel engine is of incalculable economic value, but it requires a firm foundation on solid earth rather than the unstable foundation of the upper air.

In ballistics muzzle velocity is strictly dependent upon the time schedule of the explosive, and in gas engineering piston velocity is a function of the fuel used. The combined efforts of science, engineering, and genius will never be able to build an incubator that will hatch out a goose egg in the same length of time that it will hatch out a chicken egg. It is axiomatic that large bodies move slowly, and it is equally axiomatic that large molecules of fuel burn slowly. The highest efficiency in steam power plants has been reached by using powdered coal. The humblest housewife knows that she cannot cook small potatoes and large potatoes in the same length of time at the same temperature, hence she halves and quarters them to uniform size.

This requires an expenditure of energy and also an expenditure of time. This in effect is exactly what our refineries are doing in cracking processes. The refineries are efficient because of mass production and the availability of cheap fuel for generating power to reduce the molecules of the fuel to approximately uniform size. Why should this process be changed from mass production to individual treatment, from the solid earth to the hazy atmosphere? It would seem wise that aviation be supplied with a uniform, finely pulverized fuel so that maximum power would always be available without using a portion of the energy developed for preparing the fuel in flight.

Another factor opposing high piston velocity in the Diesel engine is the manner of introducing the fuel, which greatly lengthens the time required for diffusion of the fuel in the almost impenetrable density of the compressed air within the cylinder. Present practice utilizes pressures of from 600 to 1200 lb. per sq. in. to drive a fine pencil of fuel into the combustion chamber. The force required would easily be sufficient to drive a tenpenny nail into a seasoned oak beam.

It must be remembered that the force applied is applied in practically a straight line and that gases within a closed vessel exerted equal pressure in all directions, that there are no areas within the cylinder where the air is of unequal density, and that there are no dynamic forces within the cylinder capable of creating diverse currents. Air under a pressure of 500 lb. per sq. in. becomes a very solid mass, and a thin stream of fuel injected into it under a pressure of from 600 to 1200 lb. per sq. in. forces the corpuscles of the fuel so close together that "no air can come between them," hence only the peripheral surface of the stream of fuel can come into contact with the oxygen of the air, so that instead of the fuel mixing freely with the air it is literally eroded away, and this process of diffusion is necessarily slow.

There can be no turbulence within the cylinder under these conditions to scatter and diffuse the fuel because turbulence is the result of kinetic energy applied; therefore, until the temperature rise due to compression and the injection of the fuel is sufficiently high to ionize the gases, distribution of the fuel cannot take place. This, in my opinion, will forever prohibit high piston velocity in an engine using low-grade fuel.

It has been suggested in this discussion that the building of a high-speed Diesel engine should not be considered doubtful and that the tremendous amount of research and experimentation in this field will ultimately succeed. The speaker used a very pretty, but to me a very inapt, simile when he said all that is necessary to do is to bring into close proximity the atoms of oxygen, hydrogen, and carbon and, like a lovelorn boy and girl when drawn together, a marriage was the inevitable result. It is thought that the simile did not go quite far enough.

[8] Consulting Engineer, St. Louis, Mo. Mem. A.S.M.E.

It is well known to scientists that there are very few philandering bachelors among molecules, that they are all polygamous and polyandrous, and that they are as gregarious as sheep; and both civil law and natural law require that before a marriage can take place the contracting parties must be single and legally competent; so in the act of combustion molecules do not unite with each other to form new compounds, but the molecules must be disintegrated, the atoms must be divorced and made free to seek other conjugal felicities.

Again, the simile falls down in that the union of two atoms of hydrogen and one atom of oxygen does not release energy; in fact, energy is absorbed by the union, and when once two atoms of hydrogen and one atom of oxygen become united, their honeymoon beginning perhaps in the cylinder of an engine, they float out through the exhaust and drift away arm in arm to the upper air and wander forever through ethereal space until some vagrant lightning shaft dissociates them. At no time during the union is a single dyne of energy released.

Sir J. J. Thomson, Dr. Millikan, Dr. Bohr, Lewis, Langmuir, and others have experimentally demonstrated that every individual atom is a storage battery composed of a positively charged proton and a negatively charged electron. Nature has exactly balanced these forces, and the only energy that can be unleashed in the cylinder of a gas engine is these two electrical charges, and this energy cannot be made available until some external force disrupts and destroys the perfect balance between these two charges, whether it be the energy of high compression or the jumping of an electric spark.

The molecules within the cylinder, composed of millions of atoms joined together by the resultant forces of the electrical charges in the atoms, would forever remain in a quiescent state, like a nest of hibernating ants or a hive of bees, until disturbed by an external force. It is then and only then that ionization takes place, that the bees begin to swarm forth, and the ants suddenly awaken into active energy; so the released energy of the atoms impels the piston on its working stroke.

In other words, combustion takes place in two phases or stages: the first stage is that of disintegration or ionization of molecules and atoms; the second stage is that of integration or the forming of new compounds. The first is a stage in which the stored energy of the molecular and atomic batteries is being released, when millions of negative and positive charges, like angry hornets, bombard the piston head to impel it on its working stroke, and it is only in this first stage of combustion that the dynamic energy in the fuel is transferred to the moving piston.

The second stage is a mating period when the atoms are being joined into harmonious unions, thereby reestablishing perfect static and dynamic balance between the positive and negative charges inherent in the atom.

In order to release the maximum potentiality of the fuel, not only must there be sufficient oxygen in the cylinder to supply one atom of oxygen for every two atoms of hydrogen and two atoms of oxygen for every atom of carbon, but in addition to the atoms being in sufficiently close proximity to each other to bring them within attractive range of the electrical charges, there must exist sufficient temperature to disintegrate or ionize the largest molecule present.

For these reasons I do not believe that the paper is prophetic of the success of a high-speed aeronautical Diesel engine.

Authors' Closure

The extensive discussion accorded the paper is most gratifying as indicating the general interest in the subject. The many points raised cannot be treated as completely as their importance warrants, but we would like to reply to some of the more controversial features in the interest of clarification.

Mr. Alden cites the tendency toward decreased rotational speed with increase of cylinder diameters, but we believe that this will not be a serious handicap to the large engine, especially with opposed-piston two-stroke engines. We may assume that piston speeds will remain about constant, regardless of stroke. Whether the scavenge function in two-stroke engines will prove to be the speed-limiting factor is debatable. It is of interest in this connection to study the favorable results of the analysis presented by Dr. Otto Holm in *Motorwagen* for Jan. 20 and 31, 1928. The simplification of injection systems as mentioned in the paper will eliminate adjustments of excessive accuracy, and the injection mechanism will stand more abuse than the ignition system of the gasoline engine. We are glad to note the opinion of one so experienced in fuel-pump and injection-valve construction to the effect that the manufacturing problems involved are not serious.

Mr. Scott has done much work with the two-stroke fuel-injection engine, so that his favorable comments are authoritative. He evidently anticipates no serious difficulties in the fuel-injection system. The high scavenging efficiency stated for the Junkers opposed-piston two-stroke engine shows that this operation can be performed at least as well in the two-stroke as in the four-stroke engine.

Mr. Parker errs in assuming that we consider the carburetted engine to have reached the limit of its development. Our comparisons were based on results already achieved in both types of engines, but it must be remembered that the potential development possibilities are all in favor of the Diesel. We agree that fuels of special characteristics may give more power, lower consumption, or better operation that the ordinary good quality of industrial Diesel fuel oils. Neither the literature of the subject nor our own work, however, indicates that much is to be expected in that direction.

It is possible that the variable-pitch propeller will prove more desirable for the Diesel engine, but at the same time we invite attention to the fact that the value of this device to the present carburetted engines also has been definitely proved, and its adoption, at least in the larger powers, merely awaits the development of a satisfactory construction. However, it must not be assumed that the Diesel is less flexible than the carburetted engine, for the superior acceleration of the Diesel is already considered one of its strongest points for automotive applications. Its torque is much better maintained than that of the gasoline engine at low speeds. The Diesel will not idle as slowly, though the difference is small with properly regulated injection.

The problem of control of injection at various speeds is nonexistent. It is a much simpler operation than the control of a gasoline-air mixture to the very close limits that are necessary. Change of injection pressure does adversely affect spray formation, but the reduction of spraying efficiency at reduced loads is more than offset by the increased combustion efficiency due to the additional air available.

As stated in the paper, the maintenance difficulties are difficult to evaluate. The evidence at hand leads us to expect that they will not be serious. Certainly, one cannot object to giving the injection pumps and nozzles the same amount of attention as is now required by magnetos and spark plugs. Operating reliability is undoubtedly of prime importance. The Diesel engine has in this respect a great advantage, as the injection system may be composed of a number of complete and entirely separate units, the failure of any one of which affects only the one cylinder served thereby. An eight-cylinder engine will have a total of from 40 to 60 holes for the injection of fuel, so that the clogging of one or two holes has but little effect upon the engine performance, particularly when the overload capacity and the flat shape of the fuel curve at the usual operating load are considered. The partial choke of a carburetor jet immediately affects all

cylinders served thereby, and in addition weakens the mixture ratio with resultant danger of backfire. Very careful filtration of fuel is desirable in both types of engine.

Fuel lines must be heavy, of course, but Mr. Parker's statement that they must withstand "backfire" is based on an incorrect understanding of Diesel functioning. Contrary to general belief, air bubbles in the line or nozzle of the modern injection system have no bad effect. In fact, air is so readily dissolved in the fuel at high pressures that it is impossible to use an air chamber as an accumulator for the purpose of damping out pressure fluctuations in common rail systems. No difficulty has been experienced in starting oil engines with the system empty and without priming of pumps.

Peak pressures in some types of fuel-injection systems for aircraft engines are likely to approximate 10,000 lb. per sq. in., but no difficulty is experienced in holding these pressures. It must be remembered that the lines are of small diameter and short length. The fuel system up to the primary pump is the same as on the carburetted engine, but the greater viscosity of fuel oil reduces the comparable leakage, and the high flash point greatly minimizes the danger from such leakage.

The form of propeller system to be used with very large engines is, of course, as yet undetermined, but it appears that single suitably geared direct-mounted propellers will be applicable to engines up to, say, 3000 hp. A four-blade propeller 18 ft. in diameter will efficiently absorb 2000 hp. when turning 900 r.p.m. at an air speed of 140 m.p.h. Such a propeller is quite reasonable for the large airplanes which will use engine units of this power.

With regard to comparative starting ability, acceleration, and effect of atmospheric temperature, it is well known that the Diesel will take full load immediately after starting, that its acceleration is much superior to that of the carburetted engine, and that atmospheric temperature changes have no effect other than to vary the maximum power output proportional to the change of density. The overload capacity of the Diesel is an important advantage, especially in automotive applications, since such overloads are ordinarily required for only very short periods, during which the increased fuel-consumption rate and darkened exhaust are not objectionable.

The decreased fire risk is doubtless most valuable immediately after a crash, when the fire-extinguishing equipment has probably been put out of commission. We doubt whether Mr. Parker would in such case be as happy if the tanks were filled with aviation gasoline instead of high-flash fuel oil. The two-stroke gasoline-injection engine mentioned has some interesting possibilities, especially for military use, but cannot meet the safety and economy requirements of commercial aircraft. It is being investigated by the N.A.C.A. laboratory.

Mr. Parker has misunderstood the reference to the Diesel engines on the Canadian National Railways. These sets can be considered as in the high-speed class, since they operate at speeds up to 1000 r.p.m. with a 12-in. stroke, or a piston speed of 2000 ft. per min. The gasoline engine does not perform equally well without attention for 250 hours.

If Mr. Parker will refer to the paper, he will see that we estimated the specific weight of the two-stroke aeronautical Diesel at 20 per cent *less* than that of the carburetted engine, not 10 per cent *more*. The Diesel overload capacity further increases this advantage. The advantage of working on an engine during flight is not now generally appreciated, mainly because present installations of air-cooled engines almost prohibit such attendance. It is worth noting, however, that the present airplane endurance record was made possible by reason of special provisions for servicing during flight; spark plugs being changed, rocker arms lubricated, etc. Also, nearly all airship engines are regularly serviced during flight, with or without stopping them.

As to fouling of the combustion chamber, the Diesel will continuously carry an overload of 10 to 15 per cent without smoke in the exhaust or accumulation of carbon in the cylinder. One may say that the Diesel rejects its carbon, while the gasoline engine accumulates it inside the cylinder. Decarbonization is determined by the life of the valves, rather than by detonation or preignition from carbon as in the gasoline engine. Incidentally, the exhaust-valve temperature is much lower in the Diesel.

Mr. Dempsey lists four characteristics which he thinks the aeronautical Diesel should possess. These are correct in the main, but it is quite possible that an oil lighter than 30 deg. Baumé will prove best for such engines and service. There is no more reason to require an aeronautical Diesel to run on the cheapest fuel oil available than that the carburetted aeronautical engine should run on cheap commercial gasoline.

We are in doubt whether Mr. Dempsey expects the remainder of his remarks to be taken seriously. Perhaps the best reply is to direct attention to the fact that all of the requirements for the aeronautical Diesel have been separately met, so that the remaining problem is to secure the same results in a single engine mechanism. Satisfactory b.m.e.p. and economy have been obtained at 3000 r.p.m. and piston speeds over 2000 ft. per min., so that no present limitations in this direction are anticipated.

Mr. Gerrish draws attention to several valuable items in the literature of the subject, a perusal of which will be of interest to any one seriously studying the development of the high-specific-performance Diesel. We take pleasure in drawing attention to the comprehensive research being conducted into all phases of the general problem by the National Advisory Committee for Aeronautics at its Langley Field laboratory, and which work is not as well known or utilized as its importance warrants. This Government organization is conducting its investigations with a thoroughness far beyond the possibilities of any industrial organization in this field.

Since our paper was written some months ago, the published performances of the Junkers aeronautical Diesel and the unpublished results secured by several organizations working on the problem have furnished a basis of definite accomplishment which substantiate our statements regarding the possibilities of the light-weight high-speed Diesel. News reports state that recent Junkers airplanes are designed for Diesel engines and sold with the understanding that such engines will shortly be supplied to replace the original equipment of gasoline engines.

AER-52-6

Factors in the Design of Commercial Airplanes

By CHARLES TALBOT PORTER,[1] BRISTOL, PA.

A steady and profitable market may be expected for existing equipment in remote and inaccessible places, where other forms of transportation are not available, but the real problem is to make the air transport compete successfully with the extra-fare trains. The real commodity that is being sold is transportation, and the factors involved are speed, comfort, and cost, assuming of course that safety and reliability have been demonstrated. The combination of these three factors must equal that of the fast train. The cost of air travel is of necessity high; therefore the speed-comfort combination must exceed that of the railroads. In general, the comfort of the train at least equals that of the airplane, so the latter must be sold on the speed factor alone, without sacrifice of a certain minimum requirement for comfort and at a cost that is justified by the increase in speed.

Existing air transports have a high speed of 135 to 145 miles per hour, a capacity of ten to twelve passengers, and a power output of 100 hp. per passenger. The speed has been obtained by increasing the power per passenger to nearly double that formerly thought sufficient. High power means high fuel capacity and decrease in percentage of pay load.

The author advocates the development of a 30 to 40 passenger airplane that will equal present speed requirements with a reduction of power to 50 to 60 hp. per passenger. To obtain this result he advocates abandoning direct-drive air-cooled radial engines and replacing them by geared engines, air-cooled or liquid-cooled, placed preferably inside the wing, with a remote drive to the propellers. The airplane itself should approach the flying wing, the wing loading should be high, and the landing gear should be retractable. Due to increase in landing speed the brakes should be much larger, should be operated by mechanical power, and should be capable of utilizing the full friction between the wheels and ground. The material from which the airplane is made will depend largely on a depreciation factor which is not yet clearly defined and cannot be set up until large airplanes have been in operation for a longer period of time.

THE history of American aviation during the last ten years has been as romantic as it has been remarkable, and the men in charge of the technical development find themselves in a most extraordinary position. Plodding along during the lean years, between 1918 and 1927, when their sole support came from the military authorities, the technical leaders of the industry find themselves suddenly supported by great financial resources and told to go forth and earn returns on large sums of money. This situation has its difficulties as well as its elements of strength. Probably no industry in its infancy has been in a stronger financial position to take advantage of whatever development the future may hold in store, but at the same time there is every reason to believe that the financial structure is stronger than the technical foundation. Hence a heavy responsibility rests on the aeronautical engineers to justify the confidence of the public in their chosen profession. The time has come to take careful stock of the situation and to control the direction of development in order that the resultant product may fill a definite economic need and produce a profit for both manufacturer and user.

The title of this paper was chosen to limit the discussion to large airplanes used for transportation. The term commercial airplane has in the past referred to any airplane that was not solely military in character, and this fact is a tribute to the extent to which the industry has in the past depended on the military services. In future this term should carry the same significance that the term commercial automobile conveys, and should be limited to those airplanes that are used in supplying transportation or some other business commodity.

The large commercial airplane really supplies transportation and is of value only when the commodity thus supplied can be marketed at a lower price for service rendered than similar service offered by the older and more established methods. This leads to an examination of the factors entering into the service rendered and their relative importance. These factors are speed, cost, safety, and comfort—and, most important of all, existing competition. This latter factor sets the standard that must be met or bettered to make operation an economic possibility. The author has designed airplanes for operation over the Andes and in the Peruvian hinterland where the only competition was small river steamers, connecting with Indian dugouts and mule pack trains. Although the airplanes were single-engined open-cockpit machines with a cruising speed of 85 to 90 m.p.h., the service rendered was faster, cheaper, safer, and much more comfortable than anything the competitor could supply, and hence was bound to be a success. The same condition will apply where the competition is supplied by small vessels making infrequent sailings. In fact, a steadily increasing and profitable market for air transportation, using equipment as now developed, may be expected from the more remote and inaccessible portions of the world where quick and cheap boat and rail transportation has not yet been provided. However, this type of market will not supply the demand that the industry needs, and the aeronautical engineer must produce a product that can equal the speed, cost, and comfort combination of the extra-fare train, with its dining, sleeping, and club-car accommodations.

Unfortunately, these three factors are mutually antagonistic. At present the airplane cannot compete either in price or in comfort with the extra-fare train; hence, its only reason for being is speed. Therefore, this factor must be improved upon and given priority over every other consideration. Cost, however, increases very rapidly with speed and also with comfort and may become prohibitive if both these other factors are exaggerated. However, it is probably safer for the designer to assume that, if a fast and reasonably comfortable service is rendered, the public will pay the bill.

The hardest problem for the designer is to get the proper relation between comfort and speed, assuming that the cost factor remains constant. Obviously, the maximum speed can be obtained by crowding a given number of passengers into as small a space as possible and having them "stay put," without giving them the various little accessories that contribute to their enjoyment. However, the class of passengers that can afford the high cost of air transportation is one that can afford and will demand all the conveniences of life, and will look askance at a journey, no

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

matter how swift, if it embodies any real bodily discomfort. Therefore, there is a certain minimum of comfort, and hence size and weight, which must be supplied, and the designer must start with this requirement and at the same time maintain his high speed.

It is generally claimed by air-transport operators that a cruising speed of 110 to 125 m.p.h. is necessary for successful competition with railroads. The term cruising speed is elastic and depends upon the revolutions per minute of the engines at which the pilot chooses to operate; hence, it is better to set up a criterion based on maximum speed. This figure may be set for the present at 145 to 155 m.p.h.

Having set up a high speed that must be equaled or bettered, the designer thus turns his attention to the size of body that must be provided. This will depend on the length of journey, but in general it may be assumed that flights of three to four hours will be the shortest in duration for which airplane use is justified. Each passenger will want a comfortably upholstered seat at least 20 inches wide, which should be adjustable at will. At the same time, he will require a certain freedom of movement, such as is furnished by the railroad train. The relief afforded by getting up and walking around and, in general, changing location is so great that some eminent authorities believe that in future we shall have 40-passenger airplanes carrying a maximum of 20 people.

This requirement of mobility of action points to the development of large airplanes with a total capacity of 30 to 40 passengers. Several developments of airplanes of this type are now under way, and the author believes that this size probably represents the economic limit at the present time.

Before, however, going too far with the determination of the proper passenger capacity, considerable thought must be given to the relation between size and cost of operation per passenger mile. The direct cost of fuel, oil, salaries, maintenance, and overhead is easily obtainable, but the proper factor for depreciation, due to normal wear and tear, accident, and obsolescence, is not known with any degree of certainty and cannot be known until large transports have been in operation for some years. Obviously an airplane of large capacity can be operated at less cost per passenger mile than a small one, but when depreciation on capital cost is set up, will the resultant cost be a minimum for the very large airplane or for one of intermediate size? So important is this relatively unknown depreciation factor that it may control both the size of airplane and the materials of which it is made.

Let us look briefly at the large transports now in operation and take stock of the situation, and then play the dangerous game of endeavoring to predict the line along which future developments will follow.

The present type of big transport is almost standardized as a high wing monoplane, employing three air-cooled engines, one in the nose and two below the wing. This type has been a very logical development. Three engines are the minimum number on which satisfactory flight can be maintained with one engine out; hence, this number will probably remain the minimum for subdivision of power required. There is now, however, a campaign being launched to do away with the nose engine in order to reduce fuselage vibration. To accomplish this the designer either will place his three engines entirely above the wing, or he can raise his wing above the body and mount his engines in the leading edge, or he can revert to a biplane with underslung body and the engines between the wings. The more logical development will be the use of four engines in pairs of tandems, with corresponding increase in size of airplanes.

The present transports have a high speed of 135 to 145 m.p.h., with cruising speed about 110 m.p.h. This is probably a little low for transport requirements, but even this speed had been obtained only by the use of 100 hp. per passenger, a figure that the author believes is too high for the result obtained. The ratio of useful load to gross load that may reasonably be expected with high-powered ships is 33 to 40 per cent. Out of this must come the weight of fuel and oil, and of course the more power per passenger the more of the useful load will be absorbed by the weight of fuel. The old rule for passenger ships was 50 hp. per passenger. Modern ships have doubled the power, and for this increase have given more speed, more reliability (three engines), and more comfort. The present cabins have two rows of comfortable seats and sufficient aisle space to give a reasonable amount of comfort and freedom of motion, but there is need of additional space for rest rooms or smoking rooms. This latter room should be so located and ventilated that the smell of smoke will not annoy the other passengers, especially those on the verge of airsickness.

The wing loading of modern transports, 14 to 16 lb. per sq. ft., is all that can be used with the present Department of Commerce ruling of a landing speed of 60 m.p.h. This rule, the author believes, is open to very serious objection. In an admirable paper entitled, "The Economic Relationship of Speed and Weight in Air Transportation," Mr. E. P. Warner evolves a most interesting relationship between economical cruising speed and landing speed. His conclusions are that cruising speed should not exceed 1.8 times the landing speed and that the cost of transportation at any given speed decreases rapidly as the wing loading is increased. This of course substantiates Dr. Rohrbach's theories, expounded many years ago, that in high wing loading lies the solution of the very large airplane.

In reviewing existing airplanes from the standpoint of materials used, a great variation of thought is at once apparent. There has been much talk of the advantages of all-metal construction. This is as ridiculous as to talk of all-metal houses or all-metal rowboats as having some fundamental advantage over wood. In building houses, as in shipbuilding, there is some economic size limit where metal has universally superseded wood, and this also may apply to airplanes, but the engineer should select his materials for each case for the best combination of safety, durability, cost, and performance; and while wood generally has been abandoned for body construction for reasons of safety and cost, the case of wood for wing beam construction is still very strong, and in any new project the use of wood should be investigated before definite decision is made to use other materials.

Present transports have a variation in capital cost of from $4000 to $6000 per passenger. Present indications are that no very great reduction in these figures is likely as the size is increased. It is well established that the larger the airplane the greater the attention required to detail to keep the established pay-load ratio, and hence an increasing cost. The large ship must justify itself on its apparent reduced operation costs, apparent because of the unknown depreciation factor.

Two new transports with capacity of 18 passengers have been constructed and show great promise, although they have not yet been in service long enough to prove whether they can increase the economy of operation. One of them designed under the author's direction is a high wing, externally braced monoplane of 16,000 lb. gross weight, using three 525-hp. radial air-cooled engines. The wing loading is 17 lb. per sq. ft. This ship has an excellent performance with a power loading of 87 hp. per passenger, and this should be a strong candidate for supremacy in the intermediate field. The other development is a remarkable piece of engineering work. The ship is a large biplane lightly loaded and using two 620-hp. geared water-cooled engines, which give a horsepower per passenger of 67. In fact, this airplane, compared with the older types, gives an equal performance with the same power and an increase in pay load of 50 per cent. It is open to the objection which may be applied to all twin-motored ships, that with one engine dead a satisfactory performance on the

remaining engine at altitude is difficult, if not impossible, and also the objection that the lower wing impairs the vision of the passengers, but otherwise the airplane marks a real advance in aeronautical design. One significant feature is the entrance of the liquid-cooled engine into the large transport field. This point is one of great interest and may mark a turning point in our ideas of engine-propeller efficiency.

Looking ahead, the author believes in the development of the 40-passenger airplane, but believes that present efficiencies must be improved and high performance obtained with an expenditure of 50 to 60 hp. per passenger. The first and most obvious step is to "clean up" the airplane and to increase the present propulsive efficiencies of the power plants. Present practice of stringing a number of direct-drive radial engines along the wing must be abandoned, or else the cowling must be much improved. The use of geared radials in this country has been very slow, but this change is a partial remedy at best. If the engines are to be hung in the relative wind, it would seem natural to expect the use of in-line air-cooled or the water-cooled type with Prestone cooling. The most elegant solution of the engine problem is to house all the power plants in the wing itself and to have them geared in groups to shafts which have large propellers located at some distance from the engine room. The similarity to marine practice is evident. While the development of clutches, gearing, and shafting of light weight will present quite a problem, the advantages are sufficient to make this a most promising direction for development.

Next in line will come the increase in landing speed, and at the same time the development of very effective power-operated brakes. The pilot should have at his control sufficient braking force to develop the full friction between wheels and ground at all times. This braking force with improved long-stroke landing gears and possibly a spoiler system to kill the lift of the wing should make landing at 80 m.p.h. a safe operation on any prepared landing field. The probability of forced landings should be greatly reduced by multiplicity of power plants.

Another line of endeavor should be the working out of a satisfactory retractable landing gear on large airplanes. The resistance of this unit is out of all proportion to its size and weight, and it is time it was removed from the relative wind.

Space requirements for rest rooms and sleeping accommodations seem to indicate the building of bodies with larger cross-section area, and this points to that dream of the airplane designer, the flying wing with everything inside except the propellers. This type of design, or a modification of it that improves the visibility of both pilots and passengers, seems to be a goal toward which to aim and would seem to offer the best speed-comfort combination.

A word should be said about large flying boats. The problem here is rather different. The competition moves at slower speed, and hence a reduction in top speed may be allowed without losing relative advantage as compared with the land transport. This is fortunate, as the flying boat may have to land in the open sea, and hence a lower limit on landing speed is advisable. This idea is contrary to modern European practice, where the highest wing loadings have been used on flying boats, but to the author the probability of landing a large boat in the open sea seems much greater than the necessity of putting an airplane down on an unprepared field.

After landing in rough water a flying boat should have reasonable seaworthiness and have a strong wing-tip float anchorage. This makes a strong argument for the biplane, where large area and rugged construction can be obtained for less weight than in the corresponding monoplane.

To summarize the foregoing remarks, the airplane designer, to be successful in competition with the extra-fare trains, must supply a combination of speed and comfort that will be sufficiently more appealing to the general public to justify the higher cost of air transport. In spite of the phenomenal advances of the last two years, air transport is not yet sold to the people at large. With increase in number of landing fields and improvement in the efficiency of the airplanes, there is no doubt that this sale will be consummated and that air transportation will play a prominent part in the economic life of the country.

Discussion

ARCHIBALD BLACK.[2] Perhaps the most interesting feature of the paper is the frankness with which the author faces the issue and recognizes the basic problems confronting the designer of transport airplanes. Too many designers have, in the past, found it impossible to get into their heads any semblance of appreciation of the importance of airplane-operating costs. I am particularly gratified to note how the author objects to the recent trend toward more power. This development is one of very questionable value. Increase in speed must come by the more laborious method of refining the design. Merely increasing horsepower is a thoroughly inefficient expedient, which only increases operating costs, making it a still greater problem for the traffic salesman. We must squarely face the fact that we are competing with the railroad, and if we are to carry any substantial volume of traffic, we will have to get our costs down closer to those of the railroad. This is possible if we keep down unit operating costs and increase volume of traffic simultaneously. It is indeed refreshing to observe that one designer of airplanes fully appreciates the importance of this.

B. C. BOULTON.[3] This paper, while entirely general in its character, nevertheless emphasizes several fundamental points which the writer believes are most important. First, the horsepower required per passenger in many of our present-day high-speed transports is undoubtedly too great. Although the disposable load for an airplane may amount to 40 per cent of the gross weight, yet only the passengers and baggage or the mail and express are pay load, and this pay load is only 20 to 22 per cent of the gross weight. The fuel and oil form entirely too large an item. In themselves they constitute a weight equal to approximately 65 per cent of the pay load. It is evident that a great increase in efficiency may be obtained through a reduction in the horsepower per passenger. This gain is threefold: first, the fuel and oil bill is decreased; second, the size and, hence, cost of the power-plant units are less; and third, the saving in fuel and engine weight may go directly into pay load; and inasmuch as the pay load is roughly one-fifth of the gross weight, a saving of 5 to 10 per cent in the gross weight due to reduced fuel and decrease in engine size means an increase in pay load of 20 to 40 per cent. The horsepower per passenger can be reduced by aerodynamic refinement, which decreases the resistance, by the use of geared propellers, which increases the efficiency of the power plant, and by the adoption of variable-pitch propellers, when these are perfected, which makes possible a decrease in the excess horsepower necessary to insure safety in case of failure of one of the engines. The variable-pitch propeller permits the remaining engines to continue to operate at full efficiency and also, by feathering the blade of the propeller on the dead engine, decreases its resistance. A further means of reducing the horsepower per passenger is through improved structural design—in other words, by reducing the structural weight per passenger. In this connection, it is quite possible that by employing metal monocoque construction

[2] President and General Manager, Black & Bigelow, Inc., New York, N. Y. Mem. A.S.M.E.

[3] Design Engineer, Keystone Aircraft Corporation, Bristol, Pa.

to large fuselages, both the resistance and structural weight may be reduced. A further structural refinement that may soon be possible is the use of very high strength steels in thin gages for wing spars and certain other structural parts.

It is also believed that for several years to come it will be uneconomical to design airplanes for a capacity of more than 30 to 40 passengers. There are several sound reasons for this, and all of these reasons may also be used as arguments against the development of giant dirigibles. Until the safety factor is considerably further increased, it would appear unwise to invest so large an amount of capital in a single unit or to assume a responsibility for the lives of too many passengers. Another argument against the very large airplane is the lack of economy in operation due to the problem of partial loads. It is most expensive to operate a giant airplane unless nearly filled to capacity. Furthermore, it is usually highly desirable to increase the number of trips, providing more frequent service, since much of the time gained by using the faster service afforded by an airplane is lost if the passenger has just missed the morning plane and must wait until the one leaving in the afternoon.

In conclusion, it is felt that the author's remarks about flying boats are sound and also that their use, especially when equipped with amphibian gear, is going to increase steadily, particularly along our coasts and great inland lakes. The greater safety afforded by such aircraft, which practically at all times have beneath them a natural landing field, is sure to appeal to the public and will probably outweigh the somewhat lower speed of such airplanes as compared with land types.

AER-52-7

Seaplane Design

By T. P. WRIGHT[1] and G. A. LUBURG,[1] GARDEN CITY, N. Y.

The design of the seaplane is given in detail, and the advantages of its use are described. The seaplane can generally find a landing place nearer to the center of large cities than can the land airplane. The flying boat, it is predicted, will ultimately be the method of air travel across the oceans. The market for the flying boat and the amphibian is waiting for development by the manufacturer and operator.

ALONG the waterways and coastlines of the world are thousands of miles of air routes already prepared, with nearly continuous emergency landing fields, lighthouses, landing docks, and shorelines that afford ample guide signs at all times. These facilities are available for the flying boat and the seaplane.

To this may be added the inland lakes, a large proportion of which affords landing facilities for amphibians.

From a transportation standpoint, for mail, express, and passengers, the advantages of land airplanes are most strongly demonstrated in long-distance operations, where time lost in transportation between the heart of the city and the flying field forms a small proportion of the total. The greater majority of the large cities and towns lie along a waterway. Cities are founded on the shore or bank of the river or lake, and the heart of them always lies close to the waterfront. A seaplane, therefore, has its landing field close to the center of the city, whereas a land plane must take on and discharge cargo and passengers far out where adequate facilities can be available.

From a cost standpoint the free landing field for the seaplane afforded by the water is an item not to be overlooked.

From the passengers' standpoint there is a feeling of greater safety, knowing that there is always a landing field below. Also due to its being unnecessary to fly at high altitudes in order to glide to a landing in an emergency or to cross mountains, the seaplane can be flown at a low enough altitude along the waterway to afford a close-up view of the scenery for the passengers.

Safety being the cardinal factor in air transportation, the advantages of seaplanes over land planes may be briefly listed, as follows:

(1) Existence of practically continuous emergency landing facilities. Most bodies of water have sufficient size for this purpose.
(2) Existence of terminal landing fields of practically unlimited extent.
(3) Presence of already marked routes as line of travel, especially along the seacoast, which is thoroughly lighted by lighthouses and light ships and which has shorelines which afford ample guide signs.
(4) Presence of less hazardous landing fields. A pilot, when landing in a fog, for example, would much rather land in a large bay than try to locate a comparatively small landing field.

History of the Seaplane

The seaplane was born January 25, 1911, when Glenn Curtiss at San Diego flew from and landed on the water in a land plane fitted with a pontoon. It developed quite rapidly, especially during the war, after which, particularly in this country, very little progress was made. Nations having colonies, notably England, to a certain extent foresaw the advantages of the seaplane, especially from a military standpoint, and have developed a rugged, reliable flying-boat type particularly adapted for their needs.

Since the war, airplane development in the United States, except by the Navy, has been practically entirely concerned with land planes. Within the past year, however, some attention has been paid to the design of seaplanes, with very satisfactory results.

It may be of interest to note that what was probably the first commercial seaplane route was operated between Key West and Havana in converted Navy flying boats.

General Design

Seaplanes may be divided into four classes:

(*a*) Single float
(*b*) Double float
(*c*) Flying boat
(*d*) Amphibian.

Classes (*a*) and (*b*) consist essentially of the mounting of a land plane on one or more floats instead of a wheel landing gear.

In class (*c*) the flying boat, the pontoon, and the fuselage are combined, or, as its name implies, it is a boat with wings.

The amphibian is a seaplane either with floats or a hull to which a retractable wheel landing gear is added to permit landing on the ground as well as on the water.

From an aerodynamic standpoint, the seaplane design is worked out exactly the same as a land plane and need not be further discussed. Landing load factors must be increased, due to the higher shock loads that may occur when landing on water with the absence of shock absorbers, and construction must be designed accordingly. Control surfaces must be of a size, shape, and location to take care of the center of thrust, resistance, vertical center of gravity, and yawing moments. These can be closely determined by wind-tunnel tests. Except for the amphibian, which is required to fly over land, the seaplane normally does not require the initial climb or ceiling of a land plane, thereby usually allowing an equal pay load even when giving consideration to the increased construction weight over the land plane. Take-off speed, which will be increased, will have its effect on the ability to get off from the water and must be accounted for in designing the hull.

The new problems lie in the float or hull design for operation on the water and for minimum resistance in the air.

Requirements for float or hull design should include:

(*a*) Seaworthiness at rest or at anchor. This is not for the boat alone, but for the entire machine.
(*b*) Seaworthiness and stability when under way. There must be no danger of nosing under. The tendency to "porpoise" must be kept at a minimum, but at the same time permit longitudinal control by the elevators at least above planing speed. Longitudinal and lateral stability must be inherent until the air controls become effective. Propeller thrust and torque must be taken into account.
(*c*) Low water resistance and absence of suction that would tend to prevent the hull leaving the water.
(*d*) Maneuverability, being the ability to taxi in any direction in a wind.
(*e*) Clean lines that will have a minimum of spray and disturbance of the water.
(*f*) Proper freeboard and excess buoyancy.
(*g*) Aerodynamic cleanness.

The displacement type of boat is unfitted for seaplanes due to

[1] Chief Engineer and Assistant Chief Engineer, respectively, Curtiss Aeroplane and Motor Company, Inc.

Presented at the Great Lakes Aeronautic Meeting, Cleveland, Ohio, August 31, 1929, of the Aeronautic Division of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

its high resistance and to the high suction tending to prevent its leaving the water. The single-step hydroplane has been found to be generally the best type and is most generally used in this country.

The design of pontoons or hulls is based on well-known principles that apply to ordinary planing boats or hydroplanes. It is affected, however, by the additional factors of wing lift varying as the square of the speed and by the high location of the thrust line and center of gravity. The design must provide for the keeping of the angle of incidence fairly low to cut down wing resistance until the machine is up to flying speed, at which point the tail can be dropped to get the necessary angle of attack for take-off.

The single-step hydroplane fills this requirement very nicely. Its main features are a step located a short distance aft of the center of gravity and the bottom aft of the step slanted upward relative to the bottom forward of the step at a minimum angle of about 5 deg.

In take-off the boat is headed into the wind and power is applied. At first the bow is depressed due to the high thrust, but as speed is increased, the bow rises and the stern is depressed. Planing action then commences. The flow at the step starts to jump across to the bottom aft, and air to fill in the space is admitted either at the chines or by vent tubes. As the speed increases the point of contact moves farther and farther back, until, at the point of planing, the bottom aft of the step is entirely out of the water. The planing speed is about one-third take-off speed, and at this point the air controls are starting to function. Inasmuch as the resistance increases with the speed up to planing speed, at which point it drops sharply, assistance should be given by the elevators to level off and get on the step. The peak resistance just before planing is known as the "hump" resistance and is the point past which heavily loaded machines in smooth water and no wind sometimes fail to get. Wing lift has but little effect at the lower speeds. With a 100 per cent lift at take-off speed, the lift would be 25 per cent at half take-off speed and only 1 per cent at 10 per cent take-off speed.

Due to decreased water resistance and increasing lift of the wings, speed increases rapidly from planing up to take-off. Usually the elevators are depressed to keep the machine on the water until well above take-off speed, so that there will be no liability of stalling. By raising the elevator and dropping the tail, the machine will take off with the tail end of the floats or hull remaining clear of the water. It is sometimes advisable to take off at stalling speed when the wind is strong and the sea is rough.

Landing can be made at stalling speed, which is usually done in rough water. The tail of the float touches first. This type of landing requires skill and care as the machine is likely to pancake and the controls are losing their effectiveness. Preferably, the machine is flown in at above stalling speed, so that the stern of the float and the step touch at the same time. The air controls still operate effectively, and the landing is made with a minimum of vertical component of velocity.

Float Design

Let us see how a float design as described in the foregoing will meet design requirements. These points should be as follows:

(*a*) *Seaworthiness at Rest or at Anchor.* The boat is comparatively narrow and long. Flying boats will average a beam length ratio of 5, while twin floats will run from 6 to 8. The proper longitudinal stability is easily attained. Lateral stability must be obtained by separating the twin floats to a sufficient degree or by the use of wing-tip floats in the cases of single floats and single-hull flying boats. Due to the low meticentric height and the high location of the center of gravity, inherent stability is either low or negative. Dornier overcomes the difficulty by the use of short, thick wings extending from the sides of the boat at the water line. These provide necessary buoyancy for lateral stability and clear the water when the boat starts to plane. Rohrbach's flying boats have the wing-tip floats located relatively close in. They are made larger and, in fact, support part of the load. It is really a triple-float system.

(*b*) *Seaworthiness and Stability When Underway.* When applying power there is a tendency to bury the bow. There must be sufficient displacement at the box to prevent this happening. Porpoising has a tendency to occur. This is a tendency for the boat to rock fore and aft at certain speeds. It may be due to the center of gravity coming too close to the step so that the boat balances longitudinally at that point. Moving the step aft a short distance often eliminates the tendency. Both longitudinal and lateral stability should to a great extent be controlled by the surface controls at speeds above planing. At this speed the machine rises so that the entire wing-tip floats and main float back of the step are entirely out of the water. The ailerons take care of lateral stability, and inasmuch as the usual size of machine is being supported on only about 3 to 5 ft. length of water surface, the stabilizer and elevators must provide the necessary stability to longitudinal movements. The angle of incidence of the wings can also be controlled for take-off.

(*c*) *Low Resistance and Absence of Suction.* The desirability of low resistance is self-evident. If the "hump" resistance is greater than the thrust, the machine will not plane and therefore not take off. Curved surfaces will suck down in the water at high speeds. Old-fashioned fan-tail stern boats, when run above a certain speed, are good illustrations. The bow rises and the stern squats nearly level with the water. A flat-bottomed hydroplane with clean-cut steps will plane with a fixed unit pressure as related to the speed, so that when the speed is up to take-off, the unit pressure is zero and there is no suction action.

(*d*) *Maneuverability.* It can readily be seen that a seaplane in a breeze of wind and a seaway is not the easiest thing to handle. When at anchor or taxiing head into the wind, the tail surfaces form a good weathercock. When traveling cross-wind or with the wind. it is a different matter. The single-float seaplane and the flying boat are easiest to maneuver. Twin floats are more difficult. In flying boats where the tail end is above the water and the keel length in the water is comparatively short, a water rudder is sometimes installed and improves maneuverability to a marked degree. The water rudder must either be operated independently of the air rudder or must be interconnected by springs strong enough to carry the steering forces, but with sufficient elasticity to yield to the shock load if the rudder is not in line when landing.

(*e*) *Clean Lines.* A boat traveling over the water with least disturbance and spray will normally be the one with the least resistance. Spray must be kept away from the propellers and passengers. A V-bottom with hollow flared sections at the bow will cut down the amount of spray and will throw what there is down and away from the boat.

(*f*) *Freeboard and Excess Buoyancy.* There must be proper excess buoyancy for longitudinal and lateral stability and for seaworthiness. Floats normally have a total buoyancy of approximately twice the load-water-line displacement. The proportion for flying boats runs much higher, and the freeboard must be sufficient to keep the cockpits clear of water and spray.

(*g*) *Aerodynamic Cleanness.* It is of course desirable to reduce air resistance of floats to a minimum, so as to improve performance of the seaplane when off the water without injuring in any way its handling properties while on the water. This can be accomplished by streamlining the nose of the float. There are instances of higher speeds and therefore more aerodynamic refinement in a given plane when equipped with a single float than when equipped with wheel landing gear.

Alternate Arrangements

Alternate arrangements would be as follows:

(*a*) *Single Float Seaplane.* This, as well as the twin float arrangement, is practically a land plane with floats in place of the wheel landing gear. This type (or that next described) must be employed where a land plane is to be equipped for water use. The single float is placed on the center line below the fuselage and due to its size provides adequate longitudinal stability. In a single-engine installation the propeller will come directly above the float which is located just to clear it by a few inches. The float itself protects the propeller from spray. Lateral stability is accomplished by floats attached to each lower wing. Small floats placed near the wing tips are more numerous, but in large monoplanes the wing-tip floats are sometimes made larger and brought in nearer to the main float,

carry part of the load, and make a triple-float system. Wing-tip floats get hard usage and must be securely braced and fastened.

(*b*) *Twin Float Seaplanes.* This arrangement is usually most easily substituted for the wheel landing gear. The floats can be located approximately in place of the wheels, and the struts can attach in the same fuselage fittings. This float system is especially desirable where the space below the fuselage must be clear, such as in military machines where bombs and torpedoes are dropped out of the fuselage or for commercial machines fitted for photograph work. Lateral stability is automatically taken care of by the spacing of the floats themselves. If float proportions are the same as for the single-float arrangement, the floats will be shorter in proportion to their smaller size, and longitudinal stability will be reduced. When the floats are short a tail float is sometimes added. A preferable and more general arrangement is to make the floats longer and narrower to attain proper longitudinal stability.

(*c*) *Flying Boat.* This arrangement is proving itself to be the best for general commercial use. The float and fuselage are combined and give more commodious accommodations for passengers as well as giving a feeling of greater safety over the float arrangement with its comparatively small excess buoyancy. The boat is also very much easier to enter or leave. There must be a clear passageway to the box of the boat. Beaching is always made bow to the dock or on the beach. Small single-engined open boats therefore must be of the pusher type, with the propeller well aft of the passengers. In larger boats, with either a deck or cabin top over the passengers, tractor propellers may be used. Where the stern of the boat is carried back and the tail planes are attached to it, there is ample longitudinal stability. Some designs shorten the stern of the boat and set the tail planes out on a boom structure. In this design care must be exercised to see that there is sufficient stability to preclude tipping over backward when drifting backward in a seaway. Lateral stability is accomplished by wing-tip floats the same as with a single-float arrangement. Dornier employs short wing-shaped sponsons, as already explained.

(*d*) *Amphibian.* This arrangement has a wheel landing gear as well as being a seaplane or flying boat and can operate from both land and water. As now designed it is practically a water machine in which a retractable landing gear is incorporated. This type to date has had the least attention given to it, yet will have the brightest future. If properly designed, it should have a high enough ceiling to go practically wherever a land plane can go and in addition be able to land on rivers, bays, and the innumerable inland lakes that are closed to the land machine. The amphibian naturally cannot be as efficient as the other type machines. It must have the higher structural weight of the seaplane and in addition the weight of the landing gear. It must have high enough initial climb to get out of landing fields and a low enough landing speed to land in them safely. These conditions require a reduction in the wing and power loading ratios, with a corresponding reduction in useful load. To more than overbalance, however, the amphibian can land and take off anywhere that there is a body of water of any size and can land in an emergency any where that a land plane can. If it is to be used exclusively over water, the landing gear can be removed and the useful load increased. An additional advantage is the ability to run an amphibian up on a shelving beach or runway on its own landing gear, under its own power, without outside assistance.

Detail Design

Details of the design would be as follows:

(*a*) *Step Location.* A seaplane when planing is supported by water surface that extends only a few feet forward of the step. The location of this supporting surface relative to the center of gravity must be such that there is longitudinal stability. The step location is a matter of good practice and is usually from 18 to 24 in. aft of the center of gravity. If the step comes too nearly under the center of gravity, the machine is balanced on this point rather than on the water surface as a whole and becomes unstable, usually showing a tendency to porpoise. Floats and boats, especially those with long tails, sometimes have an additional step. This step helps to break the water away from the bottom aft of the main step. It also prevents dropping the tail for take-off before the machine is up to take-off speed.

(*b*) *Bow.* The bow must have sufficient lifting power to prevent nosing under in a seaway or when power is first applied. It must not be too full, however, to have the water flow clean at high speeds. Bow lines follow high-speed boat practice, the V being fairly sharp with considerable flare so that the chine line in plan view is very full. This gives good lifting power when the bow is depressed or going into a wave and throws the spray away from the boat.

(*c*) *Stern.* The bottom lines must be straight and break cleanly at the chine line to prevent suction and leave the water easily in getting up to planing speed. In floats and boats with the tail planes carried on booms there must be sufficient buoyancy at the stern to give the proper amount of longitudinal stability to prevent tipping over backward. A transom stern will accomplish this requirement, but the increase in aerodynamical resistance prevents its use. If the stern comes to a point with a vertical sternpost, the chine and deck lines must be full to obtain the necessary displacement. If the stern comes to a horizontal V, the deck line inside elevation should be curved down to meet the bottom at an abrupt angle so that when drifting backward there is no tendency for the stern to dig under the water.

(*d*) *Bottom.* Hydroplane design teaches that, in planing, a flat bottom has least resistance. Hydroplanes now generally have more or less sharp bows with concave sections and a large flare which gradually changes to a flat bottom at the step. Flying boats and seaplanes, however, must leave and land on the water, and in taking off in a seaway or in landing there may be a contact between the flat bottom and the water that will pound the bottom severely. To lessen this pounding the seaplane bottom is given a flat V-section. Sometimes the sections are flared so that at the chine the lines are nearly horizontal. This gives the effect of a partial flat bottom with the advantages of the V preventing pounding. Also spray is thrown downward and away from the float or hull. Where the bottom is of straight V-sections a spray strip is attached to the chine line to throw the spray downward.

(*e*) *Deck.* Training seaplanes, where high performance is not necessary, sometimes have pontoons that are in plan view straight-sided with a V-bow and square stern. The deck is flat, making it easy to stand and walk on. Seaplanes requiring high performance usually have the deck lines approximately semicircular in section. Flying-boat superstructure follows boat practice altered to meet flying-boat conditions.

(*f*) *Hydrovanes.* This type of design has not been discussed, although reports of tests by Graham Bell and Baldwin, together with the successful boats built in France and Italy, show that it is more efficient than the hydroplane. Hydrovanes consist of airfoil-section wings attached to a framework below the bottom of the boat, and their action is the same in water as a wing in the air. They are not on the surface of the water like a hydroplane, but operate beneath it. Due to the great difference in density between air and water these planes are very small, and due to their high lift will lift the boat clear of the water at fairly low speeds. Practical difficulties arise, such as inability to get longitudinal control by the tail planes and danger of fouling mooring lines, floating debris, seaweed, etc. It also cannot be beached readily. The idea, however, presents advantages that warrant very serious study.

(*g*) *Structural Arrangement, Wood, Metal, Composite.* Structural design must be made to conform to the loads imposed. At anchor in a seaway the floats or hull must stand hogging and sagging stresses the same as any boat. These stresses are a maximum when the wave length equals the length of the boat. The bow in addition must be of sufficient strength to take water loads when under way. The bottom forward of the step receives the highest stresses, although the bottom aft of the step may receive high stresses in a stalled or pancake landing. Tests made by the U. S. Navy on a V-bottom seaplane under various conditions show maximum loads on the forward bottom to be 7 lb. per sq. in. at the step, gradually decreasing to 3 lb. per sq. in. at the keel and $^1/_2$ lb. per sq. in. at the chine line at a point well forward near the bow. The after-bottom loads decrease from a maximum of 6 lb. per sq. in. at the sternpost to 2 lb. per sq. in. at the step. Float design for strength is usually based upon a water pressure on the bottom whose total is the gross weight of the machine multiplied by a load factor of approximately 8 and the center of pressure of which passes through the center of gravity of the machine. This condition imposes forces in the pontoon struts and brace wires that can be easily calculated. The attaching fittings of these struts and wires are designed to take these loads and are attached to the pontoons so that the forces are carried into and distributed in the float structure.

A flying boat carries the equipment and useful load directly within itself and must be designed to carry these loads with the proper load factor, and in addition the concentrated loads of the struts, wires, and hinges supporting the wings and engines. It must also be designed to be lifted by the wings and to sustain the tail loads, the same as a fuselage in a land machine.

The skin, bottom, sides, and deck supply the larger part of the strength and rigidity as in other monocoque construction. The main trussing usually consists of a backbone running the entire length with transverse bulkheads attached to it. Secondary supports for the skin consist of transverse ribs and longitudinal stringers to prevent its buckling. The bottom in addition must take the

water loads. The backbone, sides, and bulkheads form the main supports for these loads, and the secondary supports either consist of longitudinal stringers supported by the bulkheads or by trussed transverse ribs supported by the backbone and chine. In float construction the backbone usually extends from the keel to the deck and is a longitudinal bulkhead dividing the pontoon in halves throughout a large proportion of its length. In flying boats the backbone is below the floor line and in many cases is replaced by the flat sides of the boat reinforced by a truss construction. Where holes are cut in the skin (in the deck for the cockpit, for instance), reinforcements must be incorporated to make up for the reduced strength.

Pontoon and hull construction is of three types:

(*a*) Wood
(*b*) Metal
(*c*) Composite.

Wood construction usually consists of mahogany-plywood skin and bulkheads and spruce struts and framing. The mahogany plywood is usually two thicknesses of narrow strips laid at an angle (or at right-angles) to each other with a thickness of cloth between, laid in marine glue and is fastened together with clinched copper nails or tacks. Three-ply mahogany veneer glued together with a waterproof glue is sometimes used on flat surfaces or those having a simple curvature, but unless the gluing is done perfectly, the veneer is likely to open up after a time.

Wood construction has the advantage of cheapness for experimental machines or for small production. Its greatest drawback is the absorption of water. The weight increase due to it very appreciably affects the performance of the machine.

Metal construction has been almost entirely in duralumin, although experiments are now being made with stainless steel. Corrosion due principally to electrolysis must be overcome, and especially joints between different metals must be carefully insulated by paint to prevent electrolytic action. The type of construction follows closely that of wood. There appears to be a preference for supporting the bottom between main bulkheads by longitudinal stringers rather than by transverse ribs. Metal construction will not absorb water. Its cost, however, for experimental machines or small production is nearly prohibitive. Metal pontoons are now being specialized in by some manufacturers who are standardizing them and with the increased production are able to produce for a reasonable price.

Composite construction is that employing wood framing and a metal skin. It has the advantage of the low cost of wood construction for the frames and the absence of water absorption by the metal skin. Several very successful designs have employed this type of construction, and for small production it has a decided advantage from a cost standpoint.

Conclusions

Seaplane operation, although confined to the sea and to waterways, commercially can compete to a great extent with the land planes. A large proportion of air routes can follow or can be arranged to follow waterways. Landing fields are not needed, and terminal facilities need only consist of a dock or landing stage along the waterfront in the heart of the city. Hangars and servicing facilities can be located a comparatively short distance away where land is cheap. For pioneering, transportation over, and exploration of undeveloped territory its advantages are outstanding. Expeditions using flying boats have explored the upper Amazon many miles beyond civilization. Seaplanes have flown the length of Africa, following the Nile and the chains of lakes. In the gold rush that occurred in Canada a few years ago seaplanes flew a route in a few hours that required over a week by land.

Within a few years flying boats will be designed with sufficient seaworthiness, reliability, and comfort to establish the ultimate method of air travel across the sea. With a slight sacrifice in pay load, the amphibian is well adapted for routes a greater proportion of which is over the water, the landing gear being available for an emergency.

For the private owner, the amphibian is the ideal machine. He can operate it anywhere, either over land or water, and there is nothing to compare with the thrill experienced when taking off from, or skimming over, the surface of the water.

The market for the flying boat and the amphibian is here and only waiting for development by the manufacturer and operator.

A Study on Airplane Ceiling

By LOUIS BREGUET[1] and MAURICE ROY,[1] PARIS, FRANCE

The useful torque exerted on the propeller shaft depends principally on the altitude, on the throttle setting, and on the r.p.m. of the engine. While the French Section Technique d'Aeronautique postulates that the variation of torque with altitude depends mainly on the density, the authors believe that, given good altitude adjustment and a carburetor heated to a constant temperature, the variation of torque depends directly on the relative pressure at altitude.

Having established formulas for power variation with altitude, it is possible to calculate the ceiling theoretically, provided the characteristics of the plane have been determined by tests in horizontal flight at any altitude and at any load whatsoever.

To obtain the greatest possible ceiling it is essential that:

1. **The engine should turn at full throttle the greatest possible r.p.m.**
2. **The weight of the machine per horsepower at the ground should be as low as possible.**
3. **The span loading should be as low as possible.**
4. **The propeller should be designed to have maximum efficiency at the condition of minimum power.**

With a specially designed plane and an unsupercharged engine the authors estimate that an altitude of 13,000 meters can be reached, beating previous records by some 2000 meters.

A few simple tests at one altitude with a careful record of all the elements involved can be made to give all the plans and propulsive group characteristics. The theory and practice of such experiments are fully developed in the paper.

To make full use of supercharging it is apparently necessary to change not only the pitch but also the diameter of the propeller. An alternative proposition would be to employ a variable-speed gear between engine and propeller. This fascinating idea is in some respects easier to realize than the propeller of variable pitch and diameter.

Both supercharging with altitude and undercharging at the ground offer possibilities of increasing ceiling.

Torque of an Unsupercharged Engine

THE torque Q (in kg-m.) of an aviation engine depends principally on the altitude h, on the throttle setting, which we shall characterize by a certain parameter a, and lastly on the number of revolutions n (in r.p.m.) of the engine.

Let us consider an unsupercharged engine and suppose that the altitude adjustment, which maintains constant at all altitudes the air-gas ratio of the carbureted mixture, is properly effected.

Under these conditions, the useful torque on the propeller shaft is given by

$$Q_h(a, n) = \nu Q_0(a, n) \quad \ldots\ldots [1]$$

The coefficient ν, called the coefficient of reduction of torque with altitude, depends by hypothesis only on h, and the factor $Q_0(a, n)$ represents what is known as the equivalent torque at the ground ($h = 0$) of the engine under the condition (a, n).

For a normal engine Q_0 is the torque actually developed by the engine under the conditions (p_0, ν_0, T_0) of the standard atmosphere at sea level.

For an undercharged engine, Q_0 is a fictitious torque which the engine is not allowed to develop at sea level at any throttle setting, since on such an engine this is limited at sea level.

Law of Variation of Coefficient ν With Altitude

The law officially recognized by the French S. T. I. Ae, called the standard law, for the variation of the coefficient ν with h, is based on the hypothesis that ν depends only on the relative density (relation of specific weight of air at h altitude and at the ground) of the atmosphere, and that the torque of the frictional losses of the engine keeps a constant value with the altitude, for a fixed a and n.

The standard law is expressed by the relation

$$\nu = 1.11\ \delta - 0.11 \quad \ldots\ldots [2]$$

This law, based on a few debatable experiments, justifies certain reservations. One can criticize especially its principle by noting that in considering an engine whose carburetor is heated to a constant temperature, independently of the altitude, the coefficient of such an engine ought to depend only on the relative pressure μ of the atmosphere (ratio of air pressure at h altitude and at the ground) and not on the relative density δ.

Moreover it should be noted that, in principle, the coefficient ν ought to depend on a and on n as well as on all the characteristics of the engine (operating at 2- or 4-cycle, volumetric compression, etc.), and the various arrangements effecting carburation lubrication, and cooling.

Thus, strictly, one ought to reserve for each type of engine a special law appropriate to the coefficient ν. Various forms of the law for ν have been proposed, each different from the standard law [2] and each quite debatable.

Certain recent experiments seem to indicate that, up to altitudes of the order of 10,000 meters (32,800 ft.), for engines supplied with a good altitude correction and a carburetor heated to a constant temperature, one can formulate an approximate law, both simpler and more nearly true than the standard law [2], namely,

$$\nu = \mu \quad \ldots\ldots [3]$$

To compare the laws [2] and [3] the authors have summarized in Table 1 the corresponding values of ν calculated by both of these laws, for standard altitude increasing from 1000 meters by 1000-meter steps.

TABLE 1

Standard altitude, h Meters	(Feet)	Relative density, δ	Values of coefficient ν from Standard law [2]	Approximate law [3]	Difference in per cent of [2]
0	0	1.000	1.000	1.000	—0.000
1,000	(3,281)	0.905	0.895	0.887	—0.010
2,000	(6,562)	0.820	0.803	0.785	—0.020
3,000	(9,843)	0.743	0.713	0.692	—0.029
4,000	(13,123)	0.669	0.630	0.609	—0.035
5,000	(16,404)	0.601	0.556	0.534	—0.040
6,000	(19,685)	0.539	0.486	0.465	—0.044
7,000	(22,966)	0.4815	0.425	0.405	—0.047
8,000	(26,246)	0.429	0.366	0.352	—0.039
9,000	(29,527)	0.3805	0.311	0.3035	—0.024
10,000	(32,808)	0.337	0.262	0.261	—0.004
11,000	(36,089)	0.297	0.215	0.2235	+0.035

[1] Breguet Aviation Works.

Presented at the Third National Meeting of the A.S.M.E. Aeronautic Division, St. Louis, Mo., May 27 to 30, 1929.

This table, as well as the curves of Fig. 1, shows that the simple law [3] gives, up to $h = 10{,}000$, values of ν relatively little different from those of the standard law [2]; values, moreover, which are always lower as they result from the hypothesis of reheating of the incoming mixture to constant temperature.

Expressions for h as Functions of δ and μ in the Standard Atmosphere

Let us recall that the standard atmosphere, supposedly in hydrostatic equilibrium, is characterized by the following hypotheses:

For $h = 0$: $p_0 = 1.033$ kg. per sq. cm.; $v_0 = 1.225$ kg. per cu. m.; $T_0 = 273 + 15 = 288$ deg. cent. abs. (= 59 deg. fahr.)

For $h = 0$ to 11,000 m. (36,090 ft.): $T = T_0 - 0.0065\,h$.

For $h > 11{,}000$ meters: $T = 273 - 56.5 = 216.5$ deg. cent. (= —81 deg. fahr.).

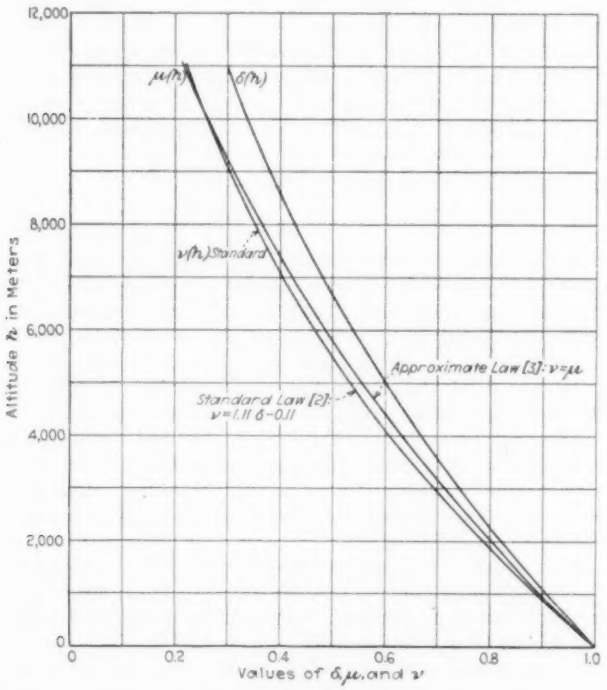

Fig. 1 Variation of δ, μ, and γ With h in Standard Atmosphere

It is easy to show that these hypotheses lead to the following laws of variation of δ and μ as functions of h:

$$\text{For } h = 0 \text{ to } 11{,}000 \text{ m., } \left\{\begin{matrix}\delta = (1 - 0.000026)^{4.255} \\ \mu = (1 - 0.000026)^{5.255}\end{matrix}\right\} \quad \ldots [4]$$

$$\text{For } h > 11{,}000 \text{ meters, } \log\frac{1}{\delta} = \frac{h - 3{,}300}{14{,}600}; \log\frac{1}{\mu} = \frac{h - 1{,}490}{14{,}600} \quad [5]$$

From these relations we deduce the following expressions for h as functions of δ and μ:

$$\text{For } h = 0 \text{ to } 11{,}000 \text{ meters, } \left\{\begin{matrix}h = 44{,}250\ (1 - \delta^{0.235}) \\ h = 44{,}250\ (1 - \mu^{0.191})\end{matrix}\right\} \quad \ldots [6]$$

$$\text{For } h > 11{,}000 \text{ meters, } \left\{\begin{matrix}h = 3{,}300 + 14{,}600 \log 1/\delta \\ h = 1{,}480 + 14{,}600 \log 1/\mu\end{matrix}\right\} \quad \ldots [7]$$

These relations permit us later to give an analytical expression to the ceiling.

Determination of the Theoretical Ceiling of an Airplane With an Unsupercharged Engine

Let us now dismiss the case of supercharged engines and occupy ourselves exclusively with normal and undercharged engines, for which we can say that the torque, at any altitude whatever, obeys the fundamental law [1].

It is known that the theoretical ceiling H or maximum altitude which an airplane can attain is characterized by the fact that, at this altitude, the plane can only fly horizontally at the single angle of incidence for which there is an exact balance between the power furnished by the engine[2] and that absorbed by the propeller, this balance permitting of but one solution.

Let us express this condition of equilibrium by indicating the effective torque of the engine. At the ceiling H let:

V_H = speed of plane (meters per sec.)
n_H = r.p.m. of propeller
a_H = throttle setting.
ν_H = coefficient of torque reduction
W_H = weight of plane (kg.)
S = wing area (sq. meters), and
D = diameter of propeller (meters).

The power supplied by the engine is (in kg-m. per sec.)

$$\nu_H \frac{2\pi}{60} n_H Q_0(a_H, n_H)$$

The power absorbed by the propeller is

$$W_H V_H \left(\frac{C_x}{C_z} \cdot \frac{1}{\eta}\right)_H$$

The condition of equilibrium between the two powers leads to

$$\nu_H \cdot \frac{2\pi}{60} n_H Q_0(a_H, n_H) = W_H V_H \left(\frac{C_x}{C_z} \cdot \frac{1}{\eta}\right)_H \quad \ldots [8]$$

which can be written

$$\frac{1}{\nu_H} = \frac{Q_0(a_\eta, n_H)}{W_H D \left(\dfrac{V}{\dfrac{2\pi}{60} nD} \cdot \dfrac{C_x}{C_z} \cdot \dfrac{1}{\eta}\right)_H} \quad \ldots [9]$$

Knowing that the efficiency of the propeller depends only on the parameter

$$\frac{V}{\frac{2\pi}{60} nD} = \gamma \quad \ldots [10]$$

and that, in horizontal flight, γ is bound to the incidence, it follows that the function

$$\xi = \frac{C_x}{C_z} \cdot \frac{\gamma}{\eta} \quad \ldots [11]$$

is, in horizontal flight, a simple function of the incidence which depends neither on the altitude nor the total weight of the plane.

The ceiling H is marked by the fact that in Equation [9] ν passes through its minimum, that is to say, the values of a, n, and i (or γ) in horizontal flight form a system rendering ν a minimum.

Moreover, one admits, with a very close degree of approxi-

[2] In this paper the authors will consider only the case of a single-engined plane. The case of the multi-engined plane would be treated in the same way and would result merely in slightly more complicated formulas, which, however, may be easily derived from those for the single-engined plane.

mation, for actual aviation engines, that the torque $Q_0(a, n)$ only depends on a, that is, for a fixed throttle setting, it varies very little with n, at least between the limits of speed utilized.

From this it can be seen from [9] that the term $1/\nu$ does not depend on n and that its numerator depends only on a, while its denominator depends only on i (the incidence). There results from this fact that at the ceiling H where ν_H is a maximum:

1 The admission of the gas is regulated to the value a_m which gives the maximum torque (case of full throttle)
2 The angle of incidence is that which gives a minimum value to the function

$$\xi = \frac{C_x}{C_z} \cdot \frac{\gamma}{\eta} \quad [11]$$

which characterizes the different possible cases of horizontal flight. In the case of incidence i_H at the ceiling, the condition of horizontal flight at the ground corresponds to the number of revolutions of the engine n_0 related to the number of revolutions n_H at the ceiling, by the expression

$$n_0 = n_H \sqrt{\delta_H} \quad [12]$$

Let us introduce in [9] the equivalent engine torque at the ground with full throttle and at n_0 revolutions by placing

$$Q_0(a_m \cdot n_H) = K_0 Q_0(a_m, n_0) \quad [13]$$

Equation [9] will then appear in the form:

$$\frac{1}{\nu_H} = \frac{Q_0(a_m, n_0) K_0}{D W_H \xi_H} \quad [14]$$

Let us put

$$X_H = \frac{Q_0(a_m, n_0) K_0}{D W_H \xi_H} \quad [15]$$

In this relation K_0 is a factor near unity and which may be taken as a first approximation equal to 1. The other elements are then known or can be determined by tests in horizontal flight at any altitude and any load whatever, as will be shown farther on, and without the necessity in any case of climbing to the ceiling, which solves in advance the problem of this determination. Having determined X_H, it is easy, on a graph giving h as a function of $1/\nu$ as established from the standard law [2], to determine H. One can also in this case, for a ceiling included between about 2000 and 7000 meters (6560 to 13,100 ft.), apply the following approximate formula:

$$H_{\text{meters}} = 325 + 18{,}090 \log X_H \quad [16]$$

from [2]. If one wishes to take account of the variation of Q_0 with the revolutions and add to the accuracy of H, he will proceed by successive approximations in first making $k_0 = 1$ in [15] and determining a first approximate value H' of the ceiling. Formula [12] will then permit an approximate calculation $n_{H'}$ of n_H which will lead to a value nearer to k_0 taking account of the relation of the definition [13]. By substituting in [14] this new value of k_0, one will get a new value for X_H which is satisfactory for the final calculation of H.

If it is desired to use the simpler law [3] proposed, up to 10,000 meters, H is given analytically by the following formula deduced from [3] and [6]:

$$H = 44{,}250 \left(1 - \frac{1}{X_H^{0.191}}\right) \text{ for } H < 10{,}000 \quad [17]$$

Other Formulas for Calculating Ceiling

The formula for determination of the ceiling H can be expressed in different ways. Let us express the equivalent power P_0 (in hp.) as

$$P_0(a_m, n_H) = n_H Q_0(a_m, n_H) \frac{2\pi}{60} \cdot \frac{1}{75} \quad [18]$$

in place of the equivalent torque Q_0 in [8] which expresses the equilibrium of the engine power and the power absorbed by the propeller. Then:

$$\frac{1}{\nu_H} = \frac{75 P_0(a_m, n_H)}{W_H V_H \left(\frac{C_x}{C_z} \cdot \frac{1}{\eta}\right)_H} \quad [19]$$

But the speed at the ceiling V_H is given by

$$V_H = \sqrt{\frac{W_H}{\frac{\rho_0}{2g} \delta_H S C_z}} = 4 \sqrt{\frac{W_H}{S}} \cdot \frac{1}{\sqrt{\delta_H}} \cdot \frac{1}{\sqrt{C_z}} \quad [20]$$

and Equation [19] can be expressed as

$$\frac{1}{\nu_H \sqrt{\delta_H}} = \frac{75 P_0(a_m, n_H)}{4 W_H \sqrt{\frac{W_H}{S}} \left(\frac{C_x}{C_z^{3/2}} \cdot \frac{1}{\eta}\right)_H} \quad [21]$$

In horizontal flight the function $\zeta = \frac{C_x}{C_z^{3/2}}$ and the efficiency η of the propeller depend on the incidence only. The function

$$q = \frac{C_x}{C_z^{3/2}} \cdot \frac{1}{\eta} = \frac{\xi}{\eta} \quad [22]$$

then depends only on the incidence.[3]

Let

$$K_H = \frac{75 P_0(a_m, n_H)}{4 W_H \sqrt{\frac{W_H}{S}} q_H} \quad [23]$$

Suppose that this quantity has been determined for a given plane. To find the ceiling it will be sufficient if one adopts the standard law [2] of variation of ν, to mark off on a graph giving h as a function of $\frac{1}{\sqrt{\delta}}$ from [2] the value H corresponding to K_H. One can also, if H lies between 2000 and 7000 meters, use the following approximate formula (from law [2]):

$$H_{\text{meters}} = 285 + 12{,}800 \log K_H \quad [24]$$

If we adopt the simpler law [3] of variation of ν for altitudes less than 10,000 meters, H could be calculated from the following formula deduced from [3] and [6]:

$$H_{\text{meters}} = 44{,}250 \left(1 - \frac{1}{K_H^{0.1345}}\right) \quad [25]$$

Note that in expression [21], K_H, which occurs in the preceding formulas, involves the number of revolutions n_H of the engine at the ceiling, a value which is not known directly, in

[3] The function q thus defined is equal to $4q'$, q' designating the function $\frac{K_x}{(K_z)^{3/2}} \cdot \frac{1}{\eta}$ that one of the authors (Louis Breguet) has named previously "moto-sustaining quality" and on which he has based the first classic French formula for ceiling.

general, and whose influence on the value of $P_0(a_m, n_H)$ is quite important. To avoid the occurrence of this value, one can show in the formula the number of revolutions n_0 of the engine in horizontal flight at the ground at the same angle of incidence as that at the ceiling. From [12] and [13] we can write

$$P_0(a_m, n_H) = P_0\left(a_m \cdot \frac{n_0}{\sqrt{\delta_H}}\right) = \frac{n_0}{\sqrt{\delta_H}} Q_0(a_m, n_0) K_0$$

$$= \frac{K_0}{\sqrt{\delta_H}} P_0(a_m, n_0) \ldots\ldots [26]$$

and [21] becomes

$$\frac{1}{\nu_H} = \frac{75 P_0(a_m, n_0) K_0}{4 W_H \sqrt{\frac{W_H}{S}} q_H} \ldots\ldots [27]$$

Comparing this with [14] and [15] it is seen at once that

$$\frac{75 P_0(a_m, n_0) K_0}{4 W_H \sqrt{\frac{W_H}{S}} q_H} = X_H \ldots\ldots [28]$$

This formula is identical with [15], and it is evident that one would have been able to pass directly from one to the other by substituting the equivalent of power $P_0(a_m, n_0)$ for the torque equivalent $Q_0(a_m, n_0)$. This comparison affords the opportunity to make an interesting observation. We have seen, in relying on the fact that the torque Q_6 is seemingly independent of the number of revolutions at full throttle admission a_m, that the incidence at the ceiling corresponds to the minimum of the function

$$\xi = \frac{C_x}{C_z} \cdot \frac{\gamma}{\eta}$$

Now, in relying on the relation [23] and neglecting in it the perceptible variation of P_0 with n, it has often been stated that the incidence at the ceiling is that which renders a minimum in horizontal flight, the function

$$q = \frac{C_x}{C_z} \frac{1}{\sqrt{c_z}} \frac{1}{\eta}$$

It is easily seen that this statement is not exact, for the minimum of q does not coincide with that of ξ, which alone corresponds truly to conditions at the ceiling. According to the type of plane and the characteristics of the engine-propeller group, the incidence at the actual ceiling can be less or more than that of the minimum of q.

As a rule for actual planes, it is the first case which is realized. One can, moreover, as will be seen further on, verify this fact by determining the coefficients ξ and q in functions of the incidence in horizontal flight, by trials in flight at one altitude and at any load whatever.

Conditions for Reaching the Highest Ceiling

Let us return to Equation [28] in which one can, as has been seen, equate k_0 to unity on a first approximation. To obtain the highest theoretical ceiling possible it is proper to combine with the ceiling the conditions which give to X_H the greatest value possible. This observation shows immediately that it is necessary at the ceiling that:

1 The engine shall turn at full throttle at the maximum number of revolutions, since n_0 is as much larger as n_H is larger.

2 The weight of the machine per horsepower at full power at the ground shall be as low as possible (power loading).

3 The weight of the machine per unit of wing span shall be as small as possible (span loading), and

4 The propeller shall be adapted so as to give in horizontal flight its maximum efficiency for the case of incidence corresponding to the minimum of $\xi = \frac{C_x}{C_z^{3/2}}$. In this case the minimum of q coincides with that of ξ and this case of incidence is, with the propeller considered, that of the ceiling. It is understood that these varying conditions are not independent, and it is not always possible to obtain them simultaneously, either because of a propeller of excessive diameter and bulk or with a relative pitch p/D too high to allow an easy take-off. The best practical solution, then, is to compromise judiciously in each case.

Possible Record of Altitude for a Plane With Normal Engine

It is interesting to see, by relying on the principles of construction actually realizable, to what height a plane can climb that is fitted with a normal engine and specially constructed with an altitude record in view. Let us establish a relation between the various weights which compose the whole. At the start, the total weight W_0 comprises:

1 Weight of the airplane structure represented by αW_0, α denoting the coefficient of lightness of the structure

2 Weight of the engine-propeller group represented by rP_0, P_0 designating the maximum engine power at the ground and r the specific weight of the group, that is, its weight per horsepower at maximum power

3 Weight of fuel which, it is assumed, corresponds to t hours of running at full power at the ground; weight represented by tmP_0, m designating the specific consumption of the engine in kilograms of gasoline and oil per effective horsepower-hour

4 The weight of the crew (1 pilot) and his equipment (instruments for flying, special clothing, oxygen apparatus, etc.) estimated at 120 kg. (265 lb.).

Under these conditions,

$$W_0 = \alpha W_0 + r W_0 + tmP_0 + 120 \ldots\ldots [29]$$

The weight W_H at the ceiling is equal to the weight at take-off W_0 less the stock of fuel and oil which is used up. Then:

$$W_H = W_0 - tmP_0 = W_0\left[1 - tm\frac{1-\alpha}{r + tm}\right] + tm\frac{120}{r + tm} \ldots [30]$$

To calculate the ceiling H, we shall apply the relation [21] in which we make $P_0(a_H, n_H) = P_0$, reverting to the supposition that the engine operates at the ceiling at the rated full-load speed which gives the maximum power at the ground.

Let us first try to render a maximum the relation

$$J = \frac{P_0}{W_H \sqrt{\frac{W_H}{S}}}$$

We have:

$$J = \frac{P_0}{W_H \sqrt{\frac{W_H}{S}}} = \sqrt{S} \frac{\frac{W_0(1-\alpha) - 120}{r + tm}}{\left\{W_0\left[1 - tm\frac{(1-\alpha)}{r + tm}\right] + tm\frac{120}{r + tm}\right\}^{3/2}} \ldots\ldots [31]$$

In this relation the coefficient of lightness α of the glider, for a given type of construction, is almost independent of W_0/S and depends only on the dimensions, increasing slightly with them. Thus one can regard α as dependent only on S for one type of construction and a given form of plane, and not on W_0.

Moreover, the coefficients r, m, and t are nearly independent of P_0 and, as a result, of W_0. In reality, nevertheless, one must consider that, the less the power of an engine-propeller group, the greater its specific weight becomes.

However this may be, let us assume S, α, r, t, and m fixed in the preceding relation [31] and seek the value of W_0 which renders this expression a maximum. It is easily found that this value is:

$$W_0 = \frac{120\ [3r + (2 + \alpha)\ tm]}{(1 - \alpha)\ (r + tm\alpha)} \quad \ldots\ldots [32]$$

for which

$$P_0 = \frac{240}{r + tm\alpha} \quad \ldots\ldots [33]$$

$$W_H = \frac{360}{1 - \alpha} \quad \ldots\ldots [34]$$

It is seen that for this optimum value of W_0, W_H is independent of the number of hours t of the fuel carried at the start. But the relation J considered is not independent, for its maximum is:

$$J_{max} = 0.385 \sqrt{\frac{S}{120}} \frac{(1 - \alpha)^{3/2}}{r + tm\alpha} \quad \ldots\ldots [35]$$

To fix these ideas, let us adopt the following hypothesis actually attainable by a plane and engine especially made for the altitude record:

S = 30 sq. m. (323 sq. ft.); α = 0.30; r = 1 kg. per metric hp. (2.2 lb. per hp.); m = 0.235 kg. per metric hp-hr. (0.518 lb. per hp-hr.); t = 2 hr.

Then

W_0 = 613 kg. (1351 lb.); P_0 = 210 hp. (metric); W_H = 514 kg. (1131 lb.).

Assume the following data:

	At start	At ceiling
Airplane structure, kg	184	184
Engine, kg	210	210
Fuel, kg	99	...
Load, kg	120	120
Total weight, kg	613	514
Load per hp., kg	2.93 (6.45 lb.)	2.45 (5.4 lb.)
Load per sq. meter, kg	20.45 (4.2 lb. per sq. ft.)	17.12 (3.51 lb. per sq. ft.)

and

$$J = 0.0985.$$

It is seen that this points to a single-seater plane with very light loading, analogous to a glider equipped with an engine having relatively great power and which represents in itself alone, despite its small specific weight (r = 1 kg. per hp.), nearly 35 per cent of the total weight at the start.

It may indeed be objected that, for so light a plane, a coefficient of lightness of 30 per cent (α = 0.30) would perhaps be difficult to realize, for one would be compelled to use material of insufficient thickness to adequately resist the secondary stresses. However, to show that such a conception is a mistaken one it may be said in passing that in working with other data, more like those corresponding to actual planes of medium weight, one would realize values of the relation J of the same order as that indicated above.

As an example, let us take a biplane of 50 sq. m. (538 sq. ft.) surface, loaded to 2000 kg. (4408 lb.) at the start, of which the structure represents 30 per cent. Assuming as before that r = 1 kg. per hp.; m = 0.235 kg. per hp-hr.; and t = 2 hr., would give P_0 = 870 hp.; W_H = 1590 kg. (3507 lb.). That is to say:

	At the start	At the ceiling
Airplane structure, kg	600	600
Engine, kg	870	870
Fuel, kg	410	...
Loading, kg	120	120
Total, kg	2000	1590
Load, per hp., kg	2.30 (5.08 lb.)	1.83 (4.04 lb.)
Load per sq. meter, kg	40 (8.2 lb. per sq. ft.)	31.8 (6.52 lb. per sq. ft.)

In this case, which does not correspond to the maximum of J for the values chosen of S, α, r, m and t, we have J = 0.0970. The maximum of this relation would be 0.125 and would correspond to the same weight (W_0 = 613 kg.) as in the preceding example, since in these examples the surface only is different and the value of W_0 giving the maximum of J is independent of this surface.

Let us now return to our first example, a light single-seater, and attempt to determine its ceiling.

For evaluating the value of q_H by substitution in [21] it is necessary to make certain hypotheses.

For the region of the ceiling we must take the minimum condition of $\zeta = \frac{C_x}{C_z^{3/2}}$ by assuming that the propeller is adapted to furnish its maximum efficiency (n = 0.75) in this region. Let us consider the parabolic polar diagram between the region of fineness (minimum of C_x/C_z) and that of the minimum of ζ. By designating by R the aspect ratio of the elliptic wing equivalent of the wing considered, the polar equation is:

$$C_x = a + \frac{1}{R\pi} C_z^2 \quad \ldots\ldots [36]$$

Let (C_{x1}, C_{z1}) be the region of fineness; then

$$\frac{C_{x1}}{C_{z1}} = \tan \varphi_1 \quad \ldots\ldots [37]$$

and

$$C_{z1} \tan \varphi_1 = \frac{2}{R\pi} C_{z1}^2$$

That is to say:

$$C_{z1} = \frac{R\pi}{2} \tan \varphi_1 \quad \ldots\ldots [38]$$

The limit (C_{x2}, C_{z2}) of the minimum of ζ is characterized by:

$$C_{x2} = \sqrt{3}\ C_{z1} \quad \ldots\ldots [39]$$

$$\zeta_2 = \zeta_{min} = 0.702 \sqrt{\frac{\tan \varphi_2}{R}} \quad \ldots\ldots [40]$$

This relation shows the influence of the extension equivalent R on the coefficient ζ_2. By increasing R, not only is the denominator of ζ_2 increased but also, in general, the numerator is reduced. Moreover, it is worth while to notice that if the aspect-ratio extension R becomes too large, the value of c_{z2} indicated above will exceed the maximum lift, c_{z1} becoming quite large and, as a result, the polar diagram can no longer resemble a parabola as far as the minimum case of ζ is concerned.

In this case, the minimum of ζ is found to be decidedly greater than the value indicated by [40].

To fix these ideas in the mind, let us assume that the airplane structure considered has a fineness $\tan \varphi_1 = 0.065$ and an aspect ratio $R = 7$. Under these conditions, the condition of fineness corresponds to $c_{z1} = 0.715$ and that of the minimum of ζ to:

$$C_{z2} = \sqrt{3} \times 0.715 = 1.235; \quad \zeta_{z2} = 0.0677$$

These values are reasonable. They correspond to those of an airplane structure having aerodynamic qualities which are exceptionally good but are nevertheless obtainable. It is to be noted, in fact, that certain tests of particularly fine wing-truss structures have shown values of the order of 0.055 for the minimum of ζ.

For the plane considered, by using the figures established above we have:

$$J = 0.0985; \quad \zeta_{\min} = 0.0677; \quad \eta_{\max} = 0.75$$

and consequently, from [21]:

$$\frac{1}{\nu_H \sqrt{\delta_H}} = \frac{75 \times 0.0985 \times 0.75}{4 \times 0.0677} = 20.5 \ldots\ldots [41]$$

According to the standard law [2] the altitude corresponding to this number is 13,560 meters (44,500 ft.), which is the theoretical ceiling of the plane considered. At this altitude the conditions of flight are characterized by:

$$\frac{W_H}{S} = 17.12 \text{ kg. per sq. cm.}; \quad V_H = 33.3 \text{ m. per sec.}$$

$$= 120 \text{ km. per hr. (74.6 m.p.h.)}$$

The effective power of the engine is reduced to about 23 hp., which is sufficient to drive a plane weighing 514 kg. (1130 lb.) at a speed of 120 km. per hr. at the region of the ceiling for which $c_{z2}/c_{x2} = 0.075$ and $\eta = 0.75$.

It is seen then that it is quite possible to reach and to exceed 13,000 meters, that is, to surpass the recent records of altitude in the vicinity of 11,000 meters, with a specially designed plane equipped with a standard engine.

It is understood of course that the preceding calculation assumes that every precaution is taken in order that, at the very high altitude contemplated, the carburation and ignition shall operate properly and without trouble.

Determination of the Aerodynamic Characteristics of an Airplane by Flying Tests

It is known that one can estimate, with a certain approximation, by calculation based on laboratory tests on small-scale models of plane and propeller, the aerodynamic characteristics of a full-sized plane.

But, in addition to the error due to the scale effect, which is yet impossible to foresee or to figure, this method of calculation involves numerous other sources of error. Among these are the airplane-propeller interaction or mutual effect and the differences in the equipment of the real plane and its model (guy wires, struts, radiators, nature and elastic properties of the wing surfaces, etc.).

Further, it is of the greatest interest to determine directly by flying tests the aerodynamic characteristics of an airplane-propeller system, and we shall therefore show how to proceed with tests in horizontal flight.

Let us first assume as correct the law of variation of the coefficient ν of reduction of the torque with the altitude.

Imagine that a plane attains a horizontal stage at a certain incidence i, a stage in the course of which one notes the following:

1 The relative pressure μ and the temperature T of the atmosphere, from which is deduced the corresponding standard altitude h
2 The aerodynamic speed V_{hi} (in meters per second) at the altitude h and incidence i
3 The speed of rotation n_{hi} (in r.p.m.) of the propeller
4 The throttle setting a_{hi}
5 The weight W (in kg.) of the plane, deduced from its weight at take-off and from the reduced load corresponding to the fuel consumed.

The power (in kg-m.) furnished by the engine is

$$\nu_h \frac{2\pi}{60} n_{hi} Q_0 (a_{hi}, n_{hi}),$$

and the torque $Q_0(a_{hi}, n_{hi})$ can be determined by tests on the testing block on the ground, during which the engine will be rotated at the revolutions n_{hi} by giving to the throttle the position corresponding to the value a_{hi} of admission.

Moreover, the power utilized for the flight considered can be written:

$$WV_{hi}\left(\frac{C_x}{C_z} \cdot \frac{1}{\eta}\right)_i \quad \text{or} \quad 4W\sqrt{\frac{W}{S}}\frac{1}{\sqrt{\delta_h}}\left(\frac{\zeta}{\eta}\right)_i$$

Equating these expressions to that of the power furnished by the engine,

$$\nu_h \frac{2\pi}{60} n_{hi} Q_0 (a_{hi}, n_{hi}) = WV_{hi}\left(\frac{C_x}{C_z} \cdot \frac{1}{\eta}\right)_i$$

$$= 4W\sqrt{\frac{W}{S}}\frac{1}{\sqrt{\delta_h}}\left(\frac{\zeta}{\eta}\right)_i \ldots\ldots [42]$$

It is particularly interesting to know, for horizontal flight, the values of:

$$\tan \varphi' = \frac{C_x}{C_z} \cdot \frac{1}{\eta}; \quad \xi = \frac{C_z}{C_s} \cdot \frac{\gamma}{\eta}; \quad q = \frac{\zeta}{\eta} \ldots\ldots [43]$$

which depend only on the incidence i, in functions of this, or better, of the lift coefficient C_z.

These quantities will be given by the formulas:

$$\tan \varphi' = \frac{\nu_h \cdot \frac{2\pi}{60} n_{hi} Q_0 (a_{hi}, n_{hi})}{WV_{hi}} \ldots\ldots [44]$$

$$\xi = \frac{\nu_h Q_0 (a_{hi}, n_{hi})}{\lambda WD} \ldots\ldots [45]$$

$$q = \nu_h \sqrt{\delta_h} \frac{\frac{2\pi}{60} n_{hi} Q_0 (a_{hi}, n_{hi})}{4W\sqrt{\frac{W}{S}}} \ldots\ldots [46]$$

As to the variable C_z, its value is:

$$C_z = 16 \frac{W/S}{\delta_h (V_{hi})^2} \ldots\ldots [47]$$

We have supposed that the law of variation of ν with h is known. In reality, the tests just indicated permit its exact determination.

It should be noted that the functions $\tan \varphi'$, ξ, and q of C_z are in horizontal flight, independent of W and h, that is to say, of the load on the plane and of the altitude of flight. One can then determine these functions by tests in flight near the ground ($h = 0$), for which $\nu = 1$.

By repeating these tests at any altitude and at any load whatever, the relations [44], [45], and [46], in which all the elements are known except ν_h, will serve

1 To determine ν_h
2 To determine which law gives the closest value for ν_h and especially if this coefficient can be expressed exclusively in terms of δ (or μ); and
3 To determine, eventually, if ν_h does not depend in a certain measure not only on h but also on a and on n.

It will be noticed that the tests mentioned are extremely simple and can be accomplished in the course of a single flight, comprising four or six runs of a number of kilometers at three or four different levels of altitude. Standard instruments only are required. It will be sufficient to check on their precision and to choose registering types with an arrangement for synchronizing their readings. For recording the variations of a, the most practical method will consist in mounting on the carbureter a simple and inaccurate arrangement for indicating the position of the throttle valve. Block tests of the engine should be made, using the same instruments and reproducing the indications registered in the course of the flight.

The preceding tests give, in terms of C_x, the functions tan φ', ζ, or q which pertain to the efficiency of the propeller. It must be recognized that these are overall coefficients of the plane-propeller system which alone determine the performance and are consequently the most interesting to measure and learn directly.

Nevertheless it might be desired to separate the influence of the propeller from that of the airplane structure. In that case it would be necessary to trace the polar diagram (C_x, C_z) of the airplane alone. This is possible, either from the model tests in the tunnel or from gliding tests with propeller stopped or rotating without producing traction, tests which permit the finding of $C_x/C_z = \tan \varphi$ in terms of C_z.

Determination of the Ceiling by Flight Tests

The method just indicated makes it possible to determine the function ζ, and therefrom, by some simple tests in flight, the angle of incidence at the ceiling.

Equation [14] gives then, directly, the theoretical ceiling (H) sought. But one can, in the tests considered, show a characteristic relation directly connected with the ceiling H of the machine.

We shall now develop this method of determining the various influences on the part which the power reserve plays in the possibility of a plane's reaching a high altitude.

Let us consider a test in horizontal flight at an altitude h, at the incidence i, and with weight W. Let V_{hi}, n_{hi}, and a_{hi} be the values of speed, number of revolutions, and throttle setting recorded in the course of this test.

The power furnished by the engine in this flight and run is

$$\nu_h \cdot 2\pi \frac{n_{hi}}{60} Q_0 (a_{hi}, n_{hi}) = WV_{hi} \left(\frac{C_x}{C_z} \cdot \frac{1}{\eta} \right)_i \quad [48]$$

which can be considered as known, if the law $\nu = f(h)$ is known.

At the incidence i, the plane can only fly at a certain altitude H_i which can be considered as the ceiling of the plane for this angle of incidence. The theoretical ceiling H that we have studied so far is the maximum of the different ceilings H_i and corresponds to a certain angle of incidence i_H.

The ceiling H_i is determined by the following equation, analogous to Equation [9]:

$$\frac{1}{\nu_{H_i}} = \frac{Q_0 (a_m, n_{hi})}{WD\xi_i} \quad [49]$$

Let us put:

$$X_{hi} = \frac{Q_0 (a_m, n_{Hi})}{Q_0 (a_{hi}, n_{hi})} \quad [50]$$

which can also be written:

$$X_{hi} = \frac{Q_0 (a_m, n_{i0})}{Q_0 (a_{hi}, n_{hi})} \cdot K_{i0} \quad [51]$$

by placing

$$K_{i0} = \frac{Q_0 (a_m, n_{Hi})}{Q_0 (a_m, n_{i0})} \quad [52]$$

$n_{i0} = \sqrt{\delta_{Hi}}\, n_{Hi}$ designating the number of revolutions of the engine in horizontal flight at the incidence, i, at the ground. The coefficient K_{i0} is in general approximately equal to unity, the equivalent torque at the ground at full admission $Q_0(a_m, n)$ being seemingly independent of the number of revolutions.

The coefficient X_{hi} thus defined is the ratio of the equivalent torque at the ground which the engine develops, on the one hand at full admission and at the number of revolutions n_{Hi} at the ceiling H_i corresponding to the incidence i, and on the other hand to the admission a_{Hi} and to the number of revolutions n_{hi} actually used on the test under the conditions (h, i). It is this that we call the coefficient of excess of power at the altitude h and at the incidence i.

From Equation [48] also,

$$\nu_h Q_0 (a_{hi}, n_{ai}) = WD \left[\frac{C_x}{C_z} \frac{1}{\eta} \frac{V}{\frac{2\pi}{60} nD} \right] = WD\xi_i \quad [53]$$

and consequently the coefficient X_{hi} defined by [51] can be written:

$$X_{hi} = \frac{Q_0 (a_m, n_{Hi})}{WD\xi_i} \nu_h$$

At the ceiling H_i corresponding to the incidence i from [49],

$$\frac{1}{\nu_{Hi}} = \frac{X_{hi}}{\nu_h} \quad [54]$$

From this it results that the relation X_{hi}/ν_h, equal to a number which depends only on i, is itself independent of h and depends only on the incidence i.

Thus it is seen that the coefficient of excess of power X_{hi} reproduces, by a nearly constant factor, $\frac{Q_0 (a_m, n_{Hi})}{WD} \nu_h$, the variation of $1/\xi$ in terms of i. For a given value of i, its value is proportional to ν_h.

If, following tests such as those examined, the curves X_{hi} are plotted in terms of i for various altitudes h, similar curves will be obtained which are related to each other in the same way as curves of the corresponding values of ν_h. The comparison of these curves will allow both the determination of the variation of ξ in terms of i (or, if one prefers, of C_z) and of ν in terms of h. This process corresponds, moreover, to that which has been indicated above under another form. Let us return now to the test on the level under the conditions (h, i) which furnish, through Equation [52], the value of X_{hi}, when k_{i0} is known. In fact putting $k_{i0} = 1$ will correct this value after having determined, with the value of X_{hi} thus obtained, a value near to the ceiling H_i.

The law $\nu = f(h)$ being supposedly known, the relation [54] will furnish the ceiling H_i corresponding to the incidence i. The following formulas can also be used:

1 If we take for ν the standard law [2], the ceiling will be determined by the following approximate formula, which holds when h and H_i lie between 2000 and 7000 meters.

$$H_i - h = 18{,}090 \log X_{hi} \text{ (for } h < 7000 \text{ m.; } 2000 \text{ m. } < H_i). \quad [56]$$

2 If we adopt for ν the law [3] proposed up to 10,000 meters, the ceiling H_i will be determined by the following accurate formula:

$$H_i - h = (44{,}250 - h)\left(1 - \frac{1}{X_{hi}^{0.191}}\right) \text{ (for } H_i \text{ and } h < 10{,}000 \text{ m.)} \quad [57]$$

The theoretical ceiling H or maximum of the various ceilings H_i corresponds to the case i_H of horizontal flight for which, at every altitude, X_{hi} is a maximum.

If one takes for altitude h the sea level, the maximum of X_{hi} becomes equivalent to the coefficient X_H defined by [15], that is,

$$(X_{hi})_{max} = X_H \text{ for } h = 0$$

In this case Equations [56] and [57] coincide with [16] and [17] which give H in terms of X_H.

The coefficient X_{hi} thus generalizes, for one altitude and any incidence whatever, the idea of the coefficient of power reserve introduced by the coefficient X_H for the particular case at sea level and at the incidence i_H corresponding to the theoretical ceiling H. Equations [56] and [57] indicate, in terms of X_{hi}, the additional altitude $(H_i - h)$ which the plane can attain starting from h level and for the case of incidence i. They show how this "relative ceiling" is connected with the coefficient of excess of power X_{hi} corresponding to the altitude at departure h and at the incidence i.

Variations of Ceiling Under Various Influences for a Plane With a Normal Engine or an Undercharged One

1—Influence of a Variation of Load

Consider two planes 1 and 2, differing only in the total load, and distinguish by the indices 1 and 2 the relative sizes of these two planes.

The ceiling H_1 of the first is given, from the relation [9] by

$$\frac{1}{\nu_{H1}} = \frac{Q_0\,(a_m, n_{H1})}{W_1 D \xi_{H1}} \quad [58]$$

The ceiling of the second, H_2, is in the same way given by

$$\frac{1}{\nu_{H2}} = \frac{Q_0\,(a_m, n_{H1})}{W_2 D \xi_{H2}} \quad [59]$$

But, the planes, the engines, and the propellers being identical, the conditions at the ceiling are the same for the two structures and $\xi_{H1} = \xi_{H2}$.

Let us place

$$\frac{Q_0\,(a_m, n_{H1})}{Q_0\,(a_m, n_{H2})} = k \quad [60]$$

This coefficient k is practically equal to 1 and can be taken, for a first approximation, equal thereto.

From [58] and [59],

$$\frac{\nu_{H2}}{\nu_{H1}} = k\,\frac{W_2}{W_1} \quad [61]$$

Two cases are to be examined, namely, whether the relation W_2/W_1 has any value whatsoever or lies in the neighborhood of unity.

(*a*) *General Case: When W_2/W_1 Has Any Value Whatsoever.* If the standard law [2] is taken for the coefficient ν, it is easy to see that there can be deduced from [61] the following relation between the relative densities δ_{H1} and δ_{H2} at the respective ceilings H_1 and H_2 of the planes considered:

$$\delta_{H2} = \delta_{H1}\,k\,\frac{W_2}{W_1} - 0.099\left(k\,\frac{W_2}{W_1} - 1\right) \quad [62]$$

If we take the approximate law [3] of the variation of ν, accurate up to 10,000 meters, the relation [61] permits the following relation between the ceilings H_1 and H_2:

$$H_2 = 44{,}250 - (44{,}250 - H_1)\left(k\,\frac{W_2}{W_1}\right)^{0.191} \quad [63]$$

To calculate H_2 from [62] or [63] it is necessary to proceed by successive approximations, first making $k = 1$ and then correcting the value of k from the approximate value of H_2 thus obtained.

(*b*) *Particular Case: W_2/W_1 Differing Little From Unity.* In this case the variation of the ceiling is evidently small, so that we can take k equal to unity.

Using the approximate law [3], accurate up to 10,000 meters, [63] is simplified and gives

$$H_2 - H_1 = (0.0191\,H_1 - 8440)\,\frac{W_2 - W_1}{W_1} \quad [64]$$

Fig. 2, which represents this formula, gives directly the variation of ceiling $(H_2 - H_1)$ which causes a relative variation determined by the load. This relation is accurate and a close enough approximation up to $H_1 = 10{,}000$ m. and $\frac{W_2 - W_1}{W_1} = \pm 10$ per cent.

2—Influence of a Variation in the Torque

Let us consider two planes 1 and 2 differing only in their engines, which are assumed to give at full admission the equivalent torques Q_1 and Q_2.

The ceiling of the first plane is determined by

$$\frac{1}{\nu_{H1}} = \frac{Q_1\,(a_m, n_{H1})}{W_{H1} D \xi_{H1}} \quad [65]$$

and that of the second by

$$\frac{1}{\nu_{H2}} = \frac{Q_2\,(a_m, n_{H2})}{W_{H2} D \xi_{H2}} \quad [66]$$

The planes and propellers being identical, we have, by hypothesis:

$$W_{H1} = W_{H2}; \quad \xi_{H1} = \xi_{H2}$$

Let us place

$$\frac{Q_2\,(a_m, n_{H2})}{Q_1\,(a_m, n_{H2})} = k \quad [67]$$

the revolutions n_{H1} and n_{H2} corresponding to the ceilings H_1 and H_2 being determined by

$$\frac{n_{H2}}{n_{H1}} = \sqrt{\frac{\delta_{H2}}{\delta_{H1}}}$$

The comparison of [65] and [66] permits us to write, taking account of [67]:

$$\frac{\nu_{H2}}{\nu_{H1}} = \frac{Q_1\,(a_m, n_{H1})}{Q_2\,(a_m, n_{H2})} \cdot \frac{1}{k} \quad [68]$$

We distinguish again two cases, according as the relation Q_2/Q_1 of the torques considered has any value whatsoever or a value differing little from unity.

(*a*) *General Case: When Q_2/Q_1 Has Any Value Whatsoever.* If we adopt for ν the standard law [2], we can deduce from [68] the following relation between the relative densities δ_{H1} and δ_{H2} at the ceilings H_1 and H_2:

$$\delta_{H1} = \delta_{H2} \cdot \frac{1}{k} \cdot \frac{Q_1}{Q_2} - 0.099 \left(\frac{1}{k} \frac{Q_2}{Q_1} - 1 \right) \quad \ldots\ldots [69]$$

If we adopt for ν the approximate law [3], accurate up to 10,000 meters, we can deduce from [68] the following simple relation between H_1 and H_2:

$$H_2 = 44{,}250 - (44{,}250 - H_1) \left(\frac{1}{k} \frac{Q_1}{Q_2} \right)^{0.191} \quad \ldots\ldots [70]$$

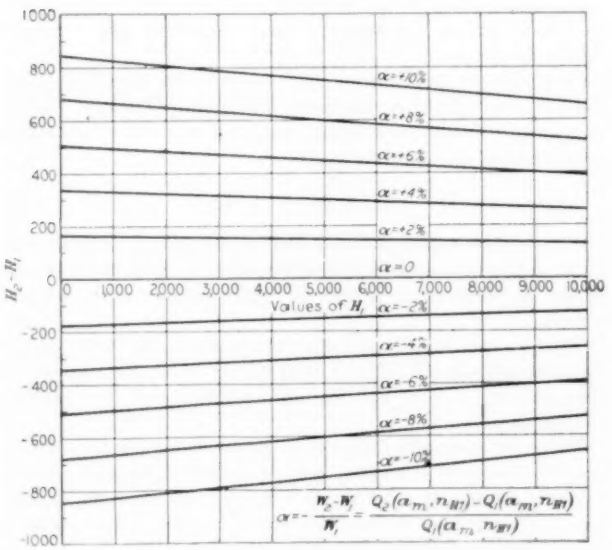

FIG. 2 VARIATION IN CEILING PRODUCED BY A SLIGHT VARIATION ($\leq$ 10 PER CENT) IN THE WEIGHT OF THE PLANE OR THE TORQUE OF THE ENGINE

To calculate H_2 by [69] or [70] it is necessary to proceed by successive approximations first making $k = 1$ and then correcting the value of k from the approximate value of H_2 thus obtained.

(*b*) *Particular Case: Q_1/Q_2 Differing But Little From Unity.* In this case the variation of the ceiling is evidently small and we can assume k to be equal to unity.

If we adopt the approximate law [3] accurate up to 10,000 m., the [70] becomes simplified and gives:

$$H_2 - H_1 = (8440 - 0.191\, H_1) \frac{Q_2 - Q_1}{Q_1} \quad \ldots\ldots [71]$$

Fig. 2, which expresses this formula, gives directly the variation of the ceiling ($H_2 - H_1$) which entails a relative variation determined from the torque. This relation is sufficiently accurate close up to $h = 10{,}000$ m. and $(Q_2 - Q_1)/Q_1 = \pm 10$ per cent.

3—*Influence of the Diameter of the Propellers and of a Reduction Gear Between Engine and Propeller*

Let us consider a plane which has been calibrated and examine the influence which a change of propeller diameter exercises on the ceiling when the engine is geared down, without changing the type of propeller—that is to say, its form and its relative pitch.

Let us utilize the ceiling formula [21] which we shall first put into a little different form. Assume the engine to be supplied with a reducing gear and let

N = number of revolutions of the engine crankshaft
P_{N0} = equivalent power of the engine on the crankshaft
η_G = mechanical efficiency of the reduction gear, assumed to be independent of the gear ratio
λ = gear ratio or ratio of the number of revolutions corresponding to n and N of the propeller and of the crankshaft.

Under these conditions, the equivalent power of the engine on the shaft of the propeller is

$$P_0\,(a,\, n) = \eta_G P_{N0} \left(a,\, N = \frac{n}{\lambda} \right) \quad \ldots\ldots [72]$$

Let us consider a plane equipped with a certain propeller 1. Let H_1 be its ceiling, corresponding to the range γ_{H1} of the propeller and to the number of revolutions N_{H1} of the crankshaft. From [21] and [72],

$$\frac{1}{\nu_{H1} \sqrt{\delta_{H1}}} = \frac{75 \eta_G P_{N_0}\,(a_m, N_{H1})}{4 W_{H1} \sqrt{W_{H1}/S} \left[\frac{\zeta}{\eta} \right]_{H1}} \quad \ldots\ldots [73]$$

Assume now that the propeller 1 of diameter D_1 is replaced by a propeller 2 of different diameter D_2. With this new propeller, the range γ_{H2}, identical with that of the ceiling with the first propeller, corresponds in horizontal flight to a certain value ζ_2 of the coefficient $\zeta = \frac{C_x}{C_z^{3/2}}$ differing from the value of ζ_{H1} which corresponds to the first ceiling.

At this range γ_{H1}, the plane equipped with the second propeller can reach a certain maximum altitude h_2 which is not its absolute but its relative ceiling for the range γ_{H1} considered for the propeller.

Suppose that the gear ratio λ of the engine is changed at the same time as the propeller and that it has a value λ_2 such that, at the altitude h_2 and for the range γ_{H1} of the second propeller, the engine turns at the same number of revolutions N_{H1} of the crankshaft as at the ceiling of the first propeller.

Finally, let us assume that the mechanical efficiency of the reducing gear and the total weight of the plane are not changed. The altitude h_2 or relative ceiling for the range γ_{H1} of propeller 2 is given by

$$\frac{1}{\nu_{h2} \sqrt{\delta_{h2}}} = \frac{75\, \eta_G P N_0 (a_m,\, N_{H1})}{4\, W_{H1} \sqrt{\frac{W_{H1}}{S}}\, [\zeta/\eta]_{h2}} \quad \ldots\ldots [74]$$

In comparing the altitudes h_2 and H_1, it is sufficient to notice that the ratio h_2/H_1 varies in the same sense as the ratio $\nu_{H2} \sqrt{\delta_{H1}}/\nu_{h2} \sqrt{\delta_{h2}}$, that is to say, by dividing [74] by [73], in the same sense as the ratio:

$$f = \zeta_{H2}/\zeta_{h2}$$

If ζ_{H1} is not a minimum, that is to say, if the case of ceiling with the first propeller does not correspond to the minimum of ζ, it is evident that ζ_{h2} can be made less than ζ_{H1} and consequently h_2 larger than H_1, that is, the ceiling of the plane can be raised by properly choosing the diameter of the second propeller. It is easy to see that:

If ξ_{H2} corresponds to a lift c_z less than that of the minimum

of ζ, it is necessary to increase the diameter D_1 of the propeller 1 to increase the ceiling;[4]

If ζ_{H2} corresponds, on the contrary, to a life e_z larger than that of the minimum of ζ, it is necessary to reduce the diameter of the propeller in order to raise the ceiling.

The conclusion is arrived at that the best propeller, for a given number of revolutions of the crankshaft at the fixed ceiling, and especially the maximum permissible for this number of turns, is that for which the ceiling corresponds to the minimum of ζ and for which, in consequence, the maximum efficiency corresponds at the same time to the said minimum. The best ratio λ of gear reduction for the engine results then from the value of the ceiling thus obtained.

Thus we find again the conditions set forth above relating to the maximum ceiling.

Ceiling of a Plane With Supercharged Engine

The preceding work is based on the assumption of a normal or undercharged engine.

It is interesting to show the influence which supercharging of the engine can exert on the ceiling.

Supercharging permits the prevention of the reduction of torque with altitude, that is to say, the modification of the law $\nu(h)$ of variation of the torque of an engine not supercharged. In particular, it allows the reestablishment of the torque Q_0 at a certain altitude.

The ceiling formulas given above are applied to the condition of giving to the law $\nu(h)$ the form corresponding to a supercharged engine, a form depending on the system of supercharging: namely, a mechanical compressor driven by the engine, or a compressor driven by an exhaust-gas turbine.

The study of the ceiling is then a case of the kind in which account must be taken of the increase of weight necessitated by the supercharging arrangements.

At any rate, supercharging permits a noticeable increase in the ceiling of an airplane. It necessitates, generally, changing the propeller in order to obtain the best utilization of the supercharged engine.

Limit of Ceiling

It is interesting to consider the limit of the increase of ceiling that can be obtained by supercharging a normal engine.

Let H_1 be the ceiling of the plane without supercharging. This ceiling, from [73], is determined by:

$$\frac{1}{\nu_{H1}\sqrt{\delta_{H1}}} = \frac{75\,\eta_{G1} Q_0\,(a_m, N_{H1})}{4\,W_{H1}\sqrt{W_{H1/s}}\,(\zeta/\eta)_{H1}} \quad \ldots\ldots [74]$$

If we assume that the engine and the propeller conform to these conditions, it is necessary that, at the ceiling H_1, the crankshaft shall turn at a speed N_{H1} equal to the maximum possible.

The supercharging limit that can be realized is that which enables the engine to give at the ceiling H_2 of the plane with a supercharged engine, the maximum power at the ground, viz., $Q_0(a_m, n_{H1})$, and consequently, to make the crankshaft turn at the same number of revolutions N_{H1} as formerly.

Let us distinguish by the index 2 the terms which characterize the flight at the ceiling H_2 of the plane with a supercharged engine.

The equation of power then gives for flight at the ceiling:

$$75\,\eta_{G2} Q_0\,(a_m, N_{H1}) = 4\,W_{H2}\sqrt{\frac{W_{H2}}{S}}\,\frac{1}{\delta_{H2}}\,(\zeta/\eta)_{H2} \ldots [75]$$

Assume that the total weight of the plane is the same at ceiling H_2 as at ceiling H_1. (Actually, however, the addition of the supercharging results in a certain increase of weight.) Dividing [74] by [75] we obtain:

$$\frac{\nu_{H1}\sqrt{\delta_{H1}}}{\sqrt{\delta_{H2}}} = (\zeta/\eta)_{H1}(\eta/\zeta)_{H2}\,\frac{\eta_{G2}}{\eta_{G1}}$$

If the propeller is chosen and adapted in the first case in a manner to give the best ceiling H_1, the case $(\zeta/\eta)_{H1}$ corresponds to the minimum of (ζ/η). Consequently, in order that H_2 shall be a maximum, it is necessary that $(\zeta/\eta)_{H2}$ shall also be equal to this minimum.

Finally let it be assumed that the reducers eventually used will have, in both cases, the same mechanical efficiency, that is, $\eta_{G1} = \eta_{G2}$. Under these conditions, the relation preceding is simplified and becomes

$$\nu_{H1}\sqrt{\delta_{H1}} = \sqrt{\delta_{H2}} \quad \ldots\ldots [76]$$

Such is the simple relation which determines the ceiling limit H_2 that the best supercharging can give a plane which has a ceiling H_1 when using a normal engine (of the same nominal power).

To show directly H_1 and H_2, assume up to $H_1 = 10{,}000$ m. the approximate law [3] of variation of ν for the normal engine, knowing $\nu = \mu$, and employ the formulas of the standard atmosphere.

The relation sought differs according to whether H_2 is less or greater than 11,000 meters, since, for this altitude the law of variation of δ and of μ in the standard atmosphere changes form. Calculation shows that $H_2 = 11{,}000$ corresponds to $H_1 = 3495$, or practically 3500 m. (12,250 ft.).

We thus obtain the following relations:

$$H_2 = 44{,}250\,[(1 - 0.0000226\,H_1)^{2.47}] \quad \ldots\ldots [77]$$

$$\text{within the limits } \begin{cases} H_1 < 3500 \text{ m.} \\ H_2 < 11{,}000 \text{ m.} \end{cases}$$

$$H_2 = 3300 + 215{,}560 \log \frac{1}{1 - 0.0000226\,H_1} \quad \ldots\ldots [78]$$

$$\text{within the limits } \begin{cases} H_1 = 3495 \text{ to } 11{,}000 \text{ m.} \\ H_2 > 11{,}000 \text{ m.} \end{cases}$$

Finally, when H_1 is small and less than 1000 m. (3280 ft.). Equation [77] can be replaced by the approximate formula:

$$H_2 = 3.47\,H_1 \quad \ldots\ldots [77a]$$

The results of applying these relations are summarized in the table at the top of the following page and shown in Fig. 3.

For an ordinary plane with normal engine, the maximum ceiling possible cannot practically exceed 10,000 m. It is seen, therefore, that the best supercharging obtainable will not make it possible to exceed altitudes of the order of 27,000 to 28,000 meters.

It must be remarked also, that the problem of the compressor establishing the ground pressure at an altitude of the order of 27,000 meters, at which the relative pressure μ of the standard atmosphere is equal to 0.018, does not appear susceptible of satisfactory solution in the present state of compressor technique.

---

[4] It is possible to show very exactly that by an increase of diameter of a propeller placed ahead of the fuselage, as on the greater number of single-engined machines, that a slight increase of the effective efficiency of the propeller can be counted on for the same range $\nu = \dfrac{V}{\dfrac{2\pi}{60}\,nD}$ of operation because of the lessening of the interference between the propeller and the plane.

From another viewpoint, it is interesting to consider the problem of adapting the propeller to the higher ceiling.

H_1	H_2	$H_2 - H_1$	H_2/H_1
0	0	0	3.47
1000	3375	2375	3.38
2000	6560	4560	3.28
3495	11000	7505	3.15
4000	12170	8170	3.04
6000	16945	10945	2.82
8000	21970	13970	2.75
10000	27280	17280	2.73

Two principal cases can be considered:

1—Changing the Propeller Without Changing the Reduction-Gear Ratio. In this case the propellers of planes 1 and 2 turn at the same speed at the respective ceilings of the planes. The incidence of flight being supposedly the same, the speeds V_1 and V_2 are related by the equation:

$$V_1/V_2 = \sqrt{\delta_{H2}/\delta_{H1}}$$

The corresponding ranges γ_1 and γ_2 of these propellers are consequently in the ratios:

$$\gamma_1/\gamma_2 = V_1/V_2 \frac{n D_1}{n D_2} = \frac{D_2}{D_1}\sqrt{\frac{\delta_{H2}}{\delta_{H1}}} \quad \ldots\ldots\ldots [79]$$

At these ranges, the propellers must be considered by hypothesis as having the same efficiency:

$$\eta_1 = \eta_2 \quad \ldots\ldots\ldots [80]$$

Moreover, their thrust coefficients α_1 and α_2 ought, for the values γ_1 and γ_2 of the cases considered, to satisfy the power equation and this condition evolves, the c_x of the plane being the same:

$$\frac{\alpha_1}{\gamma_1^2} D_1^2 = \frac{\alpha_2}{\gamma_2^2} D_2^2 \quad \ldots\ldots\ldots [81]$$

It is necessary then to choose the type, the relative pitch, and diameter of the propeller 2 in such a manner as to verify in the range γ_2 defined by [79], the conditions [80] and [81].

It is not at all certain that this may be possible, particularly in the case where H_2 differs much from H_1.

Moreover, this propeller 2 is not longer adapted to the case of take-off and may be inefficient in this connection.

In any case one is led to consider here a propeller whose pitch or diameter will be variable during flight, or even one with pitch and diameter variable simultaneously during flight.

2—Changing the Ratio of the Reduction Gear Without Changing the Propeller. In this case, the conditions are as follows: At the ceilings H_1 and H_2 the speeds of the propellers are in the ratio $\frac{n_{H1}}{n_{H2}} = \sqrt{\frac{\delta_{H2}}{\delta_{H1}}}$ with the crankshaft turning at the same speed N_{H1} it is necessary that the ratios λ_1 and λ_2 of the reduction gears mounted on the normal and on the supercharged engine be such that $\lambda_2 = \lambda_1\sqrt{\delta_{H1}/\delta_{H2}}$. The customary gearing down of the normal engine can then be transformed into a gearing up for the propeller with supercharged engine.

But if λ_2 is fixed, the propeller 2 is no longer adapted to take off under the same conditions as propeller 1 and may become ineffective.

Thus one is brought to the idea of introducing gearing between propeller and crankshaft with a gear ratio that may be varied in flight, a problem which, in certain respects, is more attractive and perhaps easier to solve than that of the propeller with variable pitch and diameter discussed in the preceding case.

Undercharging and Supercharging

Supercharging (at an altitude) of an aviation engine, like undercharging (at the ground), increases the ceiling of the plane, and each method has advantages and disadvantages which limit the practical field of application.

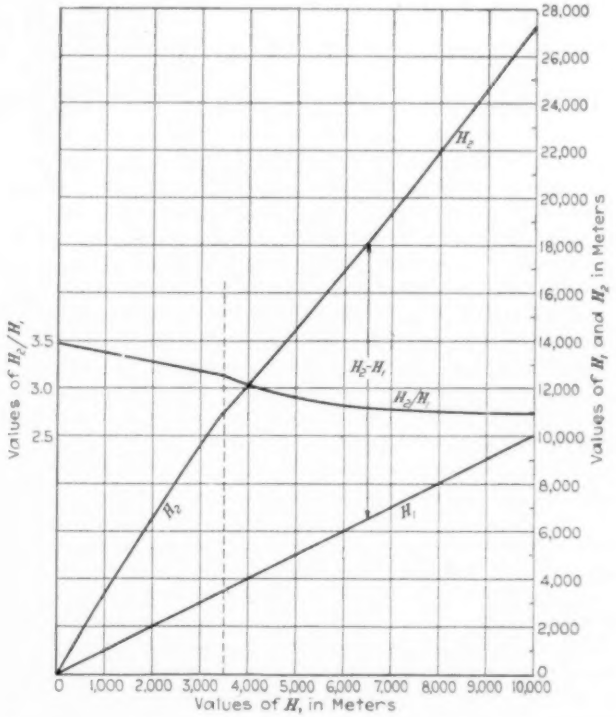

Fig. 3 Limit of Ceiling H_2 That the Best Supercharging Permits for a Normal-Engined Plane With a Ceiling H_1

If we undertake to solve the problem of superelevation of ceiling under the most advantageous conditions of lightness of weight and engine efficiency, we can consider a combination of these two procedures and this conception is capable of offering a real interest. In any case it permits us to deal with the very highest ceilings, with otherwise present unsolved accessory problems such as those of the variable-gear ratio, of the variable-pitch propeller, and of the cabin provided with an artificial atmosphere in order to maintain ground conditions.

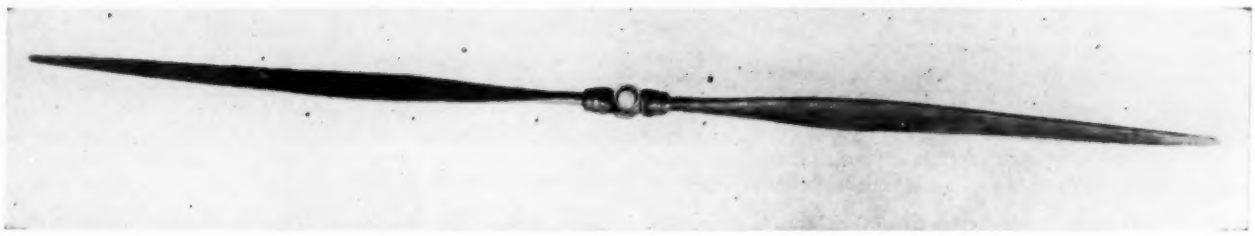

FIG. 1 FIRST DESIGN OF DETACHABLE-BLADE SOLID-STEEL PROPELLER (1918)

Development of the Drop-Forged Metal Propeller

BY FRANK W. CALDWELL,[1] PITTSBURGH, PA.

In this paper the author tells of various types of metal propellers for airplanes, and their advantages and disadvantages. These include a tubular type, a type built up of various structural members riveted or welded together, the plate type, and the drop-forged type which is the latest development. Hollow blades of aluminum alloy suitable for drop forging are used. The weight of these is slightly more than similar wooden propellers, and the limit of life has not yet been established.

MOST efforts toward the development of metal propellers previous to 1918 were concentrated along three lines: the tubular type in which efforts had been made to form a tube into a satisfactory form; the built-up type in which various structural and forming members were riveted, welded, or joined together; and the plate type, in which flat sheets were formed to provide blades for the propeller.

The tubular and built-up types had proved extremely expensive and had not been very successful in avoiding localization of stress leading to failure. These types did not appear to have great possibilities for economical production on account of the large amount of hand fitting necessary in their fabrication.

The plate type was not considered very promising on account of the low torsional rigidity of sheet and plate forms and the tendency of this form to flutter as the result of torsional oscillations.

During 1918 the author set out to develop a type of propeller suitable for drop forging. Considerations which led to the selection of this type were the relative economy of producing the desired forms by this method, the excellent properties usually obtained from sound forgings, and the freedom of selection of a form suited to the purpose.

In analyzing the design problem it appeared impossible to approach very nearly to existing forms of wooden propellers as the weight of the metal propeller would then be so great as to be out of the question. An obvious method of departure would be to thin down the propellers of the usual type with due regard to the various bending stresses and centrifugal restoring moments until the weight became comparable with existing wooden propellers. This would lead to a very thin propeller in which the bending moments due to the air pressures would have to be neutralized by the restoring moments of centrifugal force. A study of the torsional rigidity of such forms made it evident that a propeller of this kind would be very weak in torsion and that the resultant torsional instability would lead to violent fluttering.

The remaining method of approach was to decrease both width and thickness until the weight was as nearly comparable as possible with existing designs and to provide the blade area necessary to absorb the power of the engine efficiently by increase in diameter. Since the power absorbed by the propeller is proportional to the fifth power of the diameter, a relatively small increase in diameter would compensate for any deficiency in blade area.

This analysis led to the selection of a forged-steel blade of very high aspect ratio and great diameter with low camber ratios at the tip, but with comparatively thick sections in the inner part.

From the performance standpoint, it was anticipated that the following advantages would be gained in addition to the advantages of durability and dependability which were already appreciated. Obviously the larger diameter would act on a greater mass of air, and would consequently reduce the slipstream velocity and reduce the energy losses. This was already well known to the propeller designer from the momentum theory which is analogous to the conception of induced drag now made use of by the airplane designer. At the same time it was known in 1918 that the use of the thinner sections in the outer portions would contribute somewhat to the efficiency of the propeller due to the lower drag of these sections. It was not until 1920, however, that the importance of the thin sections was fully appreciated in making possible the use of higher speeds without burbling.

An analysis of the problem of a solid-steel propeller for the Liberty engine indicated that a four-blade propeller, 11 ft. 6 in. in diameter, could be built to a weight of about 110 lb., with an improvement in efficiency of about 4 per cent.

As this was a very novel departure in propeller design, it was decided to build two blades of this type for destructive whirling test. These blades designed for 200 hp. were run up to 800 hp. before failure, the failure finally occurring in the hub and not in the blades. The test was sufficiently successful to indicate that the general type of design should be developed further.

These blades showed a violent flutter at a speed of 800 r.p.m

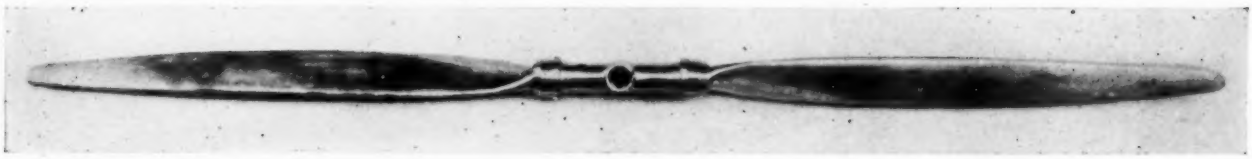

FIG. 2 FOURTH DESIGN OF SOLID-STEEL PROPELLER (1921)

to about 1400 r.p.m. Above this speed they were fairly smooth. The vibration at low speed was too bad, however, for actual use.

A second four-blade propeller of the same general design was next made up and run through a series of tests. This propeller failed in several places after a comparatively short test. The failure was traced to defective material. As the failure occurred in the outer part of the blades, they were gradually cut off until the blades were sufficiently rigid to run without vibration at all speeds.

It now appeared that the critical difficulty to be overcome in this type of propeller was the tendency toward torsional vibrations or flutter.

In order to design away from this tendency, a design was sought of reasonable weight in which the stiffness of the wooden

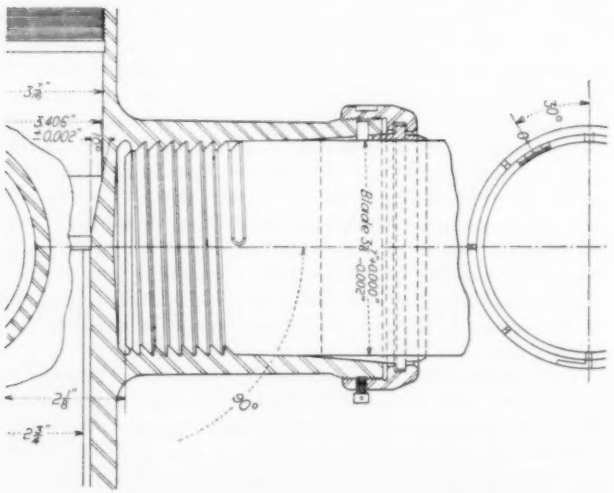

FIG. 3 THREADED TYPE OF HUB ATTACHMENT FOR SOLID-ALUMINUM-ALLOY BLADES

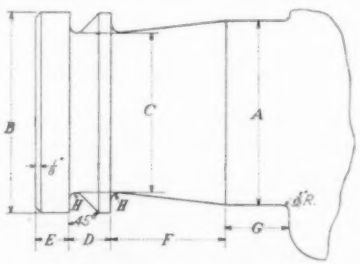
propellers would be approached as nearly as possible. A number of wooden-propeller designs were analyzed from the standpoint of stiffness, and a method of calculating defections under load was developed.

By applying this method to the solid-steel propeller designs, it was possible to approach sufficiently near to the current practice to be hopeful of eliminating the fluttering tendency. At the same time, an effort was made to localize the flexure near the tips, and to make the portion near the hub as rigid as possible.



A new solid-steel propeller, the third step in the development was now built, and this propeller ran very smoothly at all speeds and passed a very satisfactory whirling test on the electric testing stand. As a further check before permitting it to be flown, it was placed on a very rough eight-cylinder engine and run until failure. Failure occurred at the point of attachment to the hub. The blades were attached to the hub by a threaded connection with a clamp adjacent to the threads. Failure occurred at the base of the threads.

The fourth step in the development of the solid-steel blade consisted in modifying the hub design to double the cross-sectional area of the blade at the threaded section, leaving all other parts of the blade the same. This blade again passed a satisfactory whirling test on the electric motor, but again failed at the root of the threads when run on the engine.

The last of these tests on solid-steel blades was run about 1923. During 1922, however, some tests had been run on hollow blades of an aluminum alloy suitable for drop forging, and it appeared that this alloy had very good mechanical properties. On account of the lower density of the aluminum alloy, its use made it possible to make blades of greater blade area and of greater stiffness than was possible with steel. It was thus possible to approach more nearly to the conditions existing in the best wooden-propeller practice.

In designing the first aluminum-alloy propellers, the deflections which would occur under load were again studied and were compared with the wooden-propeller practice and with the most successful of the solid-steel propellers.

By designing for a flexibility intermediate between that of the smooth-running steel propeller and that of the best wooden propeller it was felt that a serviceable design was fairly sure to

FIG. 4 STANDARD SERIES OF BLADE ENDS SHOWING DOUBLE SHOULDERS

be produced. At the same time, it was possible to hold the weight down to a figure only slightly above that of the existing wooden propeller.

It was also possible to use a diameter of the hub shank very much greater than had been possible in the steel propellers, so that the danger of breaking off at the threaded connection was greatly reduced. However, considerable study was given to eliminating any bending from the threaded portion, and finally a device was adopted as worked out by T. A. Dicks, who was then connected with the Standard Steel Propeller Company. This device consisted of a cylindrical wedge inserted between the blades and the hub at a point several inches out from the end of the threaded connection. It was hoped to absorb the drive through this wedge and eliminate the bending on the threads.

The first solid aluminum-alloy propeller designed and built along these lines was built by the Standard Steel Propeller Company for the Army Air Corps and from the author's design. It was completed early in 1923.

Whirling tests were started as soon as possible. The propeller was designed for the Liberty engine of 400 hp., and the whirling test was first run for 10 hr. at 600 hp., in accordance with the usual procedure for wooden propellers. At the end of this test, it was decided to continue the test to destruction if possible, and successive 10-hr. tests were run at 800 hp., 1000 hp., 1200 hp., and 1400 hp. As 1400 hp. was the limit of the power available for testing, the test had to be discontinued without doing any damage to the propeller.

Meanwhile an engine test was run with the propeller on the Liberty engine. This test was continued for 100 hr. without damage to the propeller, and it was considered satisfactory and that a serviceable metal propeller had been produced which could be built at a moderate cost.

Meanwhile, numerous flight tests were run on the propeller, and they showed a uniform gain in efficiency of about 7 per cent over the best wooden propellers in existence. These tests were run throughout 1923 and were supplemented by service tests in the Army and Navy and in numerous commercial planes. While these tests were quite satisfactory from the standpoint of service, a good deal of trouble was met in maintaining interchangeability of balance of blades and in replacement of blades in the hub, due to the threaded connection. It was considered desirable to maintain a neat fit of the thread due to consideration of strength. On account of the neat fit, small nicks in the threads or the presence of grit made it very difficult to remove the blades from the hubs.

In order to facilitate changing pitch and to improve interchangeability of blades, a split type of hub in which the centrifugal force of the blades was taken up by retaining shoulders was developed. At the same time a clamping ring was developed, serving the double purpose of clamping the two halves of the split hub together and compensating for small errors in vertical balance of the blades.

The first split hub developed made use of a single shoulder to take up the centrifugal force. While this type was tested at

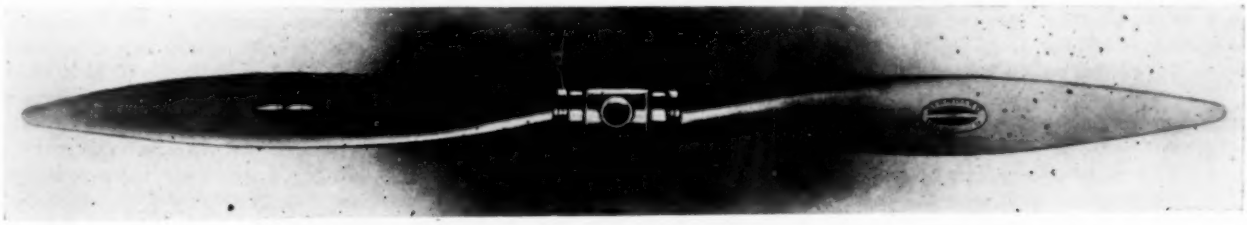

FIG. 5 STANDARD TWO-BLADE PROPELLER WITH ALUMINUM-ALLOY BLADES

overspeed with very satisfactory results, the stress analysis indicated that the shearing strength of the blade shoulder was not equal to the tensile strength of the blade root, so that the design was not well balanced from this standpoint. Consequently, a second design was developed in which the shear, crushing, and tensile strengths were equalized.

In order to check the strength of the three designs, full-size test pieces of each were made up and pulled in a testing machine with the following results: The threaded type failed in combined shear and tension at a load of 250,000 lb.; the single-shoulder type failed in shear at a load of 220,000 lb.; the double-shoulder type failed in combined shear and tension at a load of 320,000 lb.

As the double-shoulder type was obviously stronger in addition to its other advantages, it was adopted as standard, and a series of blade ends to take care of the requirements of various sizes of blades was developed from it. The efficiency of this type of connection is well illustrated by the fact that about 20,000 blades have been put in service during the last seven years, and in spite of severe abuse, none has ever pulled out at the hub.

Following the solution of the technical difficulties in producing an efficient design of moderate weight and satisfactory factor of safety, it was necessary to work out a series of designs in order to take care of the whole range of aircraft requirements from small propellers 6 ft. in diameter up to the large geared propellers ranging up to 16 ft. and for a range of from 60 to 800 hp.

In order to make this possible the range of propeller designs

FIG. 6 STANDARD THREE-BLADE PROPELLER WITH ALUMINUM-ALLOY BLADES

was divided into series which could be made from each die by modifications of blade width and diameter, and by setting the pitch. Fortunately it was found from model tests in the wind tunnel that the efficiency of the propeller was not appreciably reduced when the pitch was altered from the designed value by rotating the blades in the hub sockets. Consequently it was possible to produce a wide range of designs without an excessive number of dies so that the cost of individual designs has been held within the range of practical requirements.

Methods of inspection have been improved continually. At the present time all finished blades are etched in caustic soda and cleaned with nitric acid to permit inspection for cracks or forging defects. The quality of the forgings has been maintained at a very high standard and a comparatively small percentage of rejections is necessary due to forging defects. As in all metal parts subjected to dynamic stresses, fatigue has to be guarded against, and it is now recommended to all operators that propellers be etched and inspected after each 100 hr. of flying.

The limit of the life of blades has not yet been established. No doubt limits will have to be set on the number of hours which a propeller may be used. Probably this limit will have to be varied according to the design and the type of service.

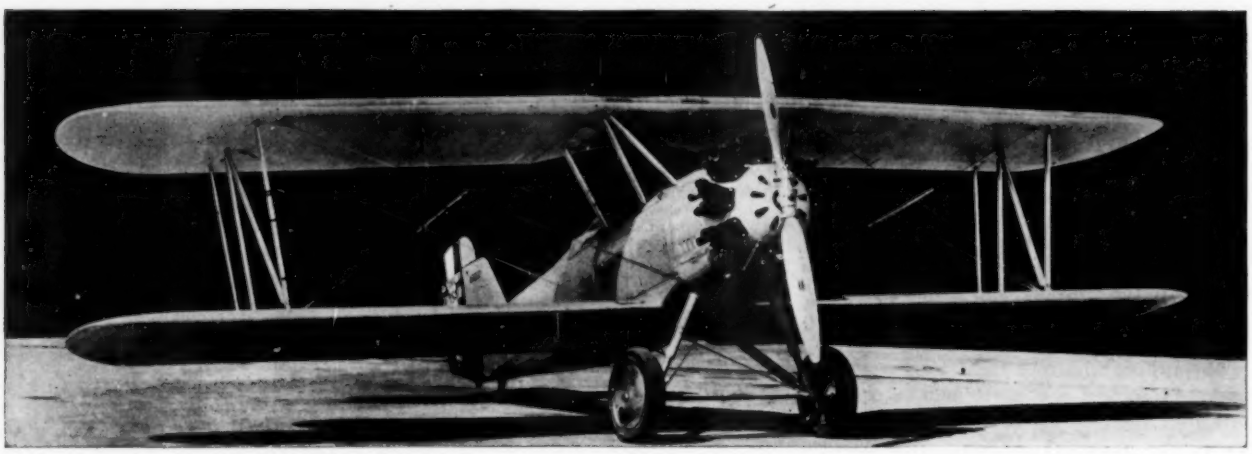

FIG. 7 STANDARD PROPELLER INSTALLED ON PLANE

A very troublesome problem has been the question of vibration. Vibration may be caused by unbalance of the propeller, by irregular form of the sections, by unequal angular setting of the blades, or by dynamic unbalance caused by errors in the track or alignment of the blades. These factors can be and are carefully controlled by inspection.

One of the most troublesome causes of vibration, however, is a periodic vibration caused by synchronization of the natural periods of the engine mount. Frequently this period can be changed by the selection of a propeller of a different size, but usually it is a matter that has to be taken care of by the airplane designer.

AER-52-10

Engineering Problems in the Operation of Air Transports

By FRANK R. CANNEY,[1] SEATTLE, WASH.

The author gives a masterly summing up of the hundred or more points that must be observed in the planning of a successful air-transport system, and reveals that there has been necessary only a slight modification of the original design of the Boeing transport plane as the result of the experience gained through its operation.

IT HAS BEEN found that, in an airplane, there are several major considerations, much the same as in an automobile or motor coach. In the first place, "power to go" is essential. This feature is quite heavily emphasized by makers of modern automobiles and is required to an even greater degree in the modern airplane.

Consider the "efficiency" and "reliability" of the power plant. It is necessary that the engine weigh as little as possible with respect to the power output, for each bit of weight added to this unit, beyond that required for reliability, displaces just that much pay load. The fuel economy is also an important factor, and in modern aviation engines should run very close to $^1/_2$ lb. per hp-hr. In considering the subject of fuel consumption, it becomes necessary to determine just how much shall be carried. This, of course, depends upon the route to be flown and distance between landings, and there should be provided a good reserve for getting around bad weather. The average time between regular stops on the transcontinental mail route is well under $2^1/_2$ hr., but against a head wind or in bad-weather conditions, it has been found desirable to have a fuel supply for better than 5 hr. Normally this will give a cruising radius of about 550 miles, but on one occasion at least it has been found necessary to refuel twice on a flight taking normally but $4^1/_2$ hr. This was on a trip from Cheyenne, Wyo., to Salt Lake City. The author found as much as 1 hr. and 55 min. difference in flying time required to make the trip from Oakland, Calif., to Salt Lake City, Utah, on two different nights of the same week. This, of course, was due to weather, the longer time being required when it became necessary to climb 16,000 ft. to avoid clouds.

After determining the amount of fuel required, or fuel per engine in the case of multimotored ships, other features of the power plant are considered. The installations of water-cooled engines, of course, run to more weight than for the air-cooled type, and in all of the Boeing transports the latter type has been adopted. This step also eliminates one complete set of plumbing from the power plant, although it may possibly complicate the oil system somewhat.

Without some auxiliary form of heat control, the air-cooled engine will not operate satisfactorily under the great variety of weather conditions encountered along the transcontinental route. For example, take the western end of the route from Oakland to Elko, Nev. The temperature at Sacramento, Calif., may be as high as 80 to 100 deg. fahr., while in Elko, only 3 or 4 hr. away, temperatures well below zero may and do exist simultaneously at the altitudes traveled there. It is for this reason that oil tanks are lagged with asbestos to retain heat, and at the same time a controllable shutter is provided in the nose of the engine cowling to cool the crankcase or not, according to what is desirable at the moment. Other items made necessary by sudden temperature changes are oil coolers with automatic bypass control and controllable air-intake heaters to prevent the formation of frost and ice within the carburetor. This last cause alone has been responsible for numerous forced landings prior to the installation of the heaters. The source of heat in this case is a small steel air scoop which is attached along the trailing edge of the round exhaust collector ring. It employs an air scoop at the upper end of either half, and serves as a streamline to the collector ring, which, due to its round section, offers considerable head resistance. A valve box in the outlet leads causes the warm air to flow either into the carburetor or to spill out as desired.

Aside from power-plant considerations, the weather affects the design in several other ways. Frost forms quickly on the windows under certain conditions, making it necessary to have them installed in the control cabin so as to be readily opened. In the first three-engined Boeing ships, these windows were designed to slide in felt-covered rubber channels, but they were frozen tight in the closed position so quickly on several occasions that it became necessary to break them out. To avoid the recurrence of this situation, they are now installed as is done in some automobile windshields—that is, with horizontal hinges and worm-operating mechanism for the windshield section, and gear-operated levers for raising and lowering the side windows. The side windows may be left open under most conditions without discomfort to the crew, as the V-shaped windshield deflects the air slightly away from the sides and causes the air to flow outward through these windows.

The angles at which the plates of glass are placed need careful attention for night flying, as lights on one side of the course may be reflected in such a way that they apparently are on the opposite side, or in most any direction. In flying among broken clouds, when only a few of the beacons may be "picked pp," this is rather disconcerting.

The pitot-static head of the air-speed indicator will freeze up in damp air at certain temperatures, but electrical heating elements are now provided to clear these instruments and they operate very nicely. Trouble has been experienced with freezing up of the venturi, which is used to operate turn indicators, but this difficulty was overcome by mounting the venturi directly on the exhaust manifold.

Drinking- and washing-water supplies are carried in tanks to the rear of the cabin just inside the fabric cover in a rather exposed position, and during cold weather may have to be drained and the water be carried in thermos containers. All water in the tanks and pipes was found to be frozen one night after a climb to 16,000 ft. where temperatures in the neighborhood of 35 deg. below zero were encountered in avoiding frost and snow clouds at lower levels. The tanks and lines are all made of annealed aluminum, and no harm was done, but neither was any water available.

The elimination of structural failures in the air has been quite complete where radically new types of construction are not

[1] Engineer, Boeing Airplane Co.

Presented at the Seattle Aeronautic Meeting, Aeronautic School, University of Washington, Seattle, Wash., May 28 and 29, 1930, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

employed and where only materials of known strength values are used. Of course the utmost attention to details and a careful inspection of parts and assemblies as to quality of materials and workmanship are required. Careful consideration must be given to flexible members in which destructive vibration may occur, and often the direction at which strut and wire hinge pins are set is determined by the deflection of the members in question. Where pins and bolts are subject to wear they must be made well oversize, or provisions made for ready and frequent replacement. The general trend now is toward the employment of ball or roller bearings, even at the sacrifice of considerable weight.

The necessity of having easy access to structural or other parts which are subject to wearing out or failure due to fatigue and other causes was responsible for leaving such parts exposed as much as possible in the original transports, but as the speed requirements are increased, it becomes necessary to "cowl in" more of these parts. It is then necessary to provide access doors for the frequent inspection of such parts, and sometimes they are quite easily overlooked. For example, on the present job no inspection door in the landing struts was provided until it was found that the springs used in the oleo shock-absorbing units failed quite regularly. Such a failure is difficult to detect without a visual inspection, but has proved expensive on a few occasions when the rather costly oleo units suffered damage.

Other design conditions are rather difficult to foresee. In the horizontal tail surfaces of the original transport, the air flow around the tip of the stabilizer was such that it spilled on to the balancing surface at the tip of the elevator so as to cause considerable vibration of that part with subsequent excessive wear on adjacent hinges. This was corrected by changing the plan of the surfaces somewhat. Much trouble also was experienced with the tail-wheel installation. Under ordinary conditions it seemed to function satisfactorily, but on muddy fields when one of the main wheels dropped into a chuck hole, the result was to pick the tail wheel up off the ground and impart a rather sharp turning effect to the whole airplane. The resulting side-swipe caused when the tail wheel dropped back into the mud was too much for the original wheel-supporting structure. It became necessary to increase the length of the caster arm in the wheel fork and install low friction bearings to insure quick and easy following action of the wheel.

The percentage of structural failures is becoming very small as time goes on, and forced landings on this account are practically nil on the organized air-transport lines of this country.

As is the case with automobiles, there are many times when it is desirable to stop "right now." Of course an airplane cannot stop as short as vehicles on the ground do at the present time, and may never be able to. Much depends on other considerations than the brakes and tires. A very fast ship, for instance, has a higher landing speed than a slow one. There seems to be a limiting ratio between the high and low speeds of any given ship, beyond which it is very difficult to go. Boeing transports are designed to land around 60 m.p.h. at sea level, however; so the main worry after that factor has been established is to get effective brake action.

The equipment procurable to date has not been entirely satisfactory for a number of reasons, mainly due, it is suspected, to the fact that airplane brakes are a rather new development, and the efforts to save weight have had a strong influence on their design.

The light steel liners, shrunk and screwed into the drums, are not very true and cause considerable efficiency loss due to spotty bearing. The woven-fabric linings used up to now have proved too soft, wearing out quickly, and are considerably affected by moisture.

The controls become rather long and complicated in large airplanes, and have so much drag that it has been found necessary to add return springs in the linkage for releasing the brakes. Rods give a more positive control than cables, or a hydraulic control is probably most desirable, but up to the present the hydraulic-brake manufacturers have not been interested in designing a system for installation in the transports. It is felt that for the company to undertake the design and construction of such a system for its own ships might be rather a costly proposition in time, money, and weight.

While the brakes now in use are of the so-called self-energizing type, the method used to apply the braking effort in small ships which weigh somewhere from 1 to 3 tons is not at all satisfactory for the large ships which weigh nearly 9 tons when loaded. Considering the fact that the brakes are just 20 in. in diameter and 2 in. wide, it seems surprising that they are at all effective.

In small ships the brakes are generally applied by simply tilting forward, with the toes, small pedals attached to the rudder stirrups. The effective lever arm of this pedal is only 5 to 6 in., with a movement at the tip a trifle over 3 in. Sometimes the pedals are reversed and the heel is used to apply the brake. The former type is used on the new Boeing transports, however, and it developed that longer pedals with more motion were required. Both the length of pedals and the amount of movement at the tips have been just about doubled. This makes them rather awkward to use, but it appears to be a necessary evil.

Two other more satisfactory types may be employed, but they have the disadvantage of being hand-operated. First, the "joy-stick" type, which is a hand lever similar to an automobile parking brake, except that it tips to the sides as well as moving straight back. Second, a straight-pull handle with ratchet for setting it to any desired tension on the brakes.

Steering of the airplane when on the ground was done with the air controls until the adoption of brakes; but now, by using a free-swiveling tail wheel and differential braking between the two main wheels, control very comparable to that effected in an automobile is attained. The means for securing the differential brake action through the devices described previously are quite simple. With the pedals, there is simply applied to one pedal a heavier load than to the other. As each pedal controls but a single brake, the resultant differential effect is obvious. With the "joy-stick" type of lever control, the connections are made in such a way that a pull straight back applies both brakes equally, while tipping it to one side applies a greater load to the brake on that side of the ship. In the last-mentioned type, where a ratchet handle is employed, any desired equal tension may be applied to both brakes through the handle. In this case, the steering is effected through the rudder controls, which are connected to the brake linkage in such a way as to give a differential effect, although they are not actually used to apply the loads.

The "joy-stick" type of control was used in the first transports and was quite effective, except that it required the use of hands which could be employed to considerable advantage at other tasks. The types used on the newer ships, although probably somewhat of an improvement, still leave something to be desired.

Good vertical control, or "steering" in the air, under normal flying conditions is quite easily effected by means of an adjustable stabilizer. This may be set for level flight, climb, or descent, and to offset changes in the center of gravity location due to different loading conditions or the movement of passengers back and forth in the cabin. The main requirements for the stabilizer-adjusting mechanism are that its operating crank be in a handy location and that it may be easily and quickly used. This is especially important where the first attempt to land in a short field may be missed. The stabilizer which is placed at the full-down adjustment just prior to landing will cause the tail to drag low without excessive use of the elevators, unless it can be rolled back up,

immediately the decision is made to circle the field for another try at landing. It is necessary to employ low-friction bearings in this system to gain the operating ease desired. The elevator, which is used to supplement the effect of the adjustable stabilizer, is aerodynamically balanced to keep the loads reasonably light.

The effectiveness of the elevators was proved one day in a flight test, when, through the leaving out of a nut and cotter in the stabilizer-adjusting mechanism, a bolt fell out causing the stabilizer to drop about 6 deg. below its normal extreme downward position. The tail was kept up and a safe landing effected, although this happened very shortly after passing the end of the field on a take-off. Needless to say, the design has been modified to prevent a recurrence of such a failure.

The vertical fin and rudder, principally the latter, have given the most difficulty of any of the control surfaces on the new transports. Pilots invariably insist on a light rudder and one that "feels" right. To give them just what they want in these respects, and still retain effectiveness sufficient to offset the turning moment when one of the wing motors goes dead, is no easy task. First, a fin with an adjustable nose section was tried, but that method did not give the desired results. Next, a smaller fin was employed and the balance and area of the rudder were increased. This was an improvement over the first attempt, but with a balanced section large enough to retain ease of control with one wing-motor dead, directional instability resulted; that is, the rudder was slightly overbalanced and caused the ship to "hunt around" slightly. At the present time a rudder large enough to give ample control is being used, but with a balance just small enough to overcome the hunting tendencies. Rather heavy control loads result when a wing motor is throttled, so to offset this a spring device which may be quickly attached to absorb the unbalanced part of the load is employed. This installation is considered only temporary, however, and a "servo" rudder is being developed. In this, the rudder will be operated by an auxiliary surface, and it will be necessary for the pilot to operate only this much smaller surface. One can never be certain of how well new devices are going to work on an airplane, but it is felt that this last scheme will prove satisfactory.

Ailerons used are of the leading-edge balanced type, and function nicely without causing too much reverse yaw, even when it has become necessary to pick up a dead engine. Experienced pilots do not care to have a dead wing engine get too low, as that spells trouble. The original Boeing tri-motors employed a set of cams to give differential aileron action and thus eliminate yaw, but this device was found to be unnecessary on the later models.

Riding comfort must be considered for both the pilot and the passengers in a transport, the same as in a car, but as the driver of a car does not have quite as many controls to operate as a pilot, the problem of the pilot becomes more involved.

Comfortably upholstered seats are provided for both the pilot and co-pilot. The left hand, or pilot's, seat is also adjustable vertically through 4 in., as about this amount is required to give best vision to pilots of different heights. The rudder control stirrups are also adjustable toward or away from the seat by about the same amount. Even then some of the shorter pilots require an extra cushion at their back, while the taller men find their knees getting up into the way of the control wheel. As mentioned elsewhere, the windows or windshield may be opened for ventilation.

In grouping the instruments it is quite difficult to satisfy all pilots who will operate the ships. After sending out questionnaires to the operating personnel, almost as many suggested arrangements were received as there were pilots. The power-plant instruments, however, are all grouped on the center panel, with right-hand engine instruments to the right of the panel, and so on. The navigation and flight instruments are placed on a panel directly in front of the pilot with the exception of the compass, which cannot be accurately compensated when in this position. It is placed to the rear of the pilot, being read by means of a fixed mirror. All electrical instruments and the instrument and navigating light switches are placed on a panel in front of the co-pilot. This panel also carries a switch for turning off the cabin lights, the electrical water-heating element, and air-speed pitot heater. Provision has also been made here for the installation of radio controls, when that equipment is available.

The pilot and co-pilot may, and usually do, wear heavy fur-lined flying clothes when cold weather is to be encountered. Some heating is provided in the control cabin, but as it becomes necessary to open the windows for visibility, due to frost forming on them at temperatures around 30 deg. below zero and less, the heating system loses its effectiveness.

In these transports, designed to carry mail, express, passengers, and luggage, considerable thought was given toward getting what was felt to be the most practical and safest general arrangement. It was decided best to carry the heavy mail, express, and luggage loads ahead of the passenger cabin, where they would serve as a bumper in case of a crash. This location also prevents the possibility of such material coming forward on the passengers in case of trouble. Access to the luggage and express compartment is through a small door forward on the left side of the airplane. This is on the same side as the main exit door, and affords an opportunity for passengers to identify their luggage readily in the event it has not been checked. All mail is handled through the second or emergency exit door on the opposite side of the ship. As mail forms the bulk of the loads carried, this arrangement is proving quite practical, and keeps the trucks used in handling this cargo at the various fields in the clear and out of the passengers' way. The lower wings are covered with metal sidewalks out beyond the wing motors, and these walks are very useful in handling the mail, luggage, and express from truck to ship and vice versa, as the wings are at the same approximate height above the ground as the body floor of an ordinary truck. A locked compartment for the mail is located just inside the door, and an aisle past this compartment allows communication between the control and passenger cabins.

Overhead racks are provided in the main cabin for light parcels, wraps, hats, and the like, although a commodious coatroom with hangers is provided for heavier coats, etc., at the rear of the cabin.

A total pay load of approximately 3500 lb. may be carried by the new transports. With the mail loads running around 1600 lb., this leaves a balance of about 1900 lb. which may be used for passengers, luggage, and express.

The passengers have very good control over the heating and ventilation of the cabin. Windows are fixed and cannot be opened, but each is provided with an adjustable ventilator which provides a pleasant draft of fresh air at the will of the passenger. In addition to these, a large fresh-air intake is provided near the top of either side wall at the rear of the cabin. These have proved to be very effective as what flow of air exists in the cabin is forward. The heating system in this ship serves a dual purpose, being used as an air exhaust when the heat is turned off. This is accomplished by making the air-heater stove around the exhaust stack in the form of a venturi with a butterfly valve to the rear of the throat. The hot-air outlet from the stove is placed at the throat of the venturi, and when the butterfly valve is opened the resultant reduction in pressure causes a reversal of flow in the hot-air ducts. These ducts are placed along the full length of the cabin just above the floor at either side, exhausting at the rear.

To make the heating system effective, as well as to deaden the engine and propeller noise, some sort of cabin insulation must be provided. A wood-fiber wool insulator, of about 1 in. thick-

ness, was first tried and found to be very effective for decreasing the noise, but had the disadvantages of being too good a water absorbent and difficult to install in such a way as to prevent air leakage at the joints. On the latest transports a special plywood is used, the core of which is balsa wood of approximately $^1/_4$ in. thickness. This is proving to be nearly as good for deadening the sound, and far superior to the wood fiber as a heat insulator, as tight joints can be made readily. Further, it lends itself readily to giving a finished appearance inside the cabin. The inside-face ply is of highly finished mahogany, which in combination with the buffed aluminum and nickel fittings makes a very presentable decorative scheme.

Passengers' seats are comfortable and light, weighing only $13^1/_2$ lb. each. This weight does not allow much for upholstery, but does include an adjustable back which may be readily reclined at will, and a light safety belt. The seat framework is all of laminated walnut to match the interior finish, except the back frame, which is hickory for strength. All the seat fittings and back hinges are of aluminum alloy, and the seats are attached to the floor in such a way that they may be removed from the cabin in just a few minutes. Compared to the steel-frame seats in the original transports, they are more rugged, yet the weight has been cut to just one-half.

The seats are arranged in rows of three, two at the left of the aisle and one to the right. A window, 18 in. by 20 in., is provided in both side walls at each row of seats. The arrangement of the side body trusses was arrived at from this window arrangement, as it was desired to leave the window openings clear of structural members. Auto-type roller shades help to cut down the glaring light, which is rather objectionable to persons not used to it, and adjustable shaded lamps at each window provide illumination for night flying. Lights of 15 candlepower were found to be satisfactory for reading purposes, as the field of illumination is small.

For the further comfort of passengers, drinking water is provided at the rear of the cabin, as well as a coat room and a wash room. The latter is provided with running hot and cold water, with a soap dispenser in the wash basin. The basin is small but sufficient. The wash room is not cramped, being large enough to allow a good sized man to stand erect or move about at will. A dry chemical toilet is provided, and is so well vented that the reduced air pressure in the wash room is apparent upon opening the door. A clock, an altimeter, and an airspeed indicator, all with 6-in. dials, are placed on the wall at the front of the passenger cabin within easy view of all, so that those interested may keep a more or less accurate log of the trip.

In the cabins of the new transports a more rugged structure is provided than in the first model, and a considerable saving of weight results for the actual structure and lining of the body. While being theoretically sufficiently strong, the long slender steel tubular members of the original body design were much more flexible than the present larger aluminum-alloy tubes. In the newer structure there is no apparent weaving or vibrating of members, and there is no doubt that passengers will feel more at ease when there is no flexing in and out of the side walls, or weaving up and down of the ceiling. This feature, together with the rigid plywood lining, which replaces a fabric lining backed up with duralumin chicken wire, gives the cabin a much more substantial appearance.

In addition to refinements in flying equipment, there was at the beginning of last year, and still remains, much room for improvement in ground equipment. In making a trip over the line, from Oakland to Salt Lake City, in August, 1928, the ground equipment did not seem so important. A blowout experienced on the rocky field at Reno did not annoy much as the weather was fine, and an overnight delay, due to the airway not being lighted, was no cause for worry. Reno is a pleasant town in which to spend the night and all abroad enjoyed the layover. We were not getting any place, however, and that is the prime purpose of air transports, to go some place and to get there quickly.

Matters were considerably improved in this respect by February of this year. In making two round trips from Oakland to Salt Lake, at that time, the only delay experienced was at Elko, Nev., one morning when it became necessary to wait from 2 a.m. to 9.15 a.m. for weather reports. An attempt was made to start up at six o'clock for the purpose of seeing what the weather was like up above, but before the motors were sufficiently warmed up for taking off, a snow storm closed in, which lasted about two hours. The pilot then decided that we should take time off for breakfast and give the weather man a chance. Difficulty in securing weather reports is being eliminated, and at the present time the radio and teletype machines should be grinding them out with clocklike precision. It was no fun that morning last February, however, on an unsheltered field covered with snow, and the thermometer reading 4 deg. when we landed.

At Oakland, Reno, and Salt Lake comfortable waiting rooms are provided with sheltered concrete loading aprons, and soon similar facilities will exist all along the line. The arrangement at Oakland is especially attractive. There you enter the main lobby which is flanked at either side by the coastwise and transcontinental operating offices. A stairway leads up through two nicely appointed waiting rooms to a passageway across the main hangar. This passage is enclosed with glass, and the whole of the hangar interior may be seen without danger to the observer or interference with the work of the ground crew. A few steps down, at the far side of the hangar, and one is in the observation lounge. This is a very comfortably furnished waiting room where passengers and their friends may chat in comfort. It is on the second floor of the field post-office building, and through the large windows on three sides an unobstructed view of the entire airport may be had. Leading from this room are stairs to the field level, and a concrete walkway with telescoping cover gives safe access to the waiting ship, at the same time affording protection from the air blast of the propellers. Compared to other arrangements observed, this layout is a very good model, although an arrangement with the administration offices, waiting rooms, etc., in an entirely separate building, has also been nicely worked out.

In conclusion, it may be said that the fundamental conception of the Boeing transport airplane, as originally laid out, has been modified only slightly as a result of the experience gained through its operation. On the other hand, hundreds of minor alterations and additions to the original design were found necessary, and only through a long process of trial and error was it possible to develop a transport which could give real satisfaction in service. To emphasize this statement, it might be pointed out that since the first flights of this ship, there has been expended approximately 2000 "man-hours" of engineering work on the project.

Assume that the design is completed before testing begins. The indications are that, regardless of the previous experience and care exercised in laying out the details of the design, it will be practically impossible to arrive at the ultimate design before the model is actually placed in service. This is due, of course, largely to the requirements of that service which cannot be accurately predicted.

AER-52-11

Aircraft-Float Design and Construction

By HOLDEN C. RICHARDSON,[1] CLEVELAND, OHIO

Designs of aircraft floats have included the canoe type, inflated bag or skid, box type, multi-rib type, canoe system with cloth over a thin smooth skin, girder type, and all-metal construction. The author follows the development and discusses necessary characteristics. Late construction is principally of aluminum alloy for both floats and boats. Bulkheads are used to carry concentrated loads, and the bottoms are sometimes reinforced by exterior longitudinals. Extruded shapes, angles, channels, and tees are becoming popular as framing members.

AIRCRAFT-FLOAT design is a special form of naval architecture meeting many of the problems of surface craft and many problems in addition not encountered by such craft. These additional conditions, in particular, affect the details of design due to the variation of load with wing lift, and impose certain new requirements at what is known as the "hump" speed, and at the "get away" speed.

Aircraft-float construction has passed from the canoe and the inflated bag on a skid, through the box-type float, the multi-rib type, the canoe system of cloth over a thin smooth skin, to the girder type, with the longitudinal system of framing, and with veneer or two-ply bottom; from there to the metal floats of aluminum-alloy or nickel and monel-metal construction. Today both design and construction follow closely the practice in high-speed boat construction, but with greater stress being laid on a light structure of adequate strength.

Seaworthiness and airworthiness requirements must be satisfied to the highest degree practicable, but as these requirements conflict with each other compromises become necessary, and these compromises are also affected by the purpose for which the plane is to be used and the disposition of the crew. The nature of the compromise depends largely on the purpose for which the design is intended and the locale of operations, and the results depend also to a degree on the system of flotation adopted.

To follow through the developments from the first successful design of a sled-type float used by Curtiss in 1910–11 would in itself require a small volume. It may suffice to state that today there are certain arrangements and features which are well recognized and generally used.

As to arrangements, these group themselves into the float and boat types. In the float types there is a system of floats which in many types are substituted for wheels, so that the floats are associated with the usual fuselage type of plane. In the boat types the hull itself forms a fuselage, or is intimately associated with it.

Another classification might be based on the float arrangement, and divides into the principal groups of central-float and twin-float systems. The central-float system is one in which the central float is the main supporting member when afloat. For lateral stability it requires some additional means. This may be in the form of the usual wing-tip float, normally just clear of the water surface, or of larger side floats contributing to lateral stability and to buoyancy at rest through partial immersion, or it may be in the form of side sponsons to the central floats which are partially immersed at rest. These lateral stabilizers are normally well clear of the surface after, or even before, full planing is attained.

Still another classification applies to a system very generally used, known as the twin-float system. In this system the main supporting members comprise the pair of symmetrically placed floats which provide both lateral and longitudinal stability; though in some forms the floats are short and a tail float is used to prevent turning over backward. This latter form is considered obsolete, and in general the main floats of any system are depended upon for longitudinal stability.

Certain float features are found in almost all of the latest hull and float designs. It will be interesting to discuss these and to point out their general effect and the reasons for their incorporation.

In naval architecture it is customary to define the lines of a vessel by means of a body plan giving sections at various points along the length of the hull, a half-breadth plan giving the contour of the waterline at different distances above the keel, and a profile plan giving the contours of the deck and keel and showing what are known as buttocks.

The first successful type had the profile of a sled. The deck was parallel with the keel, and the keel rose at the bow in an easy curve to meet the deck line, while the deck line at the stern dropped in an easy curve to meet the keel. This type was of the simplest construction. It planed nicely, but after planing had been attained and the hull was gliding on the surface of the water it was difficult to depress the tail of the float, which necessarily was well behind the center of gravity. This type of float had, however, several deficiencies, the first one being that in order to make it possible to take the air without having too much difficulty it was necessary to keep the stern fairly close to the center of gravity and this permitted a very small margin against tilting over backward. Also the curvatures at the bow and at the stern, while providing a fairly efficient streamlined form for the float, also gave the float a nosing tendency when in the air. For smooth-water work this type of float was quite good, but if the water was rough the flat bottom caused considerable punishment to be sustained by the plane. The next variation of this type consisted of the introduction of steps in the bottom of the hull. Various attempts were made to determine how many steps would be useful, and model-basin experiments indicated that little or no advantage was gained by providing more than

---

[1] Director of Engineering, Allied Motor Industries, Inc. Commander Richardson, U.S.N., was born in Shamokin, Pa., December 7, 1878. He was educated at the Shamokin High School, and was graduated from the Naval Academy in 1901 and M.I.T. in 1906, receiving his degree of M.S. in 1907. Commander Richardson was assistant Superintendent Constructor, Newport News, 1909 to 1911; Naval Constructor, Philadelphia Naval Yard, 1911 to 1916; Bureau of Construction and Repair, Aviation, 1915 to 1917; Construction Officer, Naval Air Station, Pensacola, Fla., 1916 to 1918; Superintendent Construction Bureau, Buffalo, N. Y., 1918; Chief Engineer, Naval Aircraft Factory, Philadelphia, 1919 to 1921. He has been in aeronautical activities continuously since March, 1912—at San Diego, Annapolis, Hammondsport, Pensacola, Washington, Buffalo, Rockaway, Philadelphia. He designed hulls for N.C. transatlantic seaplanes, tested all N.C.'s and assisted in planning transatlantic flight; pilot on transatlantic flight NC3, 1920 to 1924; Chief Engineer, Naval Aircraft Factory, 1924 to 1929; head Design Branch and later Matèriel Division, Bureau of Aeronautics, Navy Department; retired May 1, 1929, as Captain (C.C.) U.S.N.

Presented at the Great Lakes Aeronautical Meeting, Cleveland, Ohio, August 31, 1929, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

two hydroplaning surfaces by the introduction of a step. It was found in these early days, where there was very little reserve of power, that there was some advantage of providing ventilation for the steps, and there still appears to be some possible advantage in providing such ventilation where the float is flat bottom or where the chine of the float is relatively deeply immersed initially. As the evolution proceeded, the profile of the keel gradually became changed, and the present forms practically all embody what may be termed the "rocker form of keel," embodying what might be still recognized as the sled type of profile from the bow to the first step. This step is usually located slightly aft of the center of gravity of the plane; abaft the first step, the keel rises at an angle of between 5 and 10 deg. to the keel forward to the step, and it is usual to have this part of the keel a straight line to avoid suction which would be present if curved lines were used. In the simple float construction, this defines the profile of the modern float.

In boat construction, however, it is necessary to provide a long tail to support the tail surfaces of the airplane, and in this case it is usual to find a second step at some distance behind the first step, and this is particularly necessary if the keel is curved from the first step to the stern; abaft the second step the keel usually rises sharply and very often the tail of the hull is lifted considerably in order to keep the tail surfaces well clear of the water.

The problem of "suction" is a very serious one, presented where too much of a "rocker keel" is involved or where the keel aft of the first step is curved downwardly, as the flow of water about such a curve tends to produce an important force acting radially outward from the center of curvature of the surface. Since water is over 800 times as dense as air, this force on a very small surface in the water may become important at airplane operating speeds. However, there are advantages to the "rocker" form of keel, provided steps are properly located to break the suction involved.

Floats with a deep rocker profile for the keel generally run hard at the "hump" speed; that is, their resistance at from 20 per cent to 30 per cent of the get-away speed is higher than profiles which are not so pronounced. If, however, there is ample reserve of power so that there is no question of getting by this "hump" speed, the deep profile floats have an advantage in that at the get-away speed they run with much less resistance than the more normal type of hull, and, in addition, after planing is attained and the plane is up on the step, they may be rocked back to get greater wing lift without again bringing the tail of the float into contact.

On the other hand, just before planing is attained the waves that are thrown off from the side of the hull converge under the stern of the float, and where these two waves come together a "roach" is formed, which may in some cases again make contact with the float, and may seriously endanger the tail surfaces of the plane unless they are located at a good distance above the water.

In plan form, as shown on the half-breadth plan, practically all floats are given a substantially streamlined form, with the major ordinates somewhat forward of mid-length. This is practically the only feature of a hull design which does not have to be a compromise in the attempt to arrive at the best aerodynamic form.

The major or midship section of a float usually occurs in the vicinity of the step, and it is at this point that the greatest variation is found in up-to-date construction. The flat-bottom section is practically obsolete. The V-bottom has come into very general use for the reason that it forms a simple and efficient shock absorber, and as far as planing properties are concerned it is substantially the equal of the flat bottom or the hollow bottom, or the inverted V-bottom. The V's themselves may have straight sides, but more generally have a certain amount of hollowness introduced between the keel and the chine. Experiments on the variation of this feature, some with flat bottom, up to V's of 25 deg., show that, so far as the horsepower required for a float is concerned, the difference is almost imperceptible in the results obtained from model tests. The flatter the bottom the greater the punishment, and as a rule the dirtier is the run up to planing speed. A 20- to $22^1/_2$-deg. bottom is quite satisfactory. In recent years there has been a strong tendency to make the bottoms quite hollow at the sides, and this has the advantage of holding down the spray, but toward the get-away speed the V's at the keel are so steep that they afford almost no planing capacity, while at the same time they cause considerable drag. This drag is not alone at the keel itself, but is at the tail of the plane, due to the narrow groove, plowed in the water, closing and forming a roach, which may again make contact with the tail in the neighborhood of the get-away speed. The hollow bottom and the inverted V-bottom plane well and run clean, but do not appear to have any advantage over the straight V-bottom, and do have the disadvantage that in rough water they pound rather hard, subjecting the plane to considerable punishment.

Since 1911 in this country and abroad, and notably in England, the development of aircraft floats has been due in a large measure to the use of the model basin, and recently in Germany the same thing has taken place in the development of the hulls of large seaplanes, and recourse to model-basin tests is recommended for any one starting out on a new plan of development. Naturally the conditions of a model test are to a degree artificial, particularly in that only straight-away runs can be made, and also that the wing lift, while provided for in the model test, cannot easily be made to vary as it does on the plane due to the changing attitude of the plane in the course of the run to take off. But, admitting these artificialities, it has been found that the results obtained from model tests are an excellent indication as to the possibility of flight with a particular design, and also as to the behavior which is to be expected of the full-size structure.

A comparison of a large amount of data from model-basin tests on the three principal types of construction—the flying boat, the central float, and the twin float—shows that at hump speed the efficiencies are substantially in the order named; that is, the resistance at the hump speed is less for the boat than it is for the central float, and less for the central float than it is for the twin float. The reason for this appears to be that generally in boat construction the ratio of the waterline length to the beam is lower than in the case of the central float, etc. In the case of the boat, great length is relatively easily obtained because of the size of the boat, and also because of the necessity of a tail for the float to support the tail structure, and this provides ample longitudinal stability, whereas in the central float relatively greater length is required for this purpose, and this is also in effect true in comparing the central float with the twin-float type.

The question of the determination of the beam for a float for a long time was a puzzling one to the author, and it is believed to others, for an examination of the data available did not appear to show any particular systematic method of variation. A number of methods which have been proposed were examined, but were not found to bear close analysis, although in many cases for the particular design under consideration they gave fairly satisfactory results, but, for instance, when it came to attempting to apply this method to the three cases just referred to—that is, the boat, the central float, and the twin float—it was found that the discrepancies were wide and that in many cases ridiculous proportions would result.

Finally, after considering a great many designs from many

sources, both American and foreign, it was found that the beam required is a function of the length-beam ratio, and that this became reasonably consistent if the length and beam of the submerged portion of the hull were taken into consideration rather than the overall length, and once this was discovered, it was found that good design conformed very closely to this criterion. It is not surprising that many designs which have been flown do not conform exactly to this because up to this time there has been no satisfactory criterion for the determination of the beam of a float.

It now appears that the beam of a float can be determined by the following equation:

$$B = \frac{KW^{1/3}}{(L/B)}$$

In this formula the beam is determined in inches, and the constant may vary from 16 to 18, and the L/B ratio may vary from 3 to 7. First hand, this may appear to be no determination whatever; but it is found in practice that the L/B ratio for floats is about $4^1/_2$, for single floats about $5^1/_2$, and for twin floats about 7, if good results are to be obtained.

The latest construction is principally in aluminum alloy for both floats and boats. In the boats the hull usually incorporates two deep girders in the sides or well out to the sides, and a central-keel girder and intermediate keelsons supported by floors from chine to chine and attached to the keel.

Watertight and partial bulkheads are used to carry concentrated loads. In some cases longitudinals appear only at the chine and keel, the bottom plating being generously supported by frames, floors, or bulkheads.

In floats the decks are usually of approximately circular form, supported by frames and reinforced by longitudinals either inside or outside. The latter are favored as they avoid cutting of frames or longitudinals at their intersections, and the plating forms natural gussets.

Bottoms are sometimes reinforced by exterior longitudinals, preferably solid, for hollow sections are subject to damage which may cause them to leak and convey water to remote portions. They are also thus subjected to severe corrosion in inaccessible places.

Castings are favored for stem and stern pieces and in some cases for steps, and are also favored as fittings where longitudinal members pierce floors or bulkheads, particularly if watertightness is required. They greatly simplify connections which would otherwise be intricate. Extruded shapes, angles, channels, and trees, with or without bulbs, are becoming generally popular as framing members.

In floats subject to salt-water operations difficulty is still found with rivet heads as the forming operations of the rivets appear to alter their galvanic properties, making them especially vulnerable to attack unless they are thoroughly protected. As rivets in bottom plating are particularly subject to abrasion, it is found that machine screws are preferable and bottom plating is now commonly so secured.

Corrosion is an important factor, good results being obtained by anodic treatment of the material or by the use of alclad, but in either case priming coats of iron oxide or zinc chromate are desirable for exteriors or interiors, to be followed by lacquer or enamel coatings of good quality.

Interiors of inaccessible spaces are best protected by bitumastic coating. In tropical waters anti-fouling over bitumastic has been found a desirable finish for the bottoms of floats which are moored out. As the size of floats increase, the principles of ship construction are being more and more incorporated in the design of the details of the structure.

AER-52-12

Installation of Air-Cooled Radial Engines

By P. B. TAYLOR,[1] PATERSON, N. J.

This paper tells of some of the installation problems of air-cooled radial engines, and the author points out some improvements that are desirable. Engine exhaust and cowling systems are described, and the purposes of carburetor air heaters and cleaners are given. Variation of the viscosity of oil with temperature, together with its low heat conductivity, causes many difficulties in the lubricating system. Oil foaming is another source of concern to designers. An effective method of preventing this is to discharge the oil on a plate sloping into the oil volume and allow it to run down the sides into the oil tank.

There are many types of fuel systems, and the author gives some general considerations that should be followed in installation. To provide for inverted flight requires special arrangements to give satisfactory results.

THE reliability of an air-cooled engine depends directly upon the amount of engineering put into its installation and the degree of intelligence (if any) with which it is serviced. At the present time, the airplane manufacturer is far more interested in aerodynamics than installations, and the engine manufacturer whose engine is installed in 100 different ships, all of which are rushed to completion, does not have the necessary control of the installation details. The result does not promote reliability, and is one great hindrance to selling aviation to the public. Department of Commerce statistics show at least 50 per cent of engine failures are directly chargeable to gas-, water-, and oil-line breakage, which can be charged to stupidity and carelessness only. If this industry cannot install a few pieces of copper pipe so that they will not vibrate and fail, there is little hope that aviation will become as safe as it is now considered.

Engine Mounts

Radial engines are almost universally mounted on a ring having from eight to twelve points of attachment to the engine crankcase. This ring is attached to the ends of the longerons by eight tubes meeting on the vertical and horizontal centerline of the structure (Fig. 1). The engine crankcase which is accurately machined on the mounting faces is usually called upon to straighten the engine mount which has been distorted in welding. The author fails to see the utility of the attaching points which are not adjacent to the struts leading to the longerons, as no stretch of the imagination will subject these points to more than engine-torque load which is 200 lb. per bolt in the case of a 600-hp. engine with a nine-bolt mounting which can be easily absorbed at four attaching points.

The logical engine mount for a radial engine is a structure consisting of eight tubes from the ends of the longerons which meet at four opposite points on the engine crankcase, at which points a substantial mounting lug is incorporated in the engine crankcase which, with the tubes, forms a complete structure (Fig. 2). To hold the ends of the mount in position when not attached to the engine crankcase, they may be tied together by light tubing. The crankcase is a far more rigid structure than a tubular ring and can be made quite adequate to withstand mounting strains.

No fear need be had for the overhang of an engine beyond the mounting point if properly designed, as the air-cooled V-1460 mounted on the stand indicates (Fig. 3). This engine has been run for several hundred hours, as illustrated.

The automobile industry has been forced to rubber or spring mounts for their engines, and since the vibration of the aviation engine is far worse than the automobile, the public will certainly demand shock-absorbing mounts as soon as it knows why a plane is so uncomfortable. The airplane has the advantage of a very elastic structure throughout which can be damped easily to prevent vibration from reaching the passengers. A flight behind an engine on rubber mounts will convince the skeptic of their effectiveness.

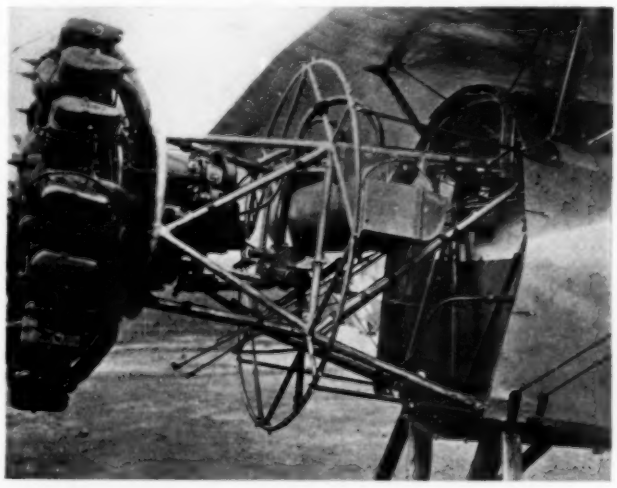

Fig. 1 Typical Radial-Engine Mounting With Four Triangular Structures Tied Into a Mounting Ring

Engine Exhaust Systems and Cowls

The simplest exhaust and cowling system is undoubtedly open stacks from rear exhaust-port cylinders. This in no way interferes with a cowl from the engine nose to the ship's lines (Fig. 4). For the past two years an effort has been made to improve this construction with both front and rear exhaust-collector ring, as open stacks often are disagreeable to the pilot and impair his vision at night. The front exhaust collector forms a neat installation, and due to its small diameter is lighter than the rear collector. Fig. 5 shows a typical installation. How-

[1] Acting Chief Engineer, Wright Aeronautical Corporation.

Presented at the Fourth National Aeronautic Meeting, Dayton, Ohio, May 19 to 22, 1930, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

ever, the rear collector can be made into just as neat an installation as the front collector. Figs. 6 and 7 illustrate such a manifold and cowl. The front collector allows the engine manufacturer to finish his part of the cowl in front of the cylinders,

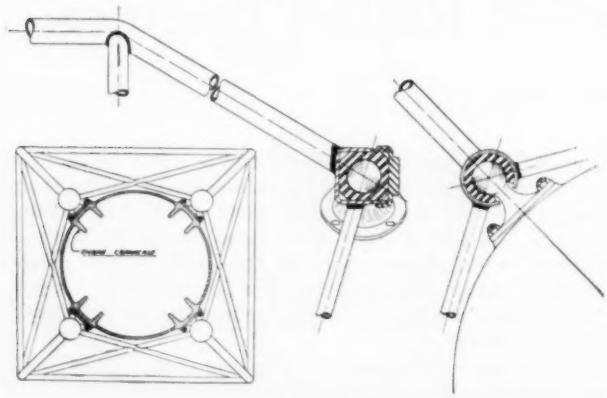

FIG. 2 FOUR-POINT ENGINE MOUNTING WITH RUBBER INSULATORS AT THE POINTS OF ATTACHMENT TO THE ENGINE CRANKCASE

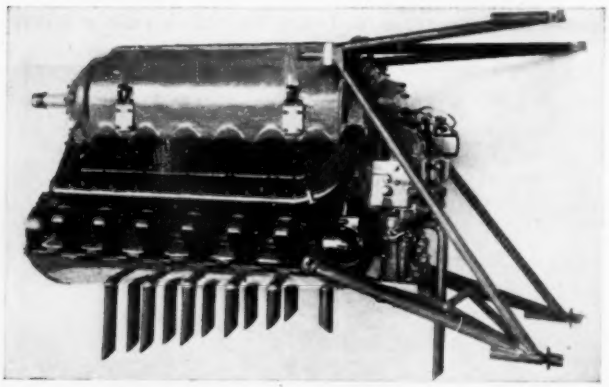

FIG. 3 WRIGHT V-1460 ENGINE MOUNTED AT THE REAR. THIS ENGINE HAS HAD SEVERAL HUNDRED HOURS OF TORQUE-STAND OPERATION MOUNTED AS SHOWN

that the engine manufacturer should complete the engine cowl and establish a ring behind the engine to which the ship's cowl will attach. If this dimension is once established, new ships can be made to conform without difficulty. In the case of the rear collector, cowl to the rear point of the exhaust system is essential in a well-appearing installation. From an aerodynamic standpoint, rear exhaust rings directly behind the cylinder have very little effect whether streamlined or not because the air flow over a radial cylinder is so turbulent that a small thing like an exhaust ring cannot make it worse. Fig. 8 shows the Pratt and Whitney Wasp Junior with such a ring.

Shutters in a nose cowl are in vogue at present, most of them adjustable by the pilot. Considering the cylinder barrels, these adjustable shutters are unnecessary since the barrel temperature of most engines will be satisfactory from 100 to 300 deg. fahr., which is a wide enough range to cover all operating conditions. The pilot makes his nose-cowl adjustment, if at all, from his oil temperature, which is a very approximate indication of barrel temperature. This subject will be discussed further under oil systems, and a different method of controlling oil temperature suggested. Nose shutters adjustable on the ground for seasonal temperature variations will simplify the duties of busy pilots without affecting the engine performance.

The principal function of standard cowl is to control the engine temperature since it has little or no effect on drag. This has been lost sight of by many plane manufacturers who accept the louvers in the nose cowl without providing a corresponding area of louvers behind the engine, and if cooling of the oil tank is desired, behind the oil tank. Air will not enter a cowl unless an exit is provided, and it will not pass over the oil tank unless the exit is behind this equipment. These principles are not at all profound but are still ignored in many installations.

Spinners were discarded several years ago because they were found to have little effect on drag and because they would not stay on. They cause a distinct improvement in cylinder cooling, however, as they mask the round section of the propeller which throws the air in a radial direction away from the louvers in the front cowl. It is hoped that if spinners are again supplied they will be provided with a continuous ring at their trailing edge with strength enough to hold them in one piece.

The N.A.C.A. cowl is most easily developed around front

FIG. 4 INSTALLATION SHOWING OPEN EXHAUST STACKS ON WHIRLWIND J-5 ENGINE

leaving more space to the plane builder in which to conform the cowl ring into the lines of the fuselage or nacelle without abrupt changes of section. It is the author's opinion, however, exhaust cylinders where the exhaust manifold forms the leading edge of the cowl (Fig. 9). By the proper use of intercylinder baffles, it is possible to obtain excellent cylinder cooling either

with or without an inner cowl. Without baffles an inner cowl is desirable to decrease the drag by reducing the quantity of air passing through the outer ring and out of the rear slots. It is also possible to work out a satisfactory N.A.C.A. cowl with rear exhaust-port cylinders, but attention must be paid to exhaust manifold cooling. Townend rings, which give promise of distinct advantages over N.A.C.A. cowls in all respects except appearance, can be fitted over most standard cowls regardless of exhaust systems. Fig. 10 shows a ship equipped by the N.A.C.A. The cooling characteristic of this cowl is in most cases better than the conventional cowl with no ring.

FIG. 5 FRONT EXHAUST COLLECTOR FITTED TO A WHIRLWIND 225 ENGINE

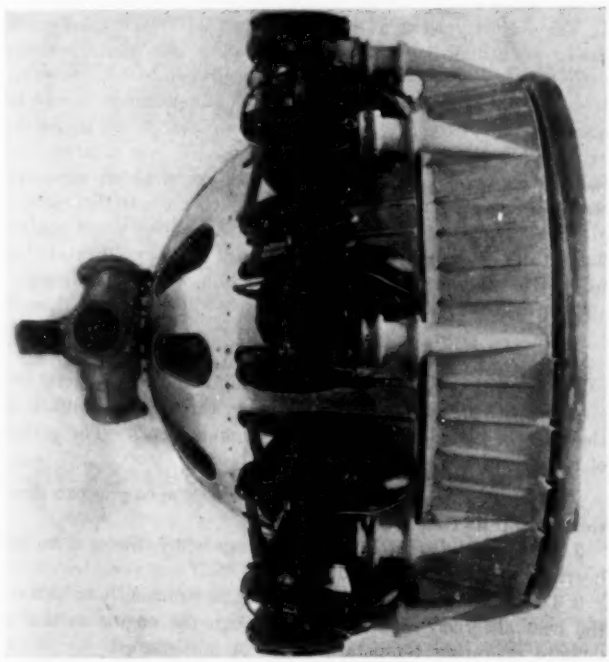

FIG. 6 WRIGHT CYCLONE ENGINE EQUIPPED WITH REAR EXHAUST COLLECTOR STREAMLINED INTO THE COWL

Recent fires from minor crashes have taken a toll of lives and done much to prevent public confidence in aviation. The cause of these fires is at present unknown, but it is suspected that uncooled exhaust manifolds play a large part. The British establish a maximum temperature for exhaust manifolds which is well below the flash point of gasoline. This reduction in temperature can be accomplished by exposing the exhaust system to the direct air blast and providing it with cooling fins. Cast-aluminum exhaust elbows provided with fins will also assist in reducing exhaust manifold temperatures. It is hoped that the N.A.C.A. will see fit to conduct experiments on crash fires to establish their exact cause. If this theory proves to be correct, a Department of Commerce regulation and an Army and Navy order on exhaust-manifold temperature would be in order.

Accessibility of engine accessories and oil connections is important for all types of exhaust systems and cowl. With conventional cowl developed around front exhaust rings or open stacks, doors are usually provided through which a mechanic can at least reach the part to be adjusted. Referring again to Fig. 6, in this installation the exhaust manifold and cowl are permanently secured together and both are supported by the

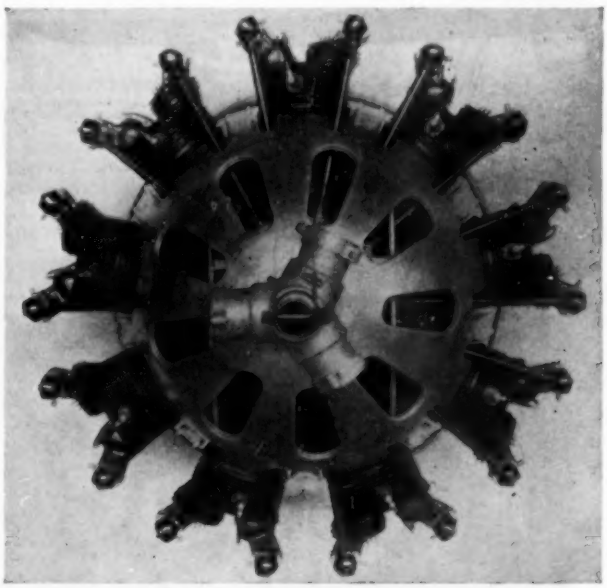

FIG. 7 WRIGHT CYCLONE REAR-EXHAUST MANIFOLD VIEWED FROM THE FRONT. NOTE THE CLEAN APPEARANCE OF THIS INSTALLATION

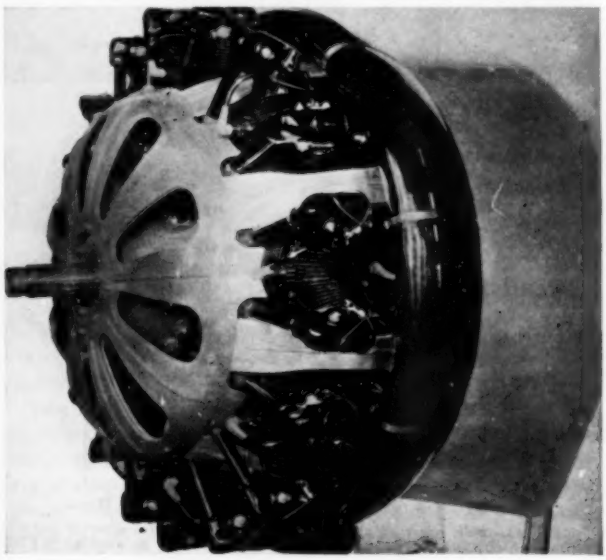

FIG. 8 PRATT AND WHITNEY WASP JUNIOR ENGINE WITH EXHAUST COLLECTOR AND NOSE COWL

exhaust flanges on the cylinders only. The exhaust ring and cowl are split on the centerline so that by removing the exhaust-flange screws the complete assembly can be removed in halves. The nose piece can be taken off over the crankshaft after removal of the propeller. Some such arrangement is advisable for all rear-exhaust systems.

FIG. 9 N.A.C.A. COWL SHOWING AN EXHAUST MANIFOLD WHICH FORMS THE LEADING EDGE OF THE COWL

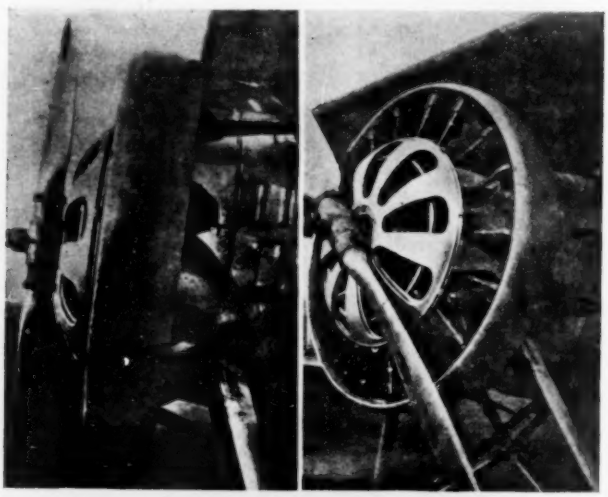

FIG. 10 ENGINE EQUIPPED WITH A TOWNEND RING
(Upper left, side view of cowling; upper right, three-quarter view of narrow-ring cowling; at bottom, front view of cowling as used on XF7C-1 airplane over service-type cowling.)

N.A.C.A. and Townend rings usually present a difficult accessibility problem. A segmental Townend ring attached to the cylinder heads under the rocker-box cover is suggested. In this case the rocker-box covers should be made angular to conform with the circumference on the ring. This permits the removal of rocker-box covers for servicing without disturbing the cowl. N.A.C.A. cowl should be made removable in halves secured by quick detachable fasteners.

CARBURETOR AIR HEATERS AND CLEANERS

Many types of carburetor air heaters have been fitted to radial engines, most of which increase the installation difficulties and spoil the appearance, often without accomplishing all of the functions for which they were designed. Air heaters and cleaners are installed for the following purposes:

1 To heat the fuel-air mixture, thus assisting the vaporization of the fuel and improving the distribution.

2 To prevent the formation of ice at the carburetor jets and throttle valve.

3 To prevent spray from entering the carburetor on seaplanes or in rain.

4 To prevent at all times foreign matter, especially sand and dirt, from entering the carburetor and causing damage or wear to moving parts.

5 To eliminate the possibility of fire caused by flame from an engine backfire.

6 To provide a control of hot and cold carburetor air for various atmospheric conditions.

In addition to the above, the unit must not interfere with installation, must not be of excessive weight or bulk, must not form an excessive restriction to volumetric efficiency in either the hot or cold position, and must not add to the fire hazard by requiring uncooled exhaust pipes under the cowl.

The unit which in the author's opinion most nearly meets all conditions is shown in Figs. 11 and 12. This heater obtains sufficient heat from under a front or rear exhaust manifold, or from open stacks, to prevent ice formation at the carburetor. It was formerly thought by some that a hot spot above the carburetor would be required to accomplish this, but experience with this and other heaters proves this belief to be erroneous. If more heat is desired for unusually cold conditions, it can be obtained on this banjo type by fitting a larger shield under the exhaust manifold, thus forcing the intake air over a larger surface of hot exhaust pipe. The heater contains an air-maze-screen cleaner impregnated with oil which collects dirt, and is also accepted by the fire underwriters as positive proof against flame from engine backfires. The use of hot or cold intake air to control oil temperature, in conjunction with the carburetor air heater, is an added advantage which will be discussed later.

LUBRICATION SYSTEM

The variation of the viscosity of oil with its temperature, coupled with its low heat conductivity, throw many pitfalls in the way of the designer of lubrication systems. The object of a lubrication system is briefly:

1 To store a quantity of oil from which the engine can draw to make up its consumption.

2 To supply oil to the pressure pump which forces it to the bearings at constant pressure.

3 To cool the oil coming from the engine sufficiently to balance the heat absorbed when passing through the engine so that a definite operating temperature can be maintained.

4 To prevent the entrance of dirt into the system which would cause wear of the working parts of the engine.

The suction line for normal operation must be of sufficient size to offer no great restriction to oil flow. It should be arranged so that the level of oil in the tank is slightly above the pressure pump to prime the latter under all conditions, since a gear pump which is universally used in oil systems, will not produce a suction unless primed. A reservoir should be left below the tank suction line to collect dirt and foreign matter which would otherwise be sucked into the engine. The line must be absolutely tight as air will be drawn through a smallest leak, and lower

the pressure delivered by the pressure pump. In cold weather this line must be protected from extreme cold as the increase in viscosity of cold oil will prevent circulation. This is usually accomplished by lagging the line with tape or asbestos cord and protecting it inside the cowl. The suction line is the main artery of the engine and should therefore receive scrupulous attention. It should be as short as possible and secured at frequent intervals to prevent vibration. Hose connections and fittings should be checked and rechecked for tightness. The service routine should always cover inspection of this pipe.

From the suction line the oil passes through a finger strainer to the pressure pump, which consists almost generally of a pair of spur gears running in a housing with appropriate inlet and outlet passages. From the gear pump the oil is usually forced through a fine-mesh screen, and from here it is delivered to the engine bearings. Oil leaking from the bearings in the main crankcase is thrown on the cylinder walls and pistons which are operating at high temperature. This oil runs down

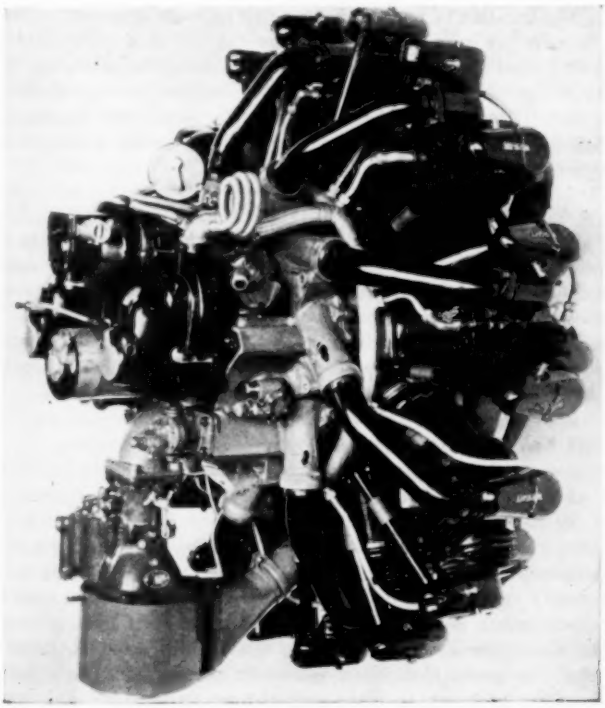

FIG. 11 REAR VIEW OF WHIRLWIND 300 ENGINE SHOWING BANJO-TYPE AIR HEATER AND CLEANER

the walls of the crankcase to the sump where it is drawn out by one or more scavenge pumps. The oil from the sump is frequently at 250 to 300 deg. fahr. during normal operation. This will astonish the pilot who has been brought up to look with horror on oil temperatures of 190 deg. fahr. The reason for this apparent discrepancy can be found in the mixture of the cold oil coming through the pressure relief valve, which mixes with the hot oil from the engine and indicates to the pilot what is considered a normal oil temperature of, say, 140 deg. fahr. Many pilots if suddenly confronted with the exact temperature of the oil in their engine crankcase would make an immediate landing and call loudly for service. The company with which the author is connected at one time placed an oil thermometer in the engine crankcase, but was immediately forced to move it to another position because no one would fly the engine.

From the oil sump, which may be little more than an embryo, the oil is sucked through one or more scavenge pumps, and returned by an outlet line to the oil tank. This line should be well braced to prevent failure, but is of nowhere near the importance of the inlet line because it is under pressure which will force a flow of oil under nearly all conditions. Should an oil leak develop, it means a dirty ship but not a forced landing unless the leak is so large that all the circulating oil is pumped out. The outlet line may pass through an oil cooler or oil strainer or both, on its way to the tank, which it should enter above the oil level. Frequently the effect of oil coolers and cooling means for oil tanks is very disappointing. This is due to the change in viscosity between hot and cold oil. The conventional oil cooler is constructed with a number of passages in parallel. The oil cannot be expected to flow equally through all passages.

FIG. 12 TYPICAL INSTALLATION OF A BANJO-TYPE AIR HEATER INSTALLED ON A WHIRLWIND 225 ENGINE

The passage having the greatest oil flow will increase in temperature and lower the viscosity. This action causes a more rapid flow in the working tube, and a complete or partial stoppage of the tubes which started with limited flow. In the oil tank the oil is cooled on the surface to which it adheres, forming a blanket to heat emission. The oil lines themselves will form a layer of slow-moving viscous oil on the outside with a fast-flowing core of hot oil in the center. The best method of efficiently cooling hot oil in a plane installation is to pass it through small flat passages in series. The pressure will then force all the oil through all the tubes which should be narrow enough to prevent the formation of an insulating layer of cold oil.

Oil coolers have long been the bugbear of plane manufacturers because of their unstable characteristics and the difficulty of installation. To require the plane manufacturer to hang an oil cooler in the slipstream of an airplane, which he has spent much thought and hard work to clean up, seems like adding insult to injury. Many small engines can obtain sufficient cool-

ing from the oil tank and lines, but most large engines and nearly all geared engines need oil coolers.

A new method of installing coolers has recently been developed which transfers the burden from the tired shoulders of the plane manufacturer to the engine manufacturer who originated this system. He has heated the oil, let him cool it. This new installation puts a series radiator in the air heater below the carburetor (Fig. 13). All the air entering the engine passes over the oil cooler and furnishes adequate circulation for the most extreme conditions. More than this, by this method the oil can be quickly warmed at starting when the cold-air doors on the heater

FIG. 13 INSTALLATION OF AN OIL COOLER IN A CARBURETOR AIR-HEATER ASSEMBLY FOR WRIGHT WHIRLWIND ENGINES

are closed and warm air from the manifold passes over the cooler. As the oil temperature rises, the pilot cracks the cold-air doors to obtain any degree of control of his oil temperature. This same control is satisfactory to furnish hot and cold air to the engine carburetor, as when the oil is cold the engine carburetor requires hot air, and when the oil is hot the engine carburetor can be operated on colder air. Heat from the oil also furnishes some of the heat for carburetion.

OIL FOAMING

How many times have pilots been forced down by low oil pressure! When on the ground they remove the relief valve, find nothing, "cuss" the engine manufacturers for building a poor engine, replace the valve, take off with full oil pressure, and continue until the same thing happens again. If the pilot had left the engine alone and smoked a cigarette instead, the trouble would have been repaired just as quickly. His trouble was not the relief valve but foam in the oil tank.

The scavenge pump or pumps of an engine must necessarily have a greater capacity than the pressure pump to prevent an accumulation of oil in the sump. Since all the oil supplied to the scavenge system comes through the pressure pump, the difference in capacity must be made up by air passing through the scavenge system back into the tank. This air becomes intimately mixed with the oil in the form of minute bubbles. An additional quantity of bubbles may be induced into the system by the return oil splashing into the volume of oil in the tank. This action can be observed when running a swift stream of water into the bath tub. Under favorable conditions, a large proportion of the water in the tub will contain small bubbles. The effect of these small bubbles in the oil is to reduce the oil pressure. Oil foaming will occur more readily under the following conditions: (1) hot oil, (2) small quantity in tank, (3) short oil return line, (4) engine having numerous scavenge pumps and a small sump, and (5) high narrow oil tank.

The question of how to prevent this pressure drop next arises. An effective method is to discharge the oil on a plate sloping into the oil volume, and allow it to run down the sides into the oil in the tank. Fig. 14 shows a suitable oil baffle for foam elimination. It is hoped that plane manufacturers and mechanics will recognize this phenomenon and stop blaming an innocent relief valve for their troubles.

FUEL SYSTEMS

There are at least as many fuel systems as airplanes, most of which resemble the engine control of a battleship in complexity, especially in multi-engine planes. A few general considerations may be in order.

1 Gasoline cannot be lifted with a suction head without causing vapor lock under certain conditions which completely breaks down the system.

2 Vertical bends with high points in a gravity-feed system will become vapor bound and stop the flow of gasoline.

3 Gear fuel pumps must be primed before they will function.

4 Fuel pumps will not operate dry for extended periods.

From these considerations it is obvious that the fuel tank must be slightly above the engine-driven pump, unless the engine pump is used to transfer gasoline from a low tank to a gravity tank from which the carburetor is fed. If the engine-driven pump is on the engine, this presents a serious limitation to the plane designer. Present conventions seem to dictate that the pump shall be mounted on the engine. It is quite possible, however, to place a diaphragm in the fuel tank with suitable valves which is actuated by oil pressure from a unit on the engine. This gives excellent satisfaction in supplying steady gasoline feed to the carburetor from a low tank without danger of vapor lock or losing prime. Such a system has been operated experimentally but never put on the market. Possibly some plane manufacturers would be interested in further developments along these lines.

Engine fuel pumps are often equipped with relief valves to maintain a constant pressure. If a hand pump is used, the carburetor floats will be subjected to high pressure from this pump unless the relief-valve line discharges behind the hand pump. Fig. 15 illustrates this point diagrammatically. When a number of tanks are employed, each working through one fuel pump, the system becomes complicated as the relief line must return to the tank from which the fuel is drawn to prevent overflow of an unused tank. In this case a short bypass to the engine fuel pump can be used, carrying the fuel discharged by the relief valve to the intake side of the pump. In this case an additional relief valve should be inserted to bypass the hand pump

to prevent damage to the carburetor float from the excess pressure of the hand pump.

As fuel-line failures not only cause forced landings but are a serious fire hazard, it is impossible to be too careful with their installation. As an illustration of carelessness in this respect, one transatlantic plane made the ocean trip with a fuel line on which two hose clamps were applied to one pipe, and the other end of the joint was stuck together with nothing. Fortunately for them no one intimately connected with this flight ever learned of this condition. Fuel lines should, of course, be braced at frequent intervals to prevent vibration and failure. Each installation is a special study, requiring experienced engineering, and is not a job for the mechanic alone. Too often the mechanic is given the entire responsibility for this most vital part of an expensive ship. His judgment and methods may be good or bad, but he will probably take the path of least resistance and neglect important details. Landing gears are designed before they are built; why should fuel systems receive less attention?

Pusher Installations

Nearly all radial air-cooled engines are designed as tractors. When they are used as pushers, a number of alterations should be made which are ordinarily overlooked. The carburetor is designed so that when the ship is accelerated, causing the gasoline to surge to the rear of the float chamber, the fuel discharge opening will not be uncovered. Reversing this unit will maintain this design characteristic, which if omitted, will result in cutting out the engine during acceleration. Modification of the air heater may also be required to accomplish this.

The intake pipes of a pusher are in front of the cylinder, and usually exposed directly to the slipstream which may cool the pipes to a point where the mixture condenses on the walls and causes rough running. Lagging of intake pipes is the obvious remedy for this condition.

Air-cooled cylinders are designed to cool the hot points of the cylinder best with the air blast of a tractor. The cooling as a pusher will therefore be less efficient resulting in poorer cylinder performance. They may require a better grade of fuel, richer mixture, or a reduction of compression ratio to insure the same degree of durability. Special cylinders would eliminate this limitation, but to date have been considered unnecessary.

The pusher installation also suffers because of the reduced slipstream velocity on the ground and in takeoff and climb. Since a propeller takes air from all directions and delivers it to the rear, the air velocity over the cylinder of a pusher is very low until flying speed is obtained. This also makes cylinder cooling more difficult. By the use of a Townend ring and special baffles the cooling of a pusher installation can be greatly improved. It will always be somewhat less effective than the equivalent tractor installation, however.

The conditions of a pusher engine apply to the rear engine of a tandem installation except for two aerodynamic effects. One is the front propeller slipstream which helps to cool the rear cylinders, and the other is the turbulence created by the forward engine which usually hinders cooling on the rear engine. Here again, the use of ring cowl and special baffles properly designed will greatly increase the cooling of both the front and rear engine. This study has not yet been completed but will undoubtedly improve tandem engine performance when the results are available.

Geared Engines

The problem of cooling the cylinders of a geared engine is necessarily more difficult than a direct-drive engine. The large-diameter slow-speed propeller delivers very little air at the cylinder barrels when running on the ground. The condition is greatly improved in the air, but is still far less satisfactory than a straight drive engine. Since one of the principal advantages of gearing is to permit operation at higher engine speed and thus higher power, the cooling requirements are even more drastic than the direct-drive engine. All the statements concerning cowl and spinners for maximum cooling apply to geared engines, and should be even more carefully applied because of the more severe requirements.

Inverted Flight

High-performance planes are invariably called upon to fly for short periods in the inverted position. This requires special

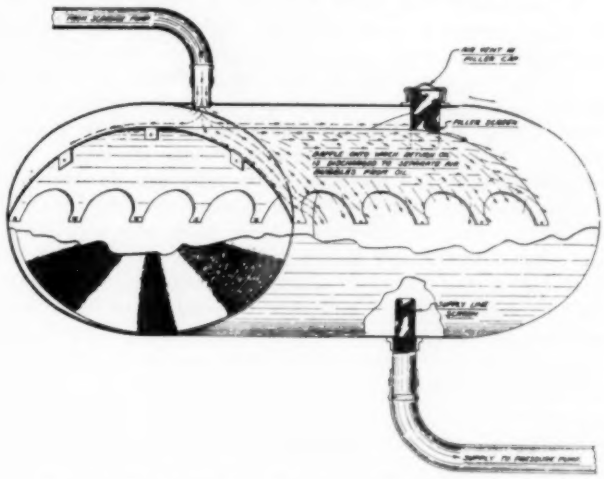

Fig. 14 Oil Tank With Baffle for Foam Elimination

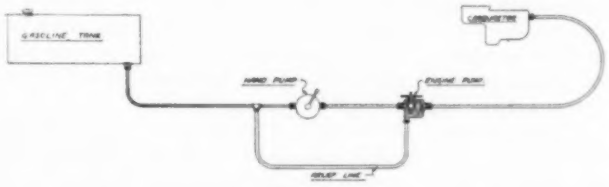

Fig. 15 Fuel System Relief Valve Line Bypassing Hand Pump

installation considerations. For indefinite inverted flight a complete carburetion and oiling system is required for the inverted position. This is very nearly a duplication of the system used in the upright position. For short periods it is possible to make small modifications which will give satisfactory results.

The fuel system must be arranged with a fuel pump having a suction line at all times below the gas level. A line to the center of a tank more than half full of gas, or a flexible line inside the tank weighted to submerge it below the surface of the fuel, will accomplish this. The carburetor must be fitted with a restriction in the gas line which will maintain an appropriate fuel-air ratio when the fuel pump is discharging through it at a predetermined pressure with the carburetor needle valve opened by the float in the inverted position. The vent in the gas tank must be brought by a pipe below the level of the bottom of the tank so that no gas will leak out when inverted. These modifications enable the fuel to get to the intake passage in combustible proportions when running at a narrow range of engine speeds. This will enable the engine fuel system to operate indefinitely.

The suction side of the oil-pressure pump should be arranged

in a similar manner to the fuel line with a weighted flexible pipe in the tank or an outlet in the middle of a tank more than half full of oil. Either system will assure engine oil pressure. No provision is made in the usual installation for scavenging the engine crankcase when inverted. The oil, therefore, accumulates in the case and is returned to the tank only when the plane is again in the normal position. The oil tank and engine breathers must be arranged to prevent spilling. This can be done either by check valves which close in the inverted position, or a pipe from the top opening of the tank leading below the lowest point of the oil system. The engine and oil tank can be connected through the breather and supplied with one vent. A check valve may be necessary to prevent filling the engine crankcase from the oil tank when inverted.

In concluding this paper the author wishes to bring out the shortcomings of both plane and engine builders. Neither have made a real study of engine installations with the idea of obtaining both aerodynamic and engine efficiency. It is the duty of each engine manufacturer to study and determine installation details, giving the best results for his particular engines, together with the best possible aerodynamic efficiency. This information should be passed on to the plane manufacturer, who should incorporate the installation details, furnished him, with the least possible modification. Many parts now supplied by the plane manufacturer should properly be supplied with the engine since they materially affect its performance. It is hoped that intelligent research and close cooperation between plane and engine manufacturers will eliminate present installation faults, and pave the way to further progress in the safety and reliability of aircraft.

Discussion

CAPTAIN T. E. TILLINGHAST.[2] This interesting and comprehensive paper shows that at least one engine manufacturer has been giving considerable thought and study to the problem of installation of radial engines. It is hoped that this paper will be made available to all airplane manufacturers and that they will read it carefully and profit by the sound advice and recommendations contained therein.

It is only natural, at this stage of the art of aviation, that the experience of two airplane manufacturers should not agree 100 per cent. It is quite remarkable that the paper should coincide so perfectly with the ideas of a competing company.

The author's remarks regarding the number of mounting points furnished on the average air-cooled radial engine are well taken. The typical engine-mount structure described and illustrated is practically in general use, and it is hardly conceivable that those points in between the four apexes of the tubular members can be doing very much work. Before one abandons this so-called mounting circle, however, he should consult those airplane manufacturers who are using a monococque type of construction, to see whether or not they desire to utilize the circle mounting. It is quite probable, of course, that the monocoque construction might end well after the engine compartment, and that the tubular structure be built in for the forward part of the fuselage to obtain complete accessibility to the engine from the outside.

As pointed out by the author, from the point of view of the airplane manufacturer, the front type of exhaust collector has a much more general application than any other type. It undoubtedly will be lighter than the rear manifold and should be at least as well cooled. There would seem to be, however, still some question as to whether this front manifold might necessitate some sacrifice in engine cooling. The writer has had no experience in this regard and would appreciate the author's opinion on this point. Another advantage of the front type manifold is visibility, where the engine is so installed in the plane that the pilot must of necessity depend upon peering between the cylinders for forward vision.

The suggestion of the establishment of a ring in back of the engine, forward of which the engine manufacturer would furnish all cowling, and aft of which the responsibility would be that of the airplane manufacturer, is a very good one. The Pratt & Whitney Aircraft Company has for some time been attempting to establish such a ring. It has met with considerable resistance, however, due to the many different shapes of fuselage already in use. It would seem as though some such system will of necessity have to be adopted, and the newer planes being designed and built can readily conform to it.

The exact location of the exhaust collector in the rear of the engine is a compromise between visibility, weight, and cooling of the manifold. Naturally, the smaller the diameter of the manifold the lighter it is going to be. It cannot be sunk into the cowling to any extent and still be cooled. If it is too great in diameter, it may interfere some with the forward vision. When radial engines first came into use, they were installed in fuselages of approximately the same shape and size as were used with the V-type engines. As a result, the visibility forward was in most cases very poor, and it was necessary for the pilot to look between the cylinders for forward vision. There are still airplanes in use with this unfortunate condition. Those manufacturers supplying airplanes equipped with radial-type engines for military purposes have now learned how to place the pilot so that he has good vision forward, which is not interfered with by the engine cylinders and is still good when the ring cowl or the completely cowled engine is used.

Tests which this company has made to date indicate that, as the author has pointed out, a manifold in the rear of the engine can be made as large in diameter as the engine itself with no increase in resistance. It would appear, then, that so far as performance of the airplane is concerned, the diameter of the collector matters but little. It is probable that, for installations with the ring cowl, the collector will be approximately the diameter of the engine and a part of the cowl, and that for installations without the ring the diameter will be about that of the cylinder head, allowing the valve ports and rocker housings to project above the collector ring. This latter arrangement permits a fair amount of vision forward between the cylinder tops.

The writer's experience in the matter of nose shutters is somewhat different from that of the author. While it is true that the temperature of the cylinder flanges varies from 100 to 300 deg. fahr., during which range the engine operates satisfactorily, the writer believes that it is an advantage to have the engine warmed up with the shutter closed. Uneven temperatures fore and aft of the cylinder barrel causes some distortion. Tests also indicate that when the throttle is first opened the piston gains in temperature rapidly and expands. The inner surface of the cylinder barrel may also gain in temperature rapidly, but the tips of the cooling fins remain comparatively cool and will not allow the cylinder to expand very much. This condition is apt to cause an unduly severe piston rubbing condition during the warming-up periods in cold weather and to necessitate the operation of the piston with excessive clearance to provide for this condition. For this reason it is recommended that the nose shutter be controlled from the cockpit and not be used with a seasonal adjustment.

The writer concurs heartily in the author's statement regarding air-exit louvers to the rear of the engine and oil tank. This company appears to have had identical experience with that of

[2] Pratt & Whitney Aircraft Corporation, Hartford, Conn.

the Wright Aeronautical Corporation. It has carefully provided cowling in front of the engine to permit adequate cooling, and the airplane manufacturer has blissfully made an airtight cowling, or practically so, to the rear of the engine.

While spinners may materially improve the air flow around cylinders when the airplane is on the ground, it is doubted if they add much to the cooling in the air where air is approaching the center of the engine at the speed of the airplane; also, as was pointed out in the paper, spinners are very difficult to manufacture so that they will be durable, and they do add nothing appreciably to performance. They have the added disadvantage of sacrificing the ability to lead cooling air to the crankcase nose, which it is believed contributes some to cooling of the oil.

One of the most important developments in connection with the cowling of a radial engine is the ring type of cowling. This detracts but little, if any, from the visibility forward, and in addition to the obtained gains in performance approximately equal to that of the completely cowled radial, they appear to add some to the cooling of the engine. They can be made in segments which are easily detachable, to allow accessibility to the rocker boxes. As a matter of fact, with a well-designed ring cowling, the accessibility to a radial engine is infinitely better than the accessibility to a V-type engine with its usual cowling. With all planes with radial engines designed from now on there appears to be no reason why they all should not provide for the ring type of cowling. It is one of the few examples of getting something for nothing. If there is any provision which the engine manufacturer can make on his engine for the installation of this cowl, he should certainly make every effort to provide it.

It is also possible to provide combination ring cowling with rear exhaust manifold, as has been so well demonstrated by the National Advisory Committee for Aeronautics. This combination does limit the visibility between cylinders, but, as already pointed out, airplane designers are now placing the pilot in a position where this type of visibility is unnecessary. This combination in no way interferes with the cooling of the engine and probably improves the cooling conditions as compared to an uncowled engine.

All engine manufacturers have had the disastrous experience of having their engines flown in the dusty fields of California and Texas. There appears to be two ways of largely eliminating the undue wear caused by the dust in the engine; namely, top air intakes, or at least intakes above the horizontal center line of the fuselage, and the use of air cleaners. The Army Air Corps has had considerable experience in these two methods of providing freedom from dirt. It is believed that both are equally efficacious. The cleaner, however, particularly the screen type, must frequently be cleaned and dipped in fresh oil. The top air intake is practically of no inconvenience. As soon as a downdraft carburetor becomes available for aircraft engines, it should be a simple matter to reverse the accessory section of an engine 180 deg. and easily provide for a top air intake.

It is unfortunately necessary to apply heat to the induction system of a carbureted engine to obtain good distribution. There are several ways in which this heat may be applied: the suction-type supercharger, the so-called hot spot, and a preheater for the air. This last method heats the air before it has gone through the carburetor and is used extensively by the Boeing Air Mail and Pacific Air Transport Line with very satisfactory results. With the hot spot and the supercharger some preheating of the air is absolutely necessary to insure against ice forming in the carburetor barrel, and if all of the heat can be applied efficiently in the preheater type without resorting to a hot spot or the supercharger it would naturally be more convenient. It has been the experience of the Pratt & Whitney engineering department, however, that the hot-spot type of heater, while not so simple in installation as the preheater type, does nevertheless give more satisfactory results, particularly in very cold weather and at altitudes where low degrees of supercharging, such as ordinary rotary induction, are employed.

In the first place, the hot spot accomplishes good distribution at a lower mixture temperature than that obtained with the use of preheated air. As a result, less horsepower is lost due to lowering of the volumetric efficiency.

In the second place, in cold weather the carburetor itself seems to be a very excellent radiator, and a great deal of heat from the preheated air is lost in passing through the carburetor before it ever reaches the fuel. To be able to operate satisfactorily in all temperatures, it has been the writer's experience that the heating arrangement must have ability to increase the temperature of the air intake by at least 200 deg. fahr. Such an increase in temperature very naturally requires a comparatively great amount of hot surface over which the intake air must pass. For these reasons the Pratt & Whitney Aircraft Company has resorted to the use of the hot spot to obtain distribution with a comparatively small amount of preheating to prevent ice formation.

The trend toward larger horsepowers for several years past has brought one face to face with the problem of some means of cooling the oil. It is probably safe to say that engines of greater than 400 hp. require some external means of oil cooling. The Army Air Corps has been able to control oil temperatures very successfully by subjecting the tanks to a flow of warm air either from the water radiator or from the cylinders in an air-cooled engine. With the adoption of larger horsepower, however, it is believed that some type of oil radiator will be necessary. Just what form and type of radiator this will be and where it will be placed, the writer is not prepared to say. Certainly the type of radiator, together with its position, as suggested by the author, is very ingenious and has much to recommend it. There seems to be little question also that the passages must be in series in so far as possible. The use of an oil radiator with but little radiation from the oil tank has a great deal to recommend it. With a bypass valve for cold weather, the oil in the tank will warm up far sooner than in a system depending upon heat radiation from the tank. When the oil gets to the temperature where it will require cooling, the bypass valve will close and the oil will be sent through the radiator. This system probably will necessitate some shutter arrangement in order that the radiator may be warmed up and filled with hot oil prior to exposure to cold air. The type and the position of the radiator described by the author seem to combine all the desired characteristics, and furthermore the radiator is not placed in the slipstream where it will cause drag.

Unquestionably commercial aviation has experienced quite some difficulty with its fuel systems. The Army Air Corps during the past ten years has evolved standard fuel systems to fit practically every need. It is believed that these fuel systems are considerably in advance of the majority of those used in commercial aviation, and it is strongly recommended that these Air Corps systems be adopted as commercial standards. They would eliminate many of the troubles now encountered commercially.

Author's Closure

Mr. Tillinghast's suggestion that the plane manufacturers be consulted before any radical change in engine-mounting structure be made is accepted. However, if this question is left entirely to the decision of the plane manufacturers, little progress will be

made, as they have little desire to change their equipment for the ring type of engine mount. The advantage of rubber installation and the four-point method of support is mainly to the engine manufacturer in protecting his crankcase and insuring against engine vibration. The manufacturer must therefore push this change down the throat of the plane manufacturer unless the operation should prove too drastic for other reasons.

The Wright Company has had a tremendous amount of experience with front-exhaust collector rings, and the cooling of Wright engines is quite satisfactory with this equipment. If the engine is to be supercharged to the point where cylinder cooling is the deciding factor in its operation, the removal of the exhaust from the front of the engine will undoubtedly reduce cylinder temperatures to some extent. It is felt that the cylinder cooling is sufficiently effective to permit the slight increase in air temperature caused by the front exhaust manifold on present engines. The installation advantages are undoubtedly sufficient to warrant this arrangement.

The author cannot subscribe to the theory that the tips of the cylinder-barrel fins will restrain the expansion of the cylinder barrel during the warming-up period to any great extent under any ordinary conditions, as he believes the heat flow in the steel cylinder barrel is sufficiently rapid to conduct the heat to the tips of the barrel fins almost as soon as it is generated. The author would like to raise the question of how many engines are warmed up with the nose-cowl shutters closed. He believes this is one control given to the pilot which he seldom takes the trouble to operate unless his oil temperature is definitely too hot or too cold.

The effectiveness of the top air intake in preventing dirt from reaching the engine was tested by the Army Air Corps and compared with an air-maze cleaner. The result, as Mr. Tillinghast states, shows little advantage for either type. The air-maze installation used for the comparison was definitely unsatisfactory to this unit, as the air maze was exposed to the direct propeller blast in the most unfavorable position from the standpoint of dirt. The new type of heater and cleaner assembly suggested in the paper completely protects the air maze from propeller blast and shields it from dirt to a large extent. In other words, some of the advantages of the top air intake are incorporated in the heater unit, to which an air-maze cleaner is also added. It is believed that it would be well worth while to repeat the comparative tests with an air-maze cleaner in a modern installation. The disadvantage of the top air intake is principally in the difficulty of installation, as wherever the intake passage is placed it will interfere with the structure or fire wall in some installation. The author recently has had occasion to examine several top air-intake installations and has found a considerable deposit of sand and dirt inside the pipe. He therefore believes that the air-maze unit is probably the more effective of the two. The use of downdraft carburetors would make possible the combination of the top air intake and air-maze cleaner, which could take the form of an inverted banjo heater with the air maze incorporated. This is an ideal installation from the point of view of elimination of dirt in the engine.

Mr. Tillinghast states that a 200-deg. temperature rise in the mixture from the air heater is desirable for carburetion. This figure, in the author's experience, is altogether too high and must necessarily greatly reduce the power of the engine. Computing the power of an engine with and without an air heater of this capacity by the means employed by the Army or Navy would entail a loss of 15 per cent in power due to the reduction of volumetric efficiency. The Wright Company has been able to produce very satisfactory air heaters in which the total temperature rise is 80 to 90 deg. fahr. Results of tests made by disinterested parties have indicated that the performance of an engine is identical whether the air is heated before or after the fuel is introduced. The elimination of exhaust piping under the cowl and a hot pipe in the mixture itself is thought to be highly desirable from the point of view of possible fire hazard. The abandoning of the hot-spot development by the Wright Company was based upon this consideration.

All-Metal Airplane Construction

By WELLWOOD E. BEALL,[1] PASADENA, CAL.

The loads to which airplanes are subjected are pretty well known so the stresses in various members can be calculated. A light structure is necessary, but strength and durability must be increased due to the demand for greater speed and more hours in the air. Metal has thus been called into construction to help the designer.

Some of the advantages from use of metal in airplane construction include ease of determining the strength of members, decreased fire hazard, less danger to passengers in case of a crash, and decreases in cost of production, labor, handling, bulk, and waste.

Use of aluminum alloys is increasing, and monocoque construction is becoming more popular. Methods of analyzing the stresses in various members are given in the paper.

STUDY of various papers and articles written by those closely connected with the airplane industry indicates that the term "all-metal construction" is sometimes applied to an airplane whose covering is fabric but whose structure is metal. An all-metal airplane should mean one whose strength members are not only of metal but whose covering is also of metal, and this type will be discussed in this paper. Most metal covering is not supported by the conventional ribs such as fabric requires, hence, an "all-metal" airplane is in a class by itself.

The substitution of metal for wood has followed the advancement of aircraft design. With the increase of knowledge of the aerodynamic qualities of the airplane, more knowledge of the application of the loads on the structures has been gained. The first airplanes consisted of structures figured by the rule of thumb. A member of any size was placed at any point the pilot-builder might deem wise, but later, as certain loads were recognized, the structure was designed to fit that load. The stick and wire structure then sufficed. As time went on more exacting design conditions were set down and structures had to become more accurate.

At the present time considerable is known of the loads to which present-day airplanes are subjected. Not only that, but due to the efforts of the government, exacting conditions of strength must be met. Hence, to design to such exacting loads material must be used that is absolutely safe and whose exact mechanical properties are known. The pay load of an airplane is an all-important item. As the importance of high pay loads is realized, a parallel thought comes to the engineers' and producers' minds. The lighter the structure the more the pay load. To lighten the structure, a greater strength-weight ratio must be had. The structural weight must be reduced, but strength and durability must become greater because of the increasing demand for speed and more hours in the air. Hence, metal has to play its part in helping the designer.

Some new construction is being carried on with metal ships covered with fabric. Metal construction has many advantages and also a few disadvantages. Every one agrees that as much metal as is economically possible should be used, but for small job-lot production schedules, small wooden parts are cheaper than metal. Where real production is paramount, metal is by far the cheapest, especially in larger and in highly stressed parts.

Use of metal permits a much closer degree of accuracy and saves weight. Metal has a moral advantage over wood in that the public feels much safer on a steel bridge than on a wooden one, and justly so. Since wood can have such varying characteristics, it is necessary to make many tests and inspections of the material that goes into wooden parts. If the properties of the wood in any part are to be known, it becomes necessary to test a piece of material cut from the same piece of wood from which the part is made. It is oftimes rather difficult to obtain a specimen for test, and in many cases next to impossible, because of the cost of the numerous tests, the wasted material, the time lost, and the inconvenience. In metal, all these tests are not necessary as the physical properties are controlled throughout its manufacture and treatment. If treated identically the properties of two runs of metal will be the same, and all parts made from standardized metals and treatments can be counted on to carry the same load and individual tests are not required.

The fire risk is another all-important factor in aerial transportation. Metal has the advantage over wood in this respect, and if the ship is all metal the only fire risk is due to the fuel and inflamable upholstery.

Another advantage of metal is in the event of a crash the passengers and crew are not subjected to the effects of broken and splintered wooden members, whereas metal members will usually bend and crumple and not break and splinter. This has been effectively proved in the case of wooden and steel railway coaches. Metal has many other advantages, such as the effect of weather on the structure, cost of production, labor, handling, production practice, bulk, waste, and of course, a structure with a much improved strength-weight ratio.

Of course the problem of corrosion of metals has to be met, and it is believed that if the proper preventatives are made very little trouble will be experienced from corrosion. Two vital problems in all-metal construction are the choice of metals and the type of structure. The metal to use in any part is a function of the type of part, the service for which the part is intended, the strength required, standardization, the weight allowable, and the cost allowable. However, even after consideration of the above functions, it is sometimes a rather difficult question. The two metals that seem to have been adopted by the designer, and which have been almost universally used are alloyed steel and aluminum alloys.

In both the United States and England steel has been used to a great extent, however, in different forms. The English are very favorable to structural members built up of highly alloyed high tensile-strength steel. These members are usually made up of very thin steel strips fabricated into various sections by rivets. Thus, material that has been thoroughly heat treated may be used, and in almost all cases the heat treating is done before fabrication. Stainless steel is also very popular. In the United States the use of steel has been in the medium steels in the form of tubes and in built-up fittings, nearly all steel parts being fabricated by welding.

The use of aluminum alloys is becoming more and more prevalent every day. Several manufacturers both here and abroad are building ships constructed entirely of duralumin with sections made from bent sheet metal fabricated with rivets. All the

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

problems connected with duralumin have not been solved as yet, but this metal has wonderful possibilities.

The form of the structure is of utmost importance. The problem seems to be whether the structure should consist of a skeleton framework which carries the loads, and is covered with a skin that merely makes the form of the ship, or whether this skin should be made to do double duty and also carry the loads, eliminating the skeleton framework. There is an increasing demand in modern airplanes for cleaner and better interiors with more unobstructed space. The answer to this is to put the skin to work and use monocoque construction, which eliminates all these interior members. More total and more unobstructed room is possible with the same outside dimensions, expensive flairing is eliminated, and better lines and contours are possible. Since a skeleton structure is a series of stressed members joined with a series of bulky joints and connections, it will run into more weight than will a single unit structure where there is no multiplicity of joints, and where the stressed material is farther away from the neutral axis and consequently does more work. In other words, a monocoque structure will show up more favorably in a strength-weight comparison. The classic example of this type of structure is the egg, whose shell has phenomenal strength yet is very thin and light in weight.

To date there has been little real work on all-metal monocoque structures. Some companies have done some research work on the problem, and one or two have built some experimental ships and a very few are now under construction. Quite a number of ships with wooden monocoque fuselages have been manufactured. Most of the work that has been done has been on the fuselages, but the wing as well might be of the monocoque type.

There are two kinds of shell-type construction, the full monocoque and the semi-monocoque. The full monocoque consists of a shell in which transverse diaphragms or bulkheads are placed. These are placed along the longitudinal axis of the shell at certain intervals determined by design characteristics and loads. The direct longitudinal, torsional, and resulting diagonal stresses are carried by the shell alone while the bulkheads are subjected to only the shear load. These buklheads also hold the shell in shape and act as formers. The semi-monocoque structure is the same as that outlined except with the addition of longitudinal stiffeners that carry some of the direct stresses, leaving the shell or skin to take care of the diagonal and torsional loads. The diagonal loads in each case are a result of the shear load.

This type of construction may be used for wings as well as for fuselages. Wings of monocoque construction will run much lighter per square foot of surface than will an all-metal wing with skeleton structure. While an all-metal full-cantilever wing will weigh in the neighborhood of 2 lb. per sq. ft., a monocoque wing will weigh only about $1^1/_2$ lb. per sq. ft. However, even this figure may be reduced if the wing is continuous from tip to tip and there is no break in the monocoque structure. It has been the author's experience with monocoque wings that they will weigh much less and simplicity will be gained if the wing is continuous.

One of the greatest problems encountered in a wing built in sections is the picking up of the load in the stressed covering and concentrating it on fittings. By a wing built in sections is meant a wing whose outer portions are fastened to a center section. Not only is the analysis very difficult, but the connection itself becomes heavy. Nearly 20 per cent of the total wing weight can be charged to the load-pick-up members and the fittings. If the wings are continuous, they can be fastened to the fuselage or cabane by means of cradles and slings. For instance, with a high-wing monoplane, a cut out on top of the fuselage would form a cradle on which the wing could be placed. Then metal bands or straps could be placed over the top to hold the wing on. Small lugs could be fabricated on the covering and then could be attached to the fuselage and to the hold-down straps to keep the wing in exact position. All the direct stresses due to lift, etc. would be taken either directly on the fuselage or by the straps. On the other hand, if the entire wing is to have only its outer portion of the monocoque type and the center section is to consist of spars in order to hold engine nacelles or landing gear, some means of attaching this shell and outer portion to the skeleton structure must be devised. The conventional wing consists of two spars and usually, if the wing is cantilever, there will then be four wing fittings on which to attach one-half of the whole wing on one semi-span section. Hence, the load must be picked up from the stressed covering and concentrated at four points. Then the load must be divided between these four points. Not only is the problem of picking up the stresses difficult, but proportioning the load in the correct manner among the fittings is difficult.

The manner of analysis of any monocoque structure is always open to question. That of semi-monocoque construction is not especially difficult if fundamental mechanics are applied to longitudinal stringers and transversal bulkheads, but with full monocoque construction the fundamental relations do not always hold. The exact path of the forces and stresses is not always known, and due to the many interruptions in the shell due to holes for various purposes these stresses cannot be traced. Several universities are equipped with light projectors with tourmalene lens which project polarized light through models of these structures made of pyrolin. Small loads are then applied to the model. The image thrown upon the screen will then show dark "tracers" indicating the flow of stresses and the highly stressed portions of the shell due to the loads applied. A great deal more work could be done in this direction and perhaps a new set of fundamental relations could be set down for use in analyzing and designing stressed shell structures. The kind of skin used in this type of structure is open to debate. Several engineers stick steadfastly to corrugated covering while others are exponents of flat skin stiffened by stringers or thin drawn sections fabricated to the skin or individual channels or corrugations riveted together. Sometimes, the question of cost, production, utility, availability, and various other considerations are the determining factors. The logical solution seems to be in the corrugated covering with the corrugations running parallel to the longitudinal axis of the structure, and their being covered over by very thin flat sheet metal. This flat sheet on the outside not only produces a very pleasing appearance, but also holds the corrugated covering into form, and makes a very rigid structure indeed.

Perhaps it may be interesting to outline briefly the procedure followed in making an analysis of a pure monocoque wing. This is a full cantilever wing fastened to the center section by four pin joints. First the type of covering must be chosen. As mentioned before this covering may consist of corrugated sheet metal with whole sheets corrugated, of channels, or of individual corrugations riveted together, or of flat sheets which have been stiffened by the addition of various forms of small bent-up sheet-metal stringers. At any rate, several tests should be made to determine the mechanical properties of a standard section. For instance, the covering might consist of a number of bent-up channels riveted together by their flanges, these channels running along the span and inside of the wing leaving the external surface smooth.

In the analysis the load on the wing is not generally taken in two planes as in the conventional wing. The lift and drag loads for all conditions are combined into a resultant load. This resultant load in its direction is the load used for analysis. The resultant component of the dead weight of the wing and the net air load per pound per inch run is plotted against the span in

inches. This curve is integrated once to find the shear at any point along the span, again to find the bending moment, and twice more to find the deflection of the wing at any point along the span.

The wing, in most cases of cantilever construction, is tapered. Sometimes only in either plan or thickness, but often in both. The moment of inertia of the stressed skin around the wing section must be calculated. This is really not very difficult. First, the centroid and neutral axes of the wing section must be located. The skin is then divided up into small individual sections, such as one channel, in the case of a wing built up of channels. The characteristics of each individual section is usually known. The axes are drawn through the centroid of the wing section, one parallel to the chord line. One is then known as the horizontal axis and the other the vertical axis of the wing section. The moment of inertia of the skin of the wing section is then calculated about each axis. The sum of the inertias of the individual channels and the areas, times the distances to the axis squared will give the moment about any axis.

Using the formulas: $I_x' = I_y \sin^2 a\ I_x \cos^2 a$

$$I_y' = I_y \cos^2 a\ I_x \sin^2 a$$

The moment of inertia for the wing section is found with the axes in any direction where "a" is the angle through which the axes are rotated. Then using the equation for bending, Mc/I, the maximum fiber stress may be found that is imposed on the stressed skin at the point of the wing where the wing section is assumed.

The ideal conditions would be, of course, to have the fiber stress on the wing remain constant throughout the span of the wing. This can be done by varying the amount of thickness or plan taper, or both. If one is fixed, the other may be varied. However, equations may be set up with both as variables, and the shape of wing determined giving the most area with the least amount of metal. The maximum allowable P/A and fiber-stress value is determined by individual tests and these values, along with the load carried, and the area, are constant. So in reality one solves only for the plan and thickness-taper ratio.

The moment of inertia will change with the wing section, and will vary all along the span. This value must then be calculated at numerous points along the span and plotted in $^1/_4$ inches against the span in inches. The value of "c," the maximum distance the metal is from the neutral axis, is plotted in inches against the span in inches. This curve will, in nearly every case, be a straight line.

The fiber stress can now be calculated at any section along the span by the basic formula. The values of I, c, and M are taken from the charts at any given point along the span and f_s is calculated. If the fiber stress is calculated at a number of points along the span, and plotted against inches along the span the efficiency of the structure is seen. The ideal condition would be to have the maximum fiber-stress curve a straight line with no slope. In other words, the maximum fiber-stress should be as close to the maximum allowable, and constant throughout the span.

If these conditions are not met and it is not feasible to change the plan form or the thickness of the wing further, it is possible to correct by varying other things. For instance, the gage of the skin can be changed at various parts, thus changing the area of the individual sections and in turn changing the total value of I of that particular wing section. If channels or built-up sections have been used, the flanges could be made longer.

The maximum allowable fiber stress has been mentioned. Sometimes this value is rather difficult to determine. It is a function, in the wing, of the spacing of the transversal diaphrams or bulkheads, and the material and shape of the individual section itself. It was mentioned that tests should be made to determine the strengths of individual sections that make up the skin. These tests should be similar to those made by the Materials Division and published in Air Corps Information Circular No. 598. These tests consist of sections tested as columns. These columns are of various lengths and of different gages of sheet material bent up into shape, giving P/A and f_s values of the sections for various L/ρ ratios. In making these tests several considerations must be made of the installation of these sections in the wing. For instance, if the channels are to be riveted together, individual tests, as shown in the circular, are reasonable, but if the stressed covering on the wing is to consist of corrugations or of sections bent from one sheet, testing individual corrugations or sections will introduce losses due to the free edge of the test sepcimen. Whereas, in the actual wing, the corrugations or sections would have no free edges and consequently be stiffer and stronger... Hence, in tests of corrugations or a number of individual sections bent up from a single sheet, more accurate results can be made by having the test specimen include several individual sections.

Another problem is the type of fixity to be used during test. The Materials Division used knife edges for the ends in the tests in circular No. 598, but where these sections are to be continuous throughout the span, squared ends will probably suffice. This type of end will give a column fixity of between $1^1/_2$ to 2 according to the individual sections. All these results should be plotted. A very good method is to plot the P/A value of any given section against L/ρ ratios varying from lengths over radius of gyrations of 10 to 150.

Transversal bulkheads are heavy in any case as they must be designed to carry the vertical shear of the structure at their location. Hence, the fewest number that it is possible to use will help produce a light-weight structure. Since these bulkheads are used to fix the lengths of the columns of the skin the determining factor of their spacing is that consideration, but the longer the column the lower the allowable fiber stress, and the heavier the skin must be. So here again an optimum value of this spacing must be found to produce the lightest weight structure.

It is often noticed on the curves of the test specimen that the allowance stress on the specimen drops off rather slowly as the L/ρ ratio is increased up to a certain point. After this point the stress drops off very swiftly. This point will indicate a certain length for any given individual section and very often this length will have its effect on the choice of bulkhead spacing.

Now, having all this data plotted and compiled and having applied it to the design, there should result an ideal wing designed accurately to fill exacting requirements. However, the exact behavior of such a structure is not always known and perhaps the design data outlined above will not foretell the results. All strength calculations are based on the characteristics of the individual sections whether they are channels or corrugations, regardless of their form. When these are all fabricated and formed into a wing or fuselage their characteristics are very apt to change somewhat. To what extent depends on several things. The ratio of skin thickness to the cross section, and the ratio of the size of each individual section to the whole section are among the most important considerations. The effect of these items and the effect of the shape of the cross section of the whole structure will introduce a factor called a form factor. This form factor can only be determined by test. In most cases the structure will be stronger as a whole due to the form factor and especially so if there are several radii in the section. A section with circular form or an eliptical fuselage increases with calculated strength considerably, much more than most sections, with the exception

of those having reverse curves. Sections that have reverse curves usually are exceptionally rigid in bending.

These remarks have been directed toward structures subjected to pure bending. In the case of a fuselage where the rudder is mounted on top, a torsional load is applied as well as a shear load. The form again is an important item. In a perfectly round section or in the eliptical fuselage section, the structure will have great torsional rigidity but in a flatter section or one in which there are reverse curves the rigidity is not so great. It has been the authors experience in testing a number of sample sections of various forms and cross sections that a torsional load in addition to a shear load which carries bending, will not materially reduce the fiber stress and consequently will not greatly reduce the total load carried.

This monocoque type of structure has proved to be very interesting and the results of the effects in its direction have been very gratifying. With the presentation and confirmation of a few new basic formulas and a way of predicting accurately a form factor for this type of structure, no reason can be seen why, in the future, the monocoque type will not become extremely popular, and there will be better airplanes carrying bigger pay loads with a faster service.

Discussion

JOSEPH S. NEWELL.[2] The writer hesitates to discuss this paper because his own ideas as to the merits of all-metal airplanes are in such a turmoil that he finds it difficult to present them to his own satisfaction. Within the past three months he has discussed the relative merits of various materials and various types of construction with designers in the East while his colleague, Professor Niles of Stanford University, made similar inquiries in the West. The results obtained were compared during the recent aircraft show at St. Louis.

The following opinions, all of which were obtained from engineers and designers of considerable repute, will indicate the reason for the writer's hesitation and they will, he feels sure, indicate the almost total lack of dependable facts on which to base all-metal airplane designs.

Regarding durability of materials it was found that aluminum alloy properly heat treated plus anodic treatment plus an oxide primer plus enamel or varnish was as good as alclad, if not better. From another source it was found that aluminum alloys could not be protected against corrosion in service by any means so far discovered, and the opinion was expressed that stainless iron would be the solution for the durability problem. On the other hand it was stated that salt-spray tests on the thin-gage sheets of stainless iron, which were required to give a structure of practicable weight, indicated that its rate of corrosion was very nearly the same as for the aluminum alloys. The most definite opinion came from one of the most experienced designers in the industry. His idea was that for durability and economy of maintenance Sitka spruce was most suitable for aircraft.

Regarding the efficiencies of different types of construction some engineers advocated the use of stiffened flat sheets, some offered corrugated sheets. Opinions as to the behavior of flat sheets with stiffeners also varied. Some engineers maintained that the skin carried most of the load, others said that it was extremely inefficient and that the stiffeners were the structural members that actually carried the loads. The writer has test data from which one may draw either conclusion, and until the preliminary tests now being conducted by some of his students at Massachusetts Institute of Technology are completed he reserves his opinion.

[2] Associate Professor of Aero-Structural Engineering, Massachusetts Institute of Technology.

He does, however, wish to differ with the author on the subject of metal permitting a closer degree of accuracy in design than wood. He admits that wood has varying properties, but he would like to emphasize the fact that the variations are such that the strengths average above rather than below the specified values for wood that passes Army and Navy specifications. It is true that a great deal of understrength spruce has been purchased by various commercial manufacturers during the past three years, but that is less the fault of the material than the inspection. The admirable work of the U. S. Forest Products Laboratory which has given form factors, allowable stresses, and specifications for spruce and other woods, all of which contribute to dependability and lightness in conventional design, can be nullified neither by statements regarding the difficulty of obtaining test specimens in wood nor by expatiating upon the dependability of metal due to the fact that the physical properties are carefully controlled throughout its manufacture and treatment. At least it hardly seems possible that such should be the case so long as mild-steel tubes will show up satisfactorily in chemical tests yet have a modulus of elasticity as low as 18,000,000, nor while the properties of stainless steels vary over so wide a range as they do at present. The modulus of elasticity of one set of specimens with which the writer has become acquainted varied from 26,000,000 to 34,000,000 lb. per sq. in., and the modulus of elasticity, it is hardly necessary to remark, is usually regarded as the most constant of the properties of metals.

As for the virtues of full-monocoque versus semi-monocoque construction it is again difficult to state which is the better. A recent set of tests indicates that flat sheets stiffened along the edges, but having no intermediate stiffeners will carry practically the same load in compression regardless of their width. This is contrary to elastic theory. These tests were fairly comprehensive as they were run on four different materials, various gages were used, and widths ranged from 4 in. to 24 in. in 4-in. increments. All specimens were 24 in. in length along the axis of loading. Very meager data on stiffened sheets, on the other hand, indicate that with a 4-in. spacing of stiffeners, a flat sheet 12 in. wide will carry the same load that would be taken by three 4-in. sheets stiffened along the edges plus the load which would be carried by the stiffeners acting as columns. These data are extremely meager and further tests may necessitate revising the above conclusions, but if it is true one is forced to conclude that full-monocoque structures involving flat sheet in compression are impracticable. Here again nothing can be established definitely due to lack of test data.

Such data are sorely needed and until aeronautical engineers possess allowable stress data comparable to that now available for the design of spruce members or of steel tubular members it is doubtful that efficient all-metal structures can be proportioned without involving expensive tests on minor parts and on major assemblies. Civil engineering practice from which most methods are derived, has nothing to assist with the thin-gage, highly stressed materials. The author states that tests must be made to determine the strength of individual sections that make up the skin. They most certainly must. The Army Air Corps has recently completed a series of tests on corrugated sheet carrying compression, and has done some work to determine relative torsional stiffnesses of box-shaped structures simulating the spars, ribs, and skin of a metal wing from which the leading and trailing edges have been removed. It is expected that these data will be published shortly and they will be of great utility since they will furnish some allowable stress data. Parallel studies of stress distribution in similar box structures subjected to torsion have been made on Zylonite models in the photo-elastic laboratories at the Massachusetts Institute of Technology. The results are now being prepared for publication.

Service for Airplane Engines

By C. H. BIDDLECOMBE,[1] NEW YORK, N. Y.

Properly equipped service stations with competent mechanics are being established at some of the principal airports to take care of airplane maintenance. These have been found necessary by airplane-engine manufacturers in order to protect both their own interest and those of the customer. The work varies from a simple engine overhaul to complete rebuilding of large aircraft, and includes such items as packing and loading large airplanes for export shipment; designing and building gliders; dismantling, trucking, and reassembling airplanes for aviation shows; demonstrating airplanes to customers, and many other details, but not including the making of new engines and airplanes.

It seems probable that the major overhaul stations will eventually function on lines similar to those of present wholesale jobbers in the automotive industry with dealers doing all repair work, and buying necessary spare parts from jobbers in the territory in which they operate. Engine manufacturers look forward to having service representation at every active airport. The author tells of various methods and equipment used in overhaul work and the care necessary to ensure satisfactory operation.

THERE is no surer or quicker method of preventing sales than failure to provide good service facilities. Until 1929, there was practically no widespread organized system of customer service for any airplane engine on the market, due of course to the fact that the comparatively few airplane engines in use were either closely grouped in the hands of a few large customers or owned by individuals who were capable of doing most of their own service work. The manufacturers' share in keeping these engines running was thus based on a spare-parts supply department at the factory and the activities of a number of traveling service men who went from customer to customer as required. This method was in use by the Wright and Pratt & Whitney companies, for example, both these firms having service men on the factory payroll, but traveling over the country and remaining with various customers long enough to deal with sundry engine troubles and overhauls as they occurred.

The Wright company's service men earned well-deserved fame by their efficiency and far-flung travels during the years prior to 1929, being sent out to customers at the North Pole, Australia, Europe, South America, etc., and one such man accompanied Admiral Byrd on the South Pole expedition. In fact, to a very large number of customers, such men as Ken Boedecker, Eddy Mulligan, Doc Maidment, and Doc Kinkade *were* the Wright Company. This system of service representation by individual factory employees was satisfactory when only a few engines were in existence outside the army and navy flying services and the large fleet operators of aircraft. This centralization of engines in the hands of a few large customers resulted in comparatively little service work being required by factory men in assisting the mechanical staffs of such customers. The practice of training mechanics employed by these customers for a brief period at the engine factory also simplified the service question. With the great increase in private ownership of engines, however, it became at once necessary to adopt a different method of giving customers service, as the factory could no longer be expected to carry the very large number of men required to cover the whole United States and a large portion of other continents. Some idea of the increase in the demand for service from engine makers may be gathered from the figures for engine production during the years 1926, 1927, 1928, and 1929; these being 834, 1397, 3263, and 7378 engines, respectively.

The 1929 production increased 126 per cent over 1928, and was nearly nine times that of 1926. Of even greater significance to the service problem is the fact that the military engines produced in 1929 exceeded those for 1928 by only 448 engines, or 32 per cent, whereas the commercial engine production went from 1850 engines in 1928 to 5517 in 1929, an increase of 3667 engines, or 193 per cent.

The horsepower of the engines produced is also an important factor, as the smaller engines are obviously more likely to be owned by individuals or small operators needing widespread and efficient service. This need looms large when it is seen that of the 5517 commercial engines built in 1929, no less than 4113 were of 300 horsepower or less, with 3082 of them between 76 and 225 horsepower, exactly the class for which service is of great importance.

With these figures to consider, it becomes clear that the establishment of authorized and properly equipped service stations, manned by competent personnel, was urgently needed as a support to the limited number of factory employees that could be sent into the field. The first steps to this end were taken by the Wright Aeronautical Corporation as early as the end of 1927, when negotiations were started in Los Angeles to locate a complete service station there to take care of customers on the Pacific Coast. It had long been evident that it was impracticable to provide satisfactory service to an ever-increasing number of private owners and smaller fixed-base operators situated nearly 3000 miles from the plant at Paterson, New Jersey.

Preliminary arrangements were made with the Pacific Airmotive Corporation of Los Angeles to act as service representatives early in 1928. This firm thus was the first fully equipped

---

[1] Consulting Engineer. Mr. Biddlecombe is British-born and took out his first papers for American citizenship on July 8, 1927. He served in the British Navy, 1906 to 1915; was transferred to Royal Flying Corps May 6, 1915; served as pilot and on administrative and executive duties 1915 to 1918 in England, France, Egypt, Italy, and Palestine. He was detailed to staff of Controller-General of Civil Aviation (Sir F. Sykes) in December, 1918, with acting rank of Major, Royal Air Force. From December, 1918, to January, 1926, Mr. Biddlecombe was engaged in the development of commercial aviation throughout Europe and the British Empire. He came to the United States in February, 1926, on leave of absence, and joined the Colonial Air Transport, then being formed, as Operations Director in March, 1926. He organized and managed operations of Contract Air Mail Route No. 1 from April, 1926, to August, 1927. He made a tour of the United States and Eastern Canada for the Wright Aeronautical Corporation to survey the whole aviation industry to determine the engine market for 1929 and 1930, remaining with the Wright company in charge of sales promotion and advertising until November, 1929. He has since continued his own business as aeronautical consultant engineer.

Presented at a meeting of the Metropolitan Section of the A.S.M.E., New York, N. Y., May 8, 1930, sponsored by the Aeronautic Division of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

independent organization to act in the capacity of airplane engine manufacturers' repair depot, as far as the author is aware, who from March to October, 1928, had an interesting and pleasant assignment to travel over the greater part of the United States for the Wright company in order to recommend locations and corporations to act in a similar capacity at other places.

During the course of these journeys, the pressing necessity for local service depots by any engine manufacturer hoping to remain in business became obvious to a marked degree. Trivial engine troubles that were curable in a few hours by an expert factory-trained mechanic assumed alarming proportions and a greatly exaggerated seriousness when the nearest point of contact with skilled service was a factory some hundreds of miles distant. The receipt of frantic long-distance telephone calls, hundred-

FIG. 1 AERIAL VIEW OF BUILDINGS AT ROOSEVELT FIELD, NEW YORK, OF AIR ASSOCIATES, INC.

word night letters, and finally acrimonious correspondence from the customer caused much worry and considerable expense to both engine maker and customer. In an appreciable number of cases of engine trouble, it was found that the customer was solely to blame for his troubles. One airplane owner complained long and bitterly to the factory that his engine was completely useless, that something was broken internally, that it vibrated terribly, and that he was entitled to a new engine free of charge at once. A factory service expert found that the propeller on the engine was very loose, the customer's mechanics having forgotten to tighten the locking nuts. Within ten minutes the engine was running perfectly.

Loose spark plugs, some even falling out in the air, loose oil, and gasoline pipes and joints, empty oil and gas tanks, unsuitable low-grade oil and gasoline were some causes that produced scores of hurry calls to the factory, and, of course, some unique alibis from careless or insufficiently educated mechanics. Another particular incident of instructive type occurred when a famous transatlantic pilot and another almost equally well-known set off from New York to Washington. When nearing Baltimore, the oil temperature rose alarmingly and the oil pressure decreased with equal rapidity. Good fortune and good flying landed the airplane on the Baltimore airport. Inspection of the oil tank by pilot No. 1 brought the exclamation, "We are out of oil, didn't you put any in this morning?" The reply was "No, I thought you did."

Instances of this kind were frequent, but it is probable that the chief troubles experienced by the majority of engine makers were caused by faulty installation of engines into airplanes. Again and again, it was found that in the desire to avoid work and save time, airplane factories installed engines in their planes in such a way that constant engine troubles were inevitable. The engine cowling made by the airplane manufacturer was frequently designed so that it was impossible for a cooling airstream to reach the cylinders; oil tanks were placed so that the oil was always overheated on warm days; parts of the engine were removed, particularly carburetors, and replaced so carelessly that they either did not function or fell off after a few hours' running.

Another prolific source of trouble to the engine maker was the use of unsuitable oil and gasoline, usually due to the engine owner having mistaken ideas on the matter of real economy in the purchase of these materials. In one case of this kind, the cylinders of an engine were worn 0.025 in. oversize after 700 hours' use. This rapid wear was traced directly to the use of a very poor oil and failure to clean the oil system and provide fresh oil at reasonable intervals. As a contrast to this, there are a large number of engines which have had over 1000 hours' service with no appreciable cylinder wear, but good oil and proper care has been used in their operation.

One of the chief troubles experienced with poor oil is the formation of an excessive quantity of sludge and carbon, leading to the blocking of an oil hole or the complete clogging of an oil screen. The author's experience while operating an air-mail line included an example of this nature; the result was major

FIG. 2 ASSEMBLING A THREE-MOTOR FORD AIRPLANE IN THE REPAIR SHOP OF AIR ASSOCIATES' PLANT AT ROOSEVELT FIELD, NEW YORK

damage to an airplane and the wrecking of an engine due to the seizing of a cam-ring bearing, which followed the stoppage of oil passing to the bearing through small holes which had become blocked by sludge and carbon particles. A particular make of oil which met the recognized standard specifications was being tested under actual service conditions, and failed to stand up. It is probable that the asphalt-base oils are more liable to this excessive carbonization and sludge deposit than those refined from a paraffin base; at least, such has been the author's experience. Gasolines unsuited for aircraft engines, particularly air-cooled engines, have also produced many service difficulties, especially a few years ago when high-grade aviation gasoline was not widely distributed. Conditions are much better today and excellent gasoline can be obtained at almost every airport. There is, however, still a danger of burning out piston heads and wrecking an engine if poor fuel is used in an emergency and this still happens occasionally.

The work of the engine service stations includes advice and

instruction to private owners on the very important question of using only proper fuel and oil and avoiding the risk of injury to life and property in attempting to save a few cents per gallon on these items.

A further minor source of trouble to the engine maker was the use of unsuitable accessories on engines and the maladjustment of proper accessories. Examples are the use of spark plugs of a type that are not approved by the engine maker and which fail constantly in service, also the use of poorly made high-tension wiring when this is renewed after an overhaul. In both cases the ignition system fails to function properly, and unless the mechanic in charge of the engine is a thoroughly experienced man, the engine maker is usually blamed for the trouble.

Many engine makers recommend and fit to their engines as standard certain makes of starters, generators, magnetos, and carburetors. In some cases the approved makes have been mal-adjusted and thus failed to operate correctly. In such cases, the engine owner invariably turned first to the engine manufacturer as the source of his troubles, and the responsibility of getting the engine running properly was generally accepted by the manufacturer, but this acceptance of the results of lack of knowledge on the customer's part could not, of course, be continued indefinitely owing to the great increase in the number of engines sold.

These general considerations emphasized most strongly the immediate need for a wholesale expansion of engine service facilities. Engine manufacturers were obliged to hasten the completion of their plans to provide universal service and widespread education in the proper use of their products in order to protect both their own interests and those of the ultimate customer.

The basic question to be answered when contemplating the

Fig. 3 Main Building of Air Associates, Inc., at Roosevelt Field, New York

setting up of a service organization is obviously the extent and location of the market for the product to be serviced. A map with pins at points where aeronautical activity is most prevalent will show many cases where towns are close together. It is equally important to know the number of airplanes in use at each particular airport. The map is divided into areas of varying size, each to be serviced by the town where flying activity is greatest in that area, and which may or may not be approximately in the center of the area. In the case of Canada, the Canadian Wright Company, manufacturing engines under license from the Wright Aero Corporation, provides service for that country, with headquarters at Montreal. A station at Mexico City is entrusted with service matters in Mexico and adjoining territory, while South American customers rely on service and spare parts from traveling factory employees pending an increased use of the airplane in that part of the world.

Throughout the United States 10 major service stations are located at Chicago, Kansas City, Boston, Philadelphia, Los Angeles, Atlanta, St. Louis, Fort Worth, Cleveland, and Memphis. In addition, there is a very completely equipped service division at the main plant of the company at Paterson, N. J. Each of these depots is equipped to give a complete engine overhaul, including cylinder grinding to oversize, etc., and a complete stock of spare parts is carried which is replenished from the factory when necessary. As a general rule, one or more of these 10 major stations is within three hours' flying time of any airport on which Wright engines are normally based. In some few cases, the base of operations is further removed than this distance, but under these circumstances, the operator himself is capable of effecting all normal repairs, and can also give service in emergency to other individuals who may be in trouble in the area near his base.

In the selection of representatives, it is necessary to use the greatest care as to their financial stability, experience in busi-

Fig. 4 Chicago Service Plant of Air Associates, Inc.

Fig. 5 Front of Service Building at Chicago Municipal Airport

ness of a nature somewhat similar to that under discussion (such as the operation of a high-grade automobile repair agency), knowledge of aeronautical matters generally, and last but most important, integrity of character. This latter point is capable of exercising a wide influence on the continued success of a manufacturer's sales in any business where a service system is used, but is particularly important to the airplane-engine maker. The results of careless work, unfair prices, and use of "pirate" spare parts not up to specification in order to increase profits temporarily, are likely to be disastrous both to the customer thus cheated and to the engine manufacturer.

It is trite to say that the oceans of the air, like Father Neptune, are unforgiving opponents to those who make mistakes; there is no back door and few alibis when an airplane engine fails at a critical moment, so that human lives and the welfare of great engine factories are to a great extent dependent on conscientious work by the service stations. It is of interest to note in passing that the airplane accidents caused by power plants in the last six months of 1928 and first six months of 1929 were about 16 per cent and 18 per cent of total accidents, respectively. These figures leave room for improvement, but indicate that the average man entrusted with engine maintenance and overhaul is doing a good job of work.

Having settled exactly where the service stations are to be located, the next step is to agree on the terms of a contract with the personnel to whom a service and spare-parts franchise is to be given. This stage of affairs should not be hurried nor

regarded lightly by the management of an engine factory who wants to retain customers. In addition to the considerations previously outlined, there are numerous questions of policy to be settled in arriving at a contract mutually satisfactory to the service agency, the factory management, and the customer.

Of these, the scale of discounts to be applied in the distribution of spare parts is perhaps of the greatest importance and likely to cause most difficulty in the absence of a clear understanding from the start of business relations. It will be appreciated that the 10 major overhaul stations given cannot provide a sufficiently wide distribution of spare parts to satisfy the needs of aviation as a whole; it is necessary also to place stocks of spares at numerous other airports throughout the country, together with facilities for minor overhauls. In the case of the Wright company, about 100 such smaller depots are in operation, and for convenience, the 10 major stations may be referred to as distributors and the minor stations as dealers.

Furthermore, there are to be considered the large transport companies operating a fleet of aircraft with a great number of one particular maker's engines; in addition, the small fixed-base operator with a smaller but still appreciable quantity of engines of one make also needs thought in drawing up a scale of trade

FIG. 6 ENGINE OVERHAUL DEPARTMENT OF AIR ASSOCIATES SERVICE PLANT AT CHICAGO MUNICIPAL AIRPORT

discounts. At the end of the line comes the private owner and the operators of a very few engines for whom the manufacturer's list price on engines and spare parts is established and maintained. The primary object in reaching and maintaining a scale of discounts is, of course, to protect the distributor and dealer against unfair competition, and to allow a sufficient price differential to permit these agents to remain in business while giving efficient service to the factory customers. It is evident that the fairly impressive investment and superior type of executive and mechanical personnel required in the conduct of a service station business cannot be attracted unless a reasonable margin of profit is available. In this connection, it should be noted that the caliber of men and standard of work required in the manufacture and overhaul of airplane engines is much higher than that normally found in other industries. As stated previously, the result of cutting costs too far by using low-grade labor or material is more likely to be a dead customer than one who is merely dissatisfied. Per contra, list prices must be competitive and large customers permitted to exercise their quantity purchasing powers if sales are to remain satisfactory.

There is ample precedent, both good and bad, to guide in drawing up contracts of this kind between airplane-engine builders and their distributors, so that one can pass over the existing practices in this field by remarking that the discount policies in force by the Wright, Pratt and Whitney, and Curtiss companies, for example, are roughly comparable each to the other and are based on the experience of automobile makers.

A second important factor in the relationship between the factory and its representatives is the extent and financial detail of free service and replacements to customers. This portion of a distributor's business is likely to be of fair magnitude at times, particularly immediately subsequent to the introduction of a new model engine. A clear agreement as to the division of expenses incurred in this type of work is of value when discussing matters prior to the granting of a distributor's franchise. The remainder of the items involved in reaching agreement on the franchise are of a more or less routine business nature, such as terms of payment and credit, reservations regarding governmental purchases of engines and parts, re-acceptance of distributors' stocks on termination of contract, etc.

Arriving at the actual operation of a distributor's or dealer's franchise, it is well to note that up to the present, no service station of either major or minor type has succeeded in obtaining sufficient volume of business from engine overhaul and repair solely. From the brief experience gained it appears that the authorized service stations which have been in operation during the past two years have obtained from 5 to 25 per cent of their gross business from the overhaul, etc., of any one make of engine; one of the most active of these dealers has received only 5 per cent of his gross business from engine overhaul work. This situation will improve when the engine factories further develop the sale of complete engines by distributors and dealers as replacements. Up to now engine sales have been made almost exclusively direct from the factories.

As a result, the engine factory representatives appointed have in many cases been engaged in the sale of airplanes, equipment, flying clothing, maps, airplane repair work, etc.; obtaining as many agencies as possible for the sale of the multifarious materials and supplies needed on and around an airport. Other overhaul franchises have been granted to airplane operators, air mail contractors, etc., as an addition to their existing activities. Almost the only type of airport business that engine service stations appear not to have yet entered is the sale of the ubiquitous "hot-dog."

An an example of the major depots now established, one may take that of Air Associates, Inc., at Chicago, Ill. This organization has invested approximately $120,000 in buildings and equipment at the Chicago municipal airport, of which about $60,000 represents building costs. Further expansion is provided for when increased business warrants the erection of more buildings. At present this station is composed of a building 80 ft. by 160 ft. of two stories, with a hangar entrance facing on to the flying field. The airplane accommodation for service and storage purposes covers about 5280 sq. ft. and provides room for about 10 average-size aircraft; the remainder of the building is divided up into workshops, offices, etc., as follows:

	Sq. ft.
Machine shop	1890
Engine test-room	320
Airplane repair and wood-working machinery	1890
Welding and sheet-metal work	880
Doping and painting shop	800
Oil and paint store	200
Stores and stock room	1300
Instrument repair room	620
Office accommodation	1600

In addition to the repair facilities noted, rest rooms, locker, and shower-bath rooms are provided for the comfort of customers, and all equipment needed for flying purposes is on sale in the

showroom. This includes flying clothing, maps, helmets, goggles, all flying instruments, in fact, everything required by pilots and passengers. The basic policy of this service station is the provision of every possible requirement in the operation of aircraft, including the supply of airplanes of various makes for which Air Associates, Inc., holds the sales agency. This somewhat comprehensive scope of the corporation's business is necessary to produce the annual turnover which cannot be obtained from the operation of an engine repair station only.

During the busy season in the summer months, the employees number about 30 people, including branch manager, sales manager, service superintendent, aircraft repair foreman, storekeeper, mechanics, and office staff.

The machine-shop equipment includes the usual drilling, grinding, and turning machines, with presses, washing tanks, engine stands, air-pressure cleaning system, and a complete range, of the special tools designed to simplify the overhaul of Wright engines.

It is estimated that the total investment required in installing a duplicate set of machine and other tools would approximate $14,750 of which $1750 would represent special tools for Wright engines. As an average for the 10 major overhaul stations listed, it can be accepted that an investment of from $35,000 to $50,000 is needed to establish an engine repair depot capable of handling every kind of overhaul. This does not of course include the erection of hangars or buildings for more extensive operations such as those conducted by Air Associates, Inc.

This corporation also operates at Roosevelt Field, Long Island, similar service that includes everything from airplane storage, and the sale of flying requisites, to the complete overhaul of of airplanes and engines, and the rebuilding of any airplane damaged by accident.

A brief description of the operation of this station is of value in the study of service stations generally. The storage hangar is situated on the edge of the flying field, in close proximity to the field operations office, weather bureau, telegraph, press offices, and the Department of Commerce office. It provides transient storage for visitors to the field and permanent storage to sportsman-pilots and to business houses who use airplanes for business purposes solely, utilizing Roosevelt Field as their home base. At the present time, about one-third of the airplanes in the hangar are used for strictly business purposes.

Lockers are provided for the convenience of the pilots, and the hangar rental charges include such services as inspection of the airplane and engine before and after each flight, inspection of gas and oil, and re-fueling at the customer's request, movement of the airplane from the hangar to the line, starting the motor and having the airplane ready, inspected, re-fueled, motor running, and warmed up, at any time specified. When the flight is finished, the owner leaves the ship on the line; it is taken in charge by the line crew and returned to the hangar, where it is inspected and wiped down. The pilot is thus relieved of all the routine work of preparation for flight; he simply telephones, requesting that his ship be on the line with the motor running and warmed up at a certain time.

All airplanes in this hangar are subjected to regular close inspection. The flight superintendent reports immediately to the field manager every detail, no matter how small, that would in any way affect the safety or operation of the airplane. If the detail is small, and can be corrected easily, it is corrected without notifying the pilot, and at no charge to him. If the defect is of some relative importance, the pilot is notified immediately and the defect is remedied as soon as his approval is received. Under no circumstances is any ship allowed to fly unless every detail is correct and in accordance with Department of Commerce regulations.

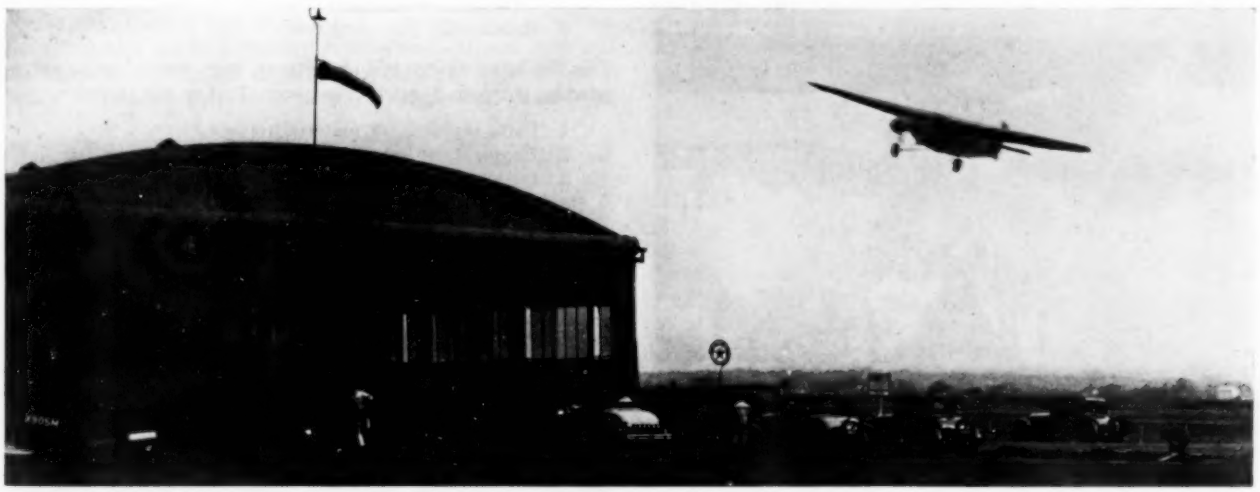

FIG. 7 WRIGHT SERVICE HANGAR AT TETERBORO, NEW JERSEY

No service work is done in this hangar with the exception of such work as washing, waxing, greasing, etc., all mechanical work, either on the airplane or the engine, being carried out in the service hangar. This hangar is situated away from the line, but in proximity to the line hangar, and can be divided roughly into four units, (1) airplane repair department, (2) welding and sheet-metal department, (3) engine-overhaul department, and (4) machine shop. One stockroom serves both the service department and the merchandise department, material being requisitioned by the service department from this stockroom as it is used on the various jobs. This stockroom also has in it the service department tool-crib, which contains all the standard small tools used by the shop, and all the special tools for motor, carburetor, and magneto overhaul. Special tools are mounted on tool boards, each board containing the special tools for one model of one make of engine. One board, for instance, has mounted on it all special tools for the Wright J-5, another board all special tools for the Wright J-6. Special tools for Pratt & Whitney "Wasp" and "Hornet" engines are kept in a large case, each tool having a separate compartment or receptacle. Com-

plete special tools for the overhaul of accessories, such as Scintilla magnetos, are kept in locked cases that can be requisitioned out as a whole and taken directly to the magneto test bench, carburetor overhaul bench, etc. All tools are taken from the tool-crib on checks; provision is made beside the position of each tool on the tool board for deposit of the check until such time as the tool is returned. Silhouettes of the tools on the tool board are colored differently for the different types of engines; thus the silhouette for a Wright J-5 valve-guide puller is black, and the puller has a black marking on it; the silhouette for a J-6 valve-guide puller is red, and the puller has a red marking on it, etc. Beside the silhouette of each tool, also, is a tag giving the name and manufacturer's part number, and it is only by means of a careful system of this kind that lost tools and needless expense can be avoided.

The airplane repair department has a two-ton hoist and

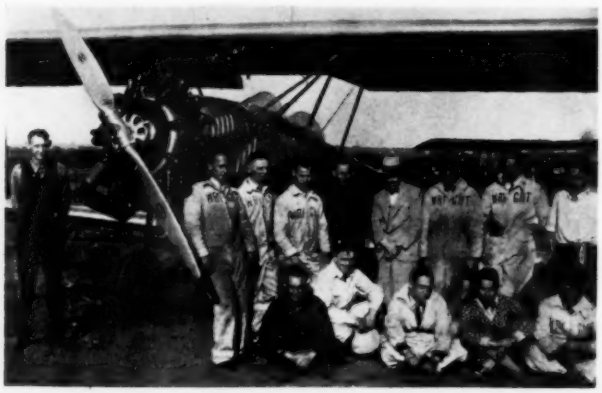

FIG. 8 WRIGHT SERVICE CREW

trolleyway running its whole length with all machinery arranged at the side, so that the maximum floor space is available. It has complete wood-working machinery, including bandsaw, universal circular saw, jointer, sander, etc. Glue mixers, sewing machine, eyelet set, and all necessary equipment for this type of work is provided; this department being equipped to do everything from putting a small patch on a wing to rebuilding the whole wing itself. Complete doping and painting equipment is installed, including cup-type guns for touch-up work and pressure-tank equipment for spray doping.

The engine overhaul department, exclusive of machine shop, occupies a space about 25 by 75 ft.; benches with maple tops run along both sides of the space and the propeller balancing equipment is located at one end. The machine shop occupies an equal space, with a large door opening from the overhaul department into this shop.

The engine overhaul department is essentially a tear-down, inspection, and build-up department. It contains no fixed tools with the exception of special master-rod reaming tools, lapping plates and fixtures, microscopes and other inspection tools, etc. It contains motor stands, on which the engines are torn down and rebuilt, and motor parts stands, on which the parts of each engine are placed and kept together.

The machine shop is equipped with all necessary machine-tool equipment, including a tool-room lathe, large and small drill presses, grinding wheels, wire-wheel and buffing stands, air-compressor, arbor presses, sand blast, spray-cleaning booth, magneto test bench, Scintilla magnet recharger, and the carburetor test bench.

A better idea of the way the equipment is used will be obtained by considering the various steps in the overhaul of an individual engine. One of the first things of interest to the customer is the price. Air Associates, Inc., was one of the first organizations to establish flat labor charges on all operations possible, and it now quotes flat labor charges on checkovers, top or complete overhaul, magneto overhaul, or any other standardized job on any of the popular models of engines. Work of complete overhaul is done on a flat labor charge; this charge will include:[6]

1 Teardown, cleaning, and inspection of all engine parts
2 All labor to recondition engine parts, with the exception of such operations as re-sleeving cylinders, re-grinding cylinders, installing valve seats, replacing rocker-boss studs, reconditioning cam and hub assemblies, installing new valve guides, etc.
3 Re-enameling all engine parts
4 Inspection and overhaul of magnetos, including re-charging the magnets
5 Reassembly and block test.

This flat labor charge includes grease, rags, emery cloth, valve-grinding compound, safety wire, etc. It does not include:

1 Parts replaced, or material replaced
2 Removal of the engine from, or installation in the ship
3 Carburetor or starter repairs
4 Gasoline or oil used for testing.

When the customer authorizes the work, he signs a numbered work order. One manila copy of this work order remains in the office of the service manager; the job number on this work order is the number on which men working on this job charge their time and against which they requisition necessary material from the stockroom. Two copies of this work order go to the office, where labor other than that done on flat charges is entered on both, and where material requisitioned on the job is also priced and entered. One of these copies is for the customer, and is given to him with the invoice when the job is finished. The other copy is a file copy, and on this copy all labor is entered, whether the job is done on a flat price or not. This gives a check as to the actual cost to Air Associates, Inc., of the work that they are selling at a flat price.

When the engine comes into the overhaul room it is torn down completely, everything of interest as to condition being noted during the process. A complete record sheet for each engine is kept up by the engine overhaul foreman from the time the engine leaves the plane until it is re-installed. This sheet contains spaces on which are entered the actual size, or the amount of wear on each part of the engine, with space for notations as to the parts replaced. A copy of this record is given to the customer when the job is finished, or is used to show him what parts need replacement during the progress of the work.

As the parts are removed from the engine they are placed in a special engine-parts rack that was developed to meet the requirements of aircraft-engine work. Each of these parts racks has space for the parts of one engine; the engine serial number is marked on a card at one end of the rack, the parts thus being kept together during the time the engine is in the shop. These racks have several shelves, and have dust-proof curtains that cover all sides; these curtains are rolled up during the time that the parts are being worked on.

The parts racks are mounted on rubber-tired rollers, and after the engine is completely dismantled the rack is run to the sand-blast and cleaning booths. A special sand-blast removes all carbon from the cylinder head and inlet and exhaust passages; a sleeve that fits the cylinder bore tightly, and plugs that fit into the valve guides, protect these surfaces during this opera-

tion. This special tool greatly reduces the time necessary for this cleaning operation, and does such a thorough job that the interior of the cylinder head is put in the same condition as when new. Another special sand-blast strips paint from the cylinders.

The parts are then thoroughly cleaned, either with Oakite or in a special ventilated booth with air pressure and gasoline. Practically all this cleaning equipment was developed to meet aircraft-engine requirements. After cleaning, the parts that can be buffed are buffed on a $1^1/_2$-hp. extended-spindle buffer; after this buffing operation various parts, such as wristpins, connecting rods, crankshaft, etc., are given a final cleaning with metal polish, so that they are in perfect shape for inspection.

When the parts have been cleaned and polished, they are brought in on the parts rack to the inspection bench, where every part is measured for wear and where all vital parts are subjected to microscopic inspection with a binocular microscope. Fillets are etched in some instances to make incipient cracks more evident, and every part is considered not only from the standpoint of being within the allowable limits of wear but also from the standpoint of being in perfect physical condition.

Many special gaging tools have been developed for this in-

FIG. 9 ENGINES DISMANTLED READY FOR INSPECTION

spection work. "Go" and "no-go" plug gages for valve guides, for instance, are made with flat sides, so that out-of-roundness can be gaged. In every instance inspection and rejection is based wholly on the permissible limits of wear set up by the engine manufacturer. In aircraft-engine work there is no place for the interjection of engineering ideas from the field except when such ideas have been thoroughly worked out by the engine manufacturer. In no case will Air Associates, Inc., deviate from the limits and instructions set up by the engine manufacturer, even at the request of a customer. Every engine turned out, therefore, is exactly as if turned out by the factory.

After the necessary replacements are determined by inspection, the rebuilding process starts. Valve seats are re-cut with special self-centering cutters, the valves are re-faced on an electric valve lapper that has been specially adapted to fit airplane-engine valves. In order to bring down the cost of an overhaul, so that reasonable flat rates can be quoted, it is necessary to utilize all possible labor-saving equipment. Where no such equipment has been available for aircraft-engine work, Air Associates, Inc., has developed it, or has adapted standard equipment so that it is suitable.

When new parts are used, each is fitted carefully so that the working clearance will be toward the lower side of the permissible limits set by the engine manufacturer. Plug gages, either purchased from the engine manufacturer, or made up

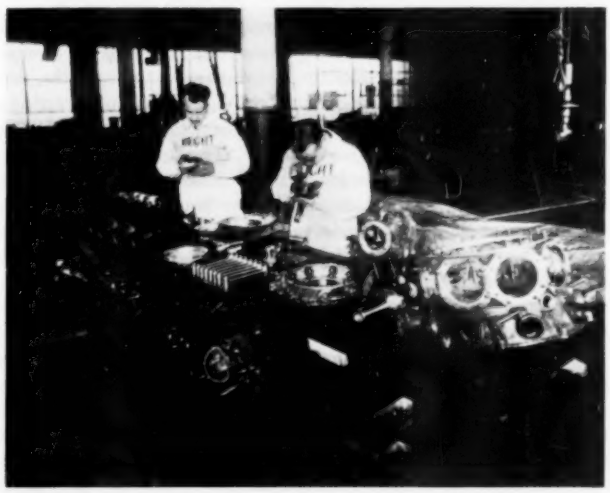

FIG. 10 INSPECTING ENGINE PARTS DURING OVERHAUL

specially, are used wherever possible. Standard tool-room micrometric equipment, cylinder gages, etc., are used freely.

The cylinders, rocker-boxes, crankcase, etc., are re-enameled, rings are fitted to the ring-grooves by carefully lapping to the desired clearance, timing is checked carefully, and when the engine is finally set up it is essentially in the same conditions as when new.

While the engine is down, the magnetos are completely dismantled and inspected, magnet readings are taken on a magnetometer and the magnets are recharged if necessary. After the magnetos are re-assembled, they are given a standard series of tests which cover a range of speed from their coming-in speed, which must not be above a certain fixed maximum, to 4000 r.p.m. Since the requirements for testing an aircraft magneto cover a much greater speed range than the requirements for an ordinary magneto, it was necessary to develop special testing apparatus for this work.

The carburetor is also completely inspected, any unduly worn parts replaced, and the float level checked before replacement on the engine. After the engine is finally re-assembled, valve timing set, tappet clearances checked, etc., it is taken to the engine test stand and given a run-in for at least 8 hr. During this period the engine is run in very carefully, and is under the supervision of an engine mechanic at all times. The instrument board from the test stand is located in a small house having windows on all sides, so that the man in charge of the engine can comfortably observe its operation during the run-in period.

During, and after, this run-in period adjustments are checked and the engine is ready for installation in the airplane after a final thorough check and inspection by the service superintendent.

The service hangar also contains an instrument repair room complete with all necessary testing equipment, where flying and engine instruments are inspected, tested, and repaired as required. In addition, a parachute packing-room in charge of an expert undertakes the inspection, repair, and periodic repacking of parachutes and the proper fitting of parachute harness.

The airplane repair division includes a welding and sheet-metal department equipped to handle any work from a minor repair to a steel axle or the making of a small section of engine cowling, up to the rebuilding of a large all-metal transport airplane. Complete stocks of duralumin sheet and tubing, Alclad flat and corrugated sheet, aluminum sheet, and tubing in various tempers, duralumin and aluminum rivets, etc., are on hand at all times, together with supplies of S.A.E. 1025 carbon steel and 4130X specification chrome-molybdenum sheet and tubing.

All repair and overhaul work is carried out in strict accordance with the regulations of the Department of Commerce, and is always subject to inspection by the representatives of the department. An engineering division provides data and drawings when it is necessary to submit any particular repair job for Department of Commerce approval. The merchandising division of the station includes a retail store and a wholesale department that supplies dealers in the trade territory of the station, shipments being made to all parts of the United States and to many foreign countries. Every conceivable practical airplane necessity is handled by this merchandising division, from cotter-pins to complete airplanes, including spares and parts for engines, starters, generators, magnetos, carburetors, propellers, etc. A card-index system is used for a perpetual inventory record and control. One of the major problems in the operation of such a widely diversified business is the gathering of personnel capable of handling the varied jobs that come to hand. These jobs range from a simple engine overhaul to the complete rebuilding of large aircraft; and include such items as packing and loading large airplanes for export shipment; designing and building gliders; dismantling, trucking, and reassembling airplanes for aviation shows; demonstrating airplanes of all types to customers; and, in general, doing everything that has ever been done in aviation with the exception of making new engines and airplanes.

From this review of the activities of a typical airplane-engine service station, it will be seen that a successful business of this kind must go far afield from the work of engine overhaul only, in order to maintain a satisfactory total volume of business, and it is evident that the further increase in airplane sales to private individuals will produce changes in the present service and distribution system for engines.

It seems probable that the major overhaul stations will eventually function on lines more nearly comparable to the wholesale jobbers in the automotive industry, with the present dealers carrying out all repair and overhaul work and buying the necessary spare parts from the jobber in whose territory they operate. To a certain extent, this is the situation at the moment, with the exception that of the 100 or so dealers holding the Wright franchise, for example, very few are equipped to undertake a major overhaul involving the need of expensive machine-tool equipment. These smaller service stations are competent to carry out minor overhauls and to keep engines in first-class running condition for the private owners lacking the time or inclination to maintain their own engines by a regular periodical inspection and adjustment. The work of the small stations is in general limited to a "top overhaul" comprising removal of all cylinders, de-carbonizing, valve grinding, replacing piston rings and small worn parts, etc., but not including such items as cylinder grinding, renewing main bearings, etc. The equipment needed by these minor stations is obviously less elaborate and expensive than that employed for major overhauls, and all the necessary facilities can usually be installed at a cost of from $10,000 to $15,000, including a stock of spare parts, but excluding any structural building costs.

The ultimate hope of most engine manufacturers is to have service representation on every active airport in the country, in the same way that popular makes of cars can be properly cared for by expert personnel in almost any town in the United States. This expansion cannot be realized, however, while it remains essential for even minor service stations to invest, say, $15,000 in order to obtain the limited amount of engine overhaul work at present available, particularly if these depots are allowed to undertake service work for only one make of engine, as is generally the case. The solution to the problem of broadening the scope of engine service in advance of a very great increase in the number of airplanes in use would thus seem to be the elimination of the policy of granting dealer franchises only on the basis that the dealer does not accept a similar franchise from a competing engine maker. It is improbable that any one make of engine, or the varying makes produced by any one manufacturing combine, can become sufficiently numerous to produce a really satisfactory volume of service work until a number of years have elapsed. To offer the benefits of expert assistance for any make of engine on any airport will obviously react favorably on airplane sales generally, and this can be accomplished more rapidly by an agreement between manufacturers whereby the best qualified repair depot in a given territory would be authorized to handle a group of varying makes of engines. This would in turn tend to simplify the distribution of spare parts, as the major repair stations would fulfil the functions of jobbers to the whole industry, carrying a large enough stock of spare parts to supply the dozen or more dealers in their territory. At present, the distribution of spare parts is by no means satisfactory to the average engine owner; even the best organized of the service systems suffer from delays and unwarranted expense in getting spares to the point where they are needed. In part, this is due to the past instability of engine production; few distributors or dealers are prepared to carry a large stock of parts that may become obsolete in a few months due to changes in engine design. In addition, few engine factories have been able to supply sufficient spares to build up a reserve in the distributors' stockrooms that is needed for carrying on the work.

With the greater stability now evident in the industry, these conditions no longer obtain, and it should be possible for an engine owner to obtain any normal requirement without having to wait for it to be provided from a far-distant factory.

There is no question that one of the most important factors in the continued growth and prosperity of the aviation industry is the service that engine manufacturers give their customers; it is thus reassuring to see that great combines such as the Curtiss-Wright, United Aircraft, and Bendix Aviation organizations are doing all in their power to establish service facilities wherever airplanes fly.

AER-52-15

Silencing the Airplane[1]

By H. L. DRYDEN,[2] WASHINGTON, D. C.

In this paper the author tells how sound is produced and defines intensity. Experiments and investigations made by the aeronautics branch of the Department of Commerce are described. These deal with the theory of engine mufflers and sound-proofing of airplane cabins. There appears to be no prospect that a device will be developed which at the cost of a pound or two of additional weight will eliminate the noise.

THE problem of silencing the airplane is one of great current interest. The noise nuisance is generally considered as one of the most potent influences tending to discourage the use of airplanes by the general public. Editorials are written about it, some people think there ought to be a law prohibiting airplanes from making noise, and directors of research look with longing eyes toward the problem, the solution of which would bring fame and fortune to them and to their organizations. Unfortunately the problem is not a simple one, and no master key to its solution has been discovered.

The aeronautics branch of the Department of Commerce through its research division in the Bureau of Standards is greatly interested in the possibility of developing practicable methods for the reduction of the noise of airplanes, and has already carried out investigations in two directions—namely, on the theory of engine mufflers and on the sound-proofing of airplane cabins. The work on sound-proofing is conducted in the sound laboratory of the bureau by V. L. Chrisler and W. F. Snyder under the general direction of Dr. Paul R. Heyl, and some of the results have been published in the May, 1929, issue of the Bureau of Standards Journal of Research. The remarks on sound-proofing in this paper are based on the work of Messrs. Chrisler and Snyder.

The purpose of the present paper is not to announce a complete solution of the problem, but rather to present from the viewpoint of a physicist a more or less ordered analysis and a statement of the ideas guiding the work at the Bureau of Standards. In the working out of this analysis the author wishes to acknowledge the wholehearted cooperation and assistance of Dr. L. J. Briggs, Chief of the Aeronautical Research Division.

The sensation of sound is produced by the presence in the air of compressional waves set up by some vibrating body. It is found by experiment that if the motion of the vibrating body is periodic, a musical sensation is produced and the pitch of the sound may be correlated with the number of vibrations of the source in unit time. If the vibrations are not periodic, a sensation of noise is produced. In the case of an airplane, several sources are present, and the resulting motion of the particles of air is an exceedingly complicated one. While it is possible to recognize certain predominant frequencies in the noise of an airplane, and while it is always theoretically possible to consider any complex vibration as the result of a large number of simple vibrations, this paper will be limited for the most part to the second attribute of sound, namely, the loudness.

Experiment shows that when the loudness of a sound increases, the amplitude of the vibration of the source and of the compressional waves in the air also increase. In any small volume of the air through which sound waves are passing there is a certain amount of energy which can be measured by suitable instruments. The amount of energy per unit volume is a measure of the intensity of the wave motion.[3] If the intensity increases, the loudness also increases, but since loudness is a sensation, the loudness cannot, strictly speaking, be measured. No meaning can be given to the statement that one sound is twice as loud as another. Nevertheless it is easily recognized that while the loudness increases with increasing intensity, a given increase in intensity by no means produces equivalent effects on the ear when starting from different levels of intensity. This has led to the construction of a scale of loudness on an "ear scale" which must be understood to obtain the proper perspective on the problem of silencing the airplane.

A certain minimum intensity is required before any sound can be heard. While the magnitude varies considerably from ear to ear and depends to some extent on the frequency, acoustical engineers have determined an average value applicable to the average ear. When the intensity approaches a value in the neighborhood of 100,000,000,000 times the threshold value, the sensation becomes exceedingly painful, and the ear begins to feel the sound rather than hear it. Thus to reduce the most intense sound to inaudibility would require the reduction of the intensity in this ratio.

For intensities between the limits given, the ear is not equally sensitive. We may imagine an experiment in which two sources of sound A and B of the same character are connected alternately to the ear, and the intensities so adjusted that the two seem equally loud to the ear. Then suppose the intensity of A is increased until the ear can just detect that it sounds louder than B. By measuring the change in the intensity, the sensitivity of the ear can be determined. To a first and sufficiently good approximation for most purposes it is found that the intensity must be increased by a certain percentage, approximately 29 per cent, no matter whether the original intensity is 1, 1000, or 1,000,000. The mathematician expresses this observation by the statement that the response of the ear is proportional to the logarithm of the intensity.

Suppose then that a start is made with the threshold intensity which is called 0 loudness and that the experiment progresses in steps such that the intensity of A is increased until a difference is heard, i.e., by a factor 1.26; B is now made equal to A, and the process is continued until the entire range of intensities is covered. The threshold loudness is called 0, the first step 1, the second 2, etc., and thus the ear or loudness scale of units known as sensa-

---

Presented at the Fourth National Aeronautic Meeting, Dayton, Ohio, May 19 to 22, 1930, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

[3] The exact definition of intensity is the amount of energy transmitted by the wave motion in unit time through a unit area in a plane normal to the direction of travel of the wave.

tion units is built up. It is found that approximately 110 units cover the scale, the exact number being dependent on the frequency. The correspondence between this ear scale, the physical intensity scale, and some familiar sounds is shown in Fig. 1.[4]

Some of the consequences of the facts which have been briefly reviewed are not very well known. Let us suppose that the intensity of the sound produced by the airplane engine is equal to the intensity of the sound produced by all other sources including the propeller, vibration of wires, etc. The complete elimination of the engine noise would reduce the physical intensity in the ratio of 2 to 1, but so far as the ear is concerned the decrease is only 3 sensation units. Unfortunate, but true. The perfect engine muffler under these conditions would improve conditions very little. Of course, the assumption as to the relative intensities may be greatly in error, and the fact has been neglected that cer-

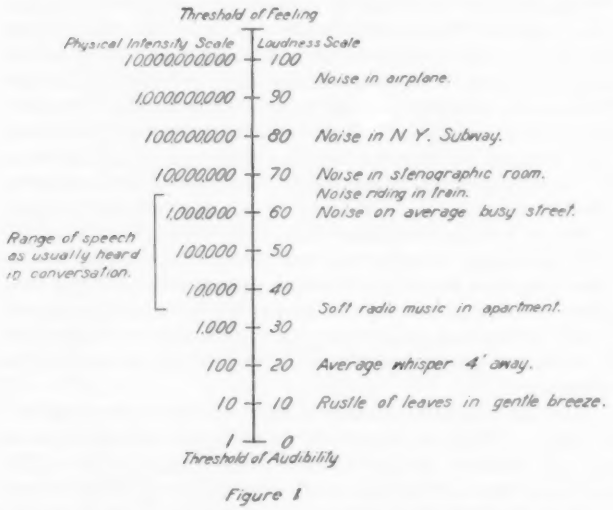

FIG. 1 PHYSICAL INTENSITY SCALE COMPARED WITH EAR SCALE

tain frequencies may produce more uncomfortable sensations than other frequencies.

The second consequence is that if the sound is once produced, the use of absorption as a remedy means that all but a small fraction of the energy must be eliminated. To reduce the sound by 20 sensation units means that 99 per cent of the energy must be eliminated, 30 sensation units 99.9 per cent, 40 sensation units 99.99 per cent, etc. The moral is that the sound should be eliminated at the source, if possible.

The source of sound has been stated to be a vibrating body. The vibrating body may be a column of air confined within more or less rigid walls or even unconfined air flowing in such a manner as to produce pressure changes of appreciable magnitude. The whistle of a bullet traveling at or above the speed of sound is produced by pressure changes in the turbulent flow of the air closing in behind the bullet. In this case the control of the sound is intimately related to the development of forms giving smooth air flow, a point that will be referred to later. The noise produced by a source of this type is usually not very intense unless the air speeds approach or exceed the speed of sound. The sources of sound of this type on an airplane are in the flow around the tips of propellers and in the flow of the exhaust gases from the engine. The only known method which is effective in dealing with sources of this type is to reduce the speed of the flowing air to well below the speed of sound.

[4] This figure is in part taken from Waterfall, *Engineering News-Record*, p. 60, Jan. 10, 1929.

In many instances, pressure waves which in themselves are of small amplitude produce much greater effects through the phenomenon of resonance. Any thin diaphragm such as the engine cowling, the fabric or plywood covering of a fuselage, any air column, as for example the air intake pipe to the carbureter, or any stretched wire has a large number of natural periods of vibration which in general are not greatly damped. Any small pressure fluctuation tends to set up vibrations in these resonating bodies which result finally in building up the intensity to a large value. This procedure may be illustrated by an ordinary tuning fork and resonator. It will be found that it is not necessary that the resonator be tuned to the fork frequency to produce a large effect. The flat top of an ordinary desk serves equally well. Attack on the source is most effective when the trouble is due to resonators, for with patience some of these may be discovered and removed or provided with sufficient damping.

PROPELLER NOISE

For several years the Bureau of Standards in cooperation with the National Advisory Committee for Aeronautics has been engaged in a study of the air flow about airfoil sections such as are used for propeller design. These experiments have been conducted at speeds from one-half the speed of sound to about 1.08 times the speed of sound. At some speed in the region from 0.7 to 1 times the speed of sound depending on the thickness, the flow about the airfoil begins to change from the smooth flow characteristic of good efficiency to the burbling type of flow which ordinarily occurs only at large angles of attack. The air no longer follows the upper curved surface nearly to the trailing edge but breaks away from the surface to form a region of violently eddying flow. In the model tests the change in flow is accompanied by a great increase in the noise. Under the conditions of the set-up, the thin airfoils spanning the stream serve as resonators which amplify the sound considerably. In this case noise is a direct evidence of inefficiency, for the lift is greatly decreased and the drag greatly increased when this type of flow begins.

The onset of the burbling flow depends primarily on the thickness of the section as compared to its chord length. The greater the thickness ratio, the lower the speed at which the inefficient flow begins. The shape of the section seems to be a far less important factor, though not without appreciable effect.

The bearing of these facts on propeller noise is somewhat as follows: For a given propeller the noise will increase as the tip speed increases. This is perhaps an obvious fact, but it is to be observed further than when the tip speed approaches the speed of sound the noise will increase at a rapid rate to an unbearable din. So far as any given propeller is concerned, it is advantageous to keep the tip speed as low as practicable from the standpoint of noise as well as of the efficiency of the propeller. Gearing may be said to be desirable, provided the gears are efficient and comparatively silent.

For propellers of varying thickness it may be expected[5] that at a given tip speed the thicker propeller will give greater noise, at least if the propellers are constructed of the same material. The blade of the propeller in most instances serves as a resonator, and the material of which the propeller is made together with the thickness determines the resonant frequencies and the magnitude of the damping. It is commonly believed that metal propellers make more noise than wooden propellers, but the question may be raised as to whether the metal propellers are or are not generally operated at higher tip speeds than wooden propellers. We know of no comparisons in which two propellers of identical design but of different materials are operated at the same tip speed.

[5] In the absence of measurements of propeller noise, the following statements must be in the form of speculations.

It is in this unsatisfactory state that the question of propeller noise must be left with the only conclusion that the tip speed should be kept as low as possible. It is interesting to speculate as to the part played by the vibration of the propeller blades and to wonder whether a blade so constructed that these vibrations were heavily damped would give considerably less noise.

Engine Noise and Muffling

It has always been a debatable question as to whether an engine muffler absorbs sound energy produced by the explosions in the engine cylinders or whether the muffler acts by modifying the flow of the exhaust gases so that the pressure changes set up are much less intense; in other words, as to whether the muffler takes a sound already existing and dissipates its energy or modifies the source so that a sound of lower intensity is produced. Some experiments have been made at the Bureau of Standards to obtain information on this point. A noise was set up in an air stream passing through a siren, the intensity being comparable with the noise of an airplane engine somewhat throttled. Mufflers of the several common types were introduced, but no appreciable change could be made in the noise unless a muffler of high resistance was used, and even then the reduction in loudness was small. While the apparatus available did not permit the simultaneous matching of air volume, frequency of impulses, and air pressure with the volume of exhaust gases, frequency, and exhaust pressure of an airplane engine, the results indicate that the muffler of an airplane engine functions primarily by so regulating the outward flow of exhaust gases that less sound is produced.

There are two well-recognized and effective principles on which mufflers may be operated, and a third principle is sometimes suggested but which is less effective than the other two. The first is the brute-force method of inserting resistance in the exhaust line so that pressure pulsations and hence the noise are reduced. Most mufflers do function somewhat in this manner, but the method is objectionable since resistance means a back pressure on the engine and hence reduced power. Practically all automobile mufflers are of this type. They are all heavy and impracticable for airplane use.

Most of the successful airplane mufflers, if any may be regarded as successful, operate on the second principle—namely, by reducing the speed of discharge of the exhaust gases. It has already been mentioned that this method is the most successful one for dealing with sources in an air stream traveling near the speed of sound. In practice the muffler utilizes some form of expansion chamber which serves to damp pressure fluctuations to some extent, but more important to cool rapidly the exhaust gases. In some designs the cooling is facilitated by providing devices to introduce a considerable amount of air which is mixed in thoroughly with the exhaust gases. It may be readily seen that the cooling of the exhaust gases produces an increase in density, and hence a given quantity (mass) of exhaust gas is expelled at a lower velocity. If sufficient cooling can be obtained, the velocity may be reduced by a factor of 2 or more. Since the speed of sound in the gas is also reduced in proportion to the square root of the absolute temperature, the ratio of the speed to the speed of sound is reduced in the ratio $\sqrt{2}$.

The third principle often advocated is to apply the methods of interference. In the laboratory, with pure tones it is sometimes possible to divide the sound path and produce at some specified location a low level of intensity. A fact often forgotten is that somewhere the intensity is twice as great. Furthermore a consideration of the relation between loudness and intensity shows that the intensity at the minimum must be of the order of one one-thousandth of the intensity at the maximum, a task which demands an almost perfect match of the amplitudes of the interfering tones. With complex sounds, the method of interference gives extremely unsatisfactory results in the laboratory. If the first thesis is granted—namely, that the larger part of the sound is set up in the air stream discharging from the end of the exhaust pipe—the use of branched pipes could not affect the major part of the sound. The only part of the sound that could be affected is the large and relatively low-frequency pressure changes due to the individual explosions. The adjustment depends on the temperature of the gases, since the speed of sound depends on the temperature, and can be correct for only one engine speed. Attempts to use the principle of interference on the note from a siren met with failure. There appears to be no successful application of this principle to engine muffling, and there are many reasons for believing that success is not likely to be encountered along this path.

Certain auxiliary matters in connection with engine muffling deserve mention. In the first place there are many sources of sound in the engine besides the exhaust. The gears, cams, valves, and other moving parts set up considerable vibration of metal parts leading to diverse kinds of noises. If care is not taken, the engine cowling and even the muffler itself, if made of thin unsupported sheet metal, may be set in vibration, leading to still further noise. In the second place, it is possible in certain types of airplanes to locate the exhaust above the upper wing so that a large mass is interposed in the direct line between the exhaust and the passenger cabin. Such a location leads to a very considerable reduction in noise.

Sound-Proofing the Cabin

The last problem to be considered is that of the sound-proofing of the airplane cabin, in which field Messrs. Chrisler and Snyder of the Bureau of Standards have carried out an extensive series of measurements. It must be recognized at the start that the problem is not alone one of sound transmission through the cabin walls, but also one of sound absorption. No matter how low the transmission of sound through the walls, the sound within the cabin will eventually build up to the same intensity as the sound outside if there is no absorption within the cabin. The low transmission simply delays the attainment of the final intensity for a short time after the starting of the engine.

Consider an airplane cabin of exposed surface area A_w placed in a field of sound energy such that the energy striking the surface per unit area per unit time is E_o. When equilibrium has been established, suppose that the energy striking any surface in the interior of the cabin per unit area per unit time is E. The condition for equilibrium is that the amount of energy entering the cabin per unit time by transmission through the walls equals the amount leaving the cabin by transmission through the walls added to the amount absorbed within the cabin. Obviously, if there is no absorption, the intensity within the cabin must equal the intensity on the outside of the cabin. If the transmission of the wall is t, the amount of energy entering per unit time is tE_oA_w. Similarly the amount leaving per unit time by outward transmission through the walls is tEA_w. If the average absorption coefficient of the exposed surface within the cabin is a, and the area of the exposed surface is A_a, the amount of energy absorbed per unit time is aEA_a. Therefore when equilibrium is reached, $tE_oA_w = tEA_w + aEA_a$

or

$$E = \frac{E_o}{1 + \frac{A_a a}{A_w t}}$$

The preceding elementary exposition, which is far from rigorous and contains several assumptions, will serve to give the general relationships. While without absorption there is no reduction of energy within the cabin, no matter how small the trans-

mission, absorption alone can accomplish little. Thus if the absorbing area equals the area of the walls, and if $a = 1$, so that all energy striking the absorbing surface is absorbed, and if $t = 1$ so that the walls are transparent, the reduction in loudness is only three sensation units. In any practical case some absorption is always present from the passengers themselves if from no other source. Each passenger has an absorption equivalent to a little less than 5 sq. ft. of surface having 100 per cent absorption. Because absorption is always present, a reduction in the transmission can accomplish a great deal. Fig. 2 shows the variation of $\frac{E}{E_o}$ with $\frac{aA_a}{A_w}$ for several values of t. The advantage of low transmission when the absorption is reasonably high is evident.

When the transmission of single sheets of material is investigated, it is found that the intensity on the physical scale of the

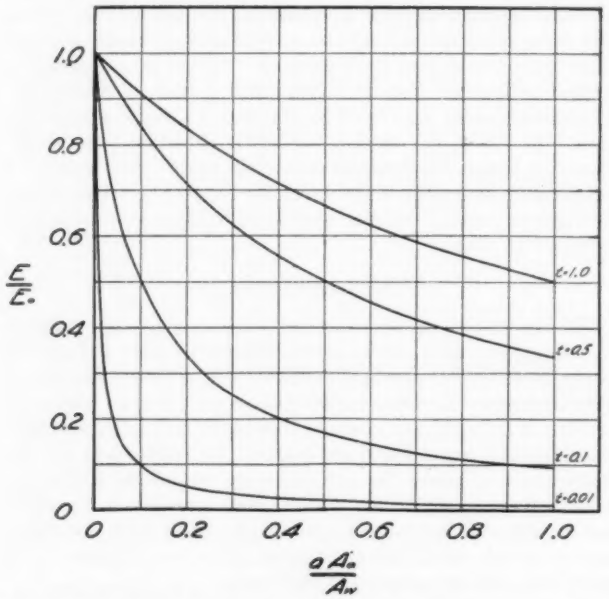

Fig. 2 Graphs to Show Advantage of Low Transmission When Absorption Is Reasonably High

sound received on the side opposite the source is approximately proportional to the reciprocal of the 0.73 power of the weight per unit area—in other words, to the reciprocal of the product of the density of the material and the thickness raised to 0.73 power. Because of the relation of the ear scale to the physical scale, the reduction of loudness in sensation units plotted against the logarithm of the weight per square foot gives a straight line. To obtain a reduction of 10 sensation units requires a material weighing 0.1 lb. per sq. ft., 20 sensation units 0.5 lb. per sq. ft., 30 sensation units about 3 lb. per sq. ft. It may be recalled that a material giving a reduction of 30 sensation units transmits only 0.001 of the energy falling on it.

The relation between the transmission and the weight was found by Messrs. Chrisler and Snyder to hold for wrapping paper, airplane fabric, glass, plywood, aluminum, and building board. The prospect of securing a satisfactory reduction of loudness by simple sheets of a single material is not very bright, and attention was turned to composite structures. In the sound insulation of buildings, air spaces prove to be of great value so that one of the first attempts was to use two sheets with an air space between. With light materials, as for example sheets of aluminum, the transmission through two sheets separated by an air space was greater than through a single sheet. The use of air spaces is entirely ineffective in the sound insulation of airplane cabins.

The next trial was the use of absorbent material between the two panels, a process that is not very effective in building construction. For the much lighter panels which must be used on airplanes, actual test showed that the use of absorbent material between the panels was very effective. With balsam wool, cotton, or hair felt as the filling materials, composite panels were built which gave a reduction as great as for a homogeneous material of twice the weight or more. With a blanket made from kapok fibers, such as are used in life preservers, a panel was constructed which gave a reduction as great as for a homogeneous material of three times the weight. This sound absorbent weighs only 1.14 lb. per cu. ft. A reduction of 30 or 35 sensation units is obtained with a wall weighing about 1 lb. per sq. ft.

The area of the walls of the cabin of modern commercial airplanes is usually from 30 to 50 sq. ft. per passenger. The casual reader might then suppose that 30 to 50 lb. per passenger additional weight would be required to provide the sound protection for each passenger weighing, say, 150 lb., and thus that about one-fifth the useful passenger load must be devoted to sound insulation. This is far from the case. In the first place the cabin must have some kind of walls in any case. If they are of airplane fabric, they will weigh only 0.1 lb. per sq. ft.; if of plywood, about 0.5 lb. per sq. ft.; if of aluminum, about 0.3 lb. per sq. ft. In the second place a modern cabin has some type of interior finish or lining for appearance sake. The weight of the wall that would be provided in any case without thought of sound insulation should be subtracted from the 1 lb. per sq. ft. of the sound-insulating constructing. Experience has shown that the additional weight is likely to be of the order of only 10 to 15 lb. per passenger—say, about 0.3 lb. per sq. ft. At this price the noise in the cabin may be reduced to about that in a railway coach in motion, so that conversation may be carried on with ease.

This concludes the brief survey of the present situation with regard to silencing the airplane. There appears no prospect that any single device will be developed which at the cost of a pound or two of additional weight will eliminate the noise. The imagination of the inventor is to be envied who proposed to have the sound actuate a loud speaker in such a way as to produce a new noise of equal amplitude to the original, but of opposite phase so that by interference no sound at all would be heard, but there appears no hope of progress along this line. By the same token it is unnecessary to resort to ear plugs, telephone sets, or speaking tubes. At the present time a great deal can be done by careful attention to detail to provide greater comfort to the passenger, and at a moderate increase in weight. It will prove more profitable to carry 8 passengers in comfort than 9 or 10 in conditions almost unbearable.

Discussion

S. A. Reed.[6] It is fortunate that this subject is being investigated by the Bureau of Standards and especially by Dr. Dryden, whose good work is recalled in research for the N.A.C.A. on airfoils. Mr. Fokker recently said that the noise from the engine exhaust can be eliminated easily to a great degree, so there is little doubt that propeller noise is the main factor. Dr. Dryden of course did not mean to say that vibration of some object is the only source of sound, which would mean that if a propeller is noisy its blades must be in violent vibration. In a siren there is no vibration, but merely a series of impulses in rapid succession. Other experimental sources of sound also exist without vibration.

In 1922 the N.A.C.A., under "Reports and Memoranda," published an account by the writer of experiments with models leading up to the development of a propeller, and it mentioned

[6] Reed Propeller Co., New York, N. Y.

that a control exactly like the propeller model was usually run, but with zero pitch; also that the writer was working at a range of tip speeds from about 800 up to 1500 ft. per sec. The sound with blades at zero pitch was of great intensity, with a perfectly pure musical note of absolutely definite pitch, and this musical pitch depended solely upon the number of blades and the rotation per second.

In 1925 A. Fage read a paper before the Royal Society in England, in which he said the same thing, viz.: that he found that the acoustic frequency corresponding to the pitch of the sound from a propeller is the number of blades multiplied by the rotations per second. The writer found that in the sound one might detect octaves of the fundamental note, but with blades of zero pitch other overtones appeared not to be present. With a propeller having pitch angles, with thin tips, there may be tones of minor intensity due to vibration of the blade. If there is flutter, of course there may be much confused noise, but fluttering propellers are usually rejected and do not go into service. Thus it may be concluded that the main sound from a propeller is due not to any fault which can be corrected, but is inherent.. As soon as tip speeds exceed about 900 ft. per sec. the intensity increases sharply; this fact is recalled in connection with racing propellers, where tip speeds are usually not less than 1000 ft. per sec.

That the propeller sound is not due to blade vibration to any considerable degree also seems quite clearly proved by the fact that the sound does not correspond in pitch to the estimated frequency of blade vibration. Blade vibration will be either free or forced. The free will be of constant frequency for all speeds, and dependent only upon the blade dimensions and material. The forced, due to thrust, may change somewhat with the speed, but certainly will not follow it accurately, as Fage and the writer have found.

It is not easy to calculate in advance the natural period of vibration of a propeller blade. The usual form of the blades of metal propellers has a rather steady taper in width and thickness from a stout root to a thin tip, and this form is unfavorable to free vibration, due to damping.

A recent paper by Liebers in Germany endeavors to calculate the vibration period of a thin metal propeller blade, and a conclusion similar to the foregoing appears to have been reached. Liebers' experiments were made with relation to the danger of blade fracture, and not to the question of noise.

In the writer's experiments referred to, the tachometer was invariably checked by noting and identifying the musical pitch, and then referring to a table of tone frequencies. A small mouth organ was used marked with the notes of the musical scale, and any one with a fairly correct ear can do this, using any musical instrument, marked with a scale. This was done hundreds of times and never failed to find exact agreement with the tachometer, and in later experiments in an open field with 90 hp. and models of 4-ft. diameter the writer would identify the note, and then predict to an assistant, who was observing the tachometer, exactly what he would find.

In the writer's paper for the N.A.C.A., reference is made to the classic experiments of Mach and Boys, who obtained refraction pictures on a photographic plate showing a longitudinal section of the conical waves spreading from the tip and tail of a rifle bullet, compression at the tip and dilatation at the tail.

These pictures are also now made by U. S. Army engineers at Frankford arsenal, and are very suggestive of conditions which may exist at the sharp leading and trailing edges of thin-blade metal propellers near the tips, and it should be noted that such would occur at zero pitch as well as with a thrust pitch, and that the velocity of propagation through the air would be entirely independent of slipstream velocity.

Some Characteristics of Light Alloys for Aircraft

By H. W. GILLETT,[1] COLUMBUS, OHIO

In this paper the author tells of the various light alloys that might be used to advantage in aircraft construction, and gives their advantages and drawbacks. As fast as the disadvantages are overcome, whether they relate to price fabricability, or other properties, the improved material will find increased use in aircraft. Progress in aeronautics is linked closely with the metallurgy of light alloys.

ACCORDING to the opinions of representative designers,[2] the use of metal in aircraft construction is on the increase. Wood and fabric wings still predominate on the smaller single-engined craft, especially on those makes not in large production, while in large transport planes, wing construction is almost exclusively metal. The wings are about the only major non-metallic part left on most planes, and they show a marked trend toward metal.

Apparently, the time will come before long when if aircraft, both airplanes and dirigibles, were drained of fuel and oil, piled up in one big junk heap, and set fire to, the whole mass would hardly get warm, so little wood and fabric would be present. One could pick out some rubber, glass, upholstery, etc., from the pile, but much the greater part of the weight would be metal. About half of the metal would be light alloys. By volume, the light alloys would greatly preponderate.

Since light alloys bulk so large in aircraft, it is logical that they should be considered in any comprehensive symposium on aircraft, especially one that takes the engineering angle. They have been so considered, time and again, and there are so many recent papers and articles[3] dealing with light alloys for aircraft, that there is nothing especially new or striking to report, nor can one bring to bear any fresh point of view.

It is not necessary to repeat the tables of properties of the light alloys that are available in many publications. Instead the subject will be considered more from the qualitative point of view, using round figures and approximations, when any figures are required. First, what are the light metals that serve as bases for light alloys for aircraft?

The light metals comprise aluminum, magnesium, beryllium, silicon, alkaline-earth metals like calcium, and the alkali metals like sodium, and lithium. The alkali and alkaline-earth metals are so readily attacked by moisture that they do not serve as materials of construction. Tiny amounts of them may find use as alloying elements, but as the base for structural alloys, they are quite out of the picture. There is no present hope for rendering them immune to corrosive attack.

Silicon is brittle, and alloys high enough in silicon to class as light alloys are brittle too. If and when high-silicon alloys can be produced that will be tough and workable instead of brittle and structurally useless, their corrosion resistance would be a factor in their favor. Many metals once considered to be inherently brittle and useless as structural materials, have yielded to the attack of the metallurgist, and become tough under proper treatment, tungsten being an outstanding example. Silicon is relatively cheap and silica is abundant. Some day silicon alloys may be in the picture, but that day will probably not be soon.

Beryllium

Beryllium is an unknown, rather than a rare metal. There is much beryl in the world, and when there is sufficient demand for beryllium so that it is prospected for, there will probably be plenty available for aircraft uses. So far, the metal has been produced on a laboratory scale only. It has been made, and its heavy alloys (those low in beryllium) studied quite exhaustively by Siemans and Halske.[4]

In this country, Cooper made the metal years ago. Hopkins and Meyer,[5] and Vivian,[6] have described the production of the metal in the laboratory. It is alleged[7] that it has also been produced in Austria.

Archer and Fink[8] studied aluminum-beryllium alloys containing only small amounts of beryllium and found them quite unpromising, as did Rawdon. The opportunity for beryllium alloys suitable for aircraft seems to lie in the beryllium-base alloys, i.e., those high in beryllium.

There has been very little done and less published in regard to light beryllium-base alloys for aircraft use, though some hints have been given.[9] Published German data have not dealt with light alloys at all. The Beryllium Development Corporation is alleged to have, in the last few months, put much effort on the making, casting, fabrication, and heat-treatment of light beryllium alloys. An experimental plane with alloys high in beryllium taking the place of those now made of duralumin and other alloys of aluminum, is said to be in contemplation. At the time of writing, however, the situation is as follows: While it is said that most of the difficulties intervening between the existence of raw ingot metal and the existence of useful alloys of that metal in fabricated form ready to be used in the construction of aircraft have been solved, and while it is alleged that many of the engineering data on the properties of the alloys, which must be in existence before aircraft design can make use of the alloys, have been collected, beryllium alloys for the making of aircraft parts are not on the open market, nor are their properties a matter of public record.

Beryllium alloys must therefore be classed as a potentiality not an actuality, from the standpoint of the aircraft engineer. They form a most interesting potentiality because of certain inherent advantages that will be touched upon later. But unless a surprising amount of success has crowned the efforts of the past few months, there will still be required a long period of patient research before beryllium alloys are available for aircraft construction. When they are, the price will be high in comparison to other light alloys. It is costly to purify the ore, costly to reduce the ore to metal, and the alloys will be costly to fabricate.

Magnesium Alloys

Magnesium alloys are an actuality. Yet they have been singularly slow in finding much use in aircraft. An "all-magnesium alloy" experimental plane was built years ago, and the methods of fabrication and the properties of the alloys have long been known. Their technology is well developed. Facilities for large-scale production of magnesium have long existed in this country, due to its use for flares, etc., in the war. Production could be expanded almost at a moment's notice if a real demand existed. The small demand has been disappointing to those who expected the magnesium industry to duplicate the growth of the aluminum industry. It is very doubtful if, outside of the war production for uses other than structural, the magnesium industry of this country at least, and probably of the world, has as yet made profit enough to take the whole enterprise out of the red.

The mechanical properties of magnesium alloys are quite satisfactory for aircraft use. Were there a large demand so that quantity production were in order, the price should be but little above that of aluminum. Magnesium "ores," whether solid minerals or brines, are plentiful, and while the cost of extraction of the pure metal, and of the fabrication of its alloys, will probably be a bit above that of aluminum, there is little prohibitive in the cost situation if and when real large-scale uses appear. The cost under relatively small production has been high enough so that when one merely considers the replacement of iron, steel, brass, or bronze by some light alloy, he normally chooses the cheaper aluminum alloys. Such a substitution accomplishes a big jump in weight reduction. The specific gravities are approximately: Steel 7.85, aluminum 2.7, magnesium 1.75, beryllium 1.85. The smaller jump from aluminum to magnesium is seldom considered worth the extra cost, when either group of alloys would serve. Pistons for automotive engines made of aluminum alloys do pretty nearly all that can be expected of magnesium-alloy pistons. Only when the last refinement in weight reduction is imperative, as in the rotors of a supercharger, has magnesium shown a great tendency to replace aluminum. There is likely to be more of a drift toward magnesium for such parts as are automatically protected from corrosion, such as engine parts that are constantly covered with oil.

That structural members, wing coverings, etc., are not ordinarily made from magnesium alloys is due to an inherent deficiency of magnesium and its alloys. They are prone to corrode. Considerable advance has been made toward, but not to, incorrodibility. The impure magnesium of not so many years ago, would corrode away in storage unless protected from atmospheric moisture. Present-day purified magnesium is far more resistant.

The older alloys containing copper as a strengthening element, were highly corrodible. These are now almost obsolete, and the chief alloys used today, one containing about 4 per cent aluminum and $^1/_4$ to $^1/_2$ per cent manganese, and others alloyed with zinc, are quite fairly corrosion-resistant in moist air. But few aircraft designers would dare use even these alloys around salt water or in salt air for parts whose structural strength must be maintained.

Chlorides are not healthy for magnesium; they promote corrosion very badly, and magnesium sheet, tubing, and other thin-section materials used in the presence of chlorides would require the use of an impervious, durable, protective coating. Such coatings are not yet available.

In an extensive investigation by the Bureau of Standards it was found that, in Washington, D. C. air, bare magnesium alloys of the more corrosion-resistant types were scarcely damaged after six month's exposure, but on the other hand, sheet specimens exposed at Coco Solo (Canal Zone), although protected by the most promising protective coatings now known, "resembled lace" after less than three months exposure, so severe was the corrosion.

So far, the best advice that can be given in respect to the use of sheet magnesium alloys is a slight modification of the old song, to read, "Hang your clothes on a hickory limb, but don't go near salt water." The Army Air Service confines it uses of magnesium to castings, since any army plane may have to be used near the sea coast.

On an inland mail or transport line, use of sheet magnesium alloys might be considered if there were a real protective coating. Hicks[10] says, "The ideal large plane is one in which the geometric extremities of the wings, fuselage, and control surfaces are of properly protected magnesium alloy, the intermediate and adjacent sections of the wings and fuselage of duralumin, and the middle portions of the fuselage and wing root of alloy steel." So far, no "proper protection" is known for conditions of service near salt water. Hence, the use of magnesium in aircraft will be pretty much limited to heavy sections, such as crank-case castings and experimental propeller forgings, or to such things as meter cases and small parts not requiring structural strength. Use of magnesium for such purposes is increasing, but hope for the satisfactory protection of sheet magnesium seems to be about abandoned.

Cost and Production

The price of ingot aluminum in 1892 was a little less than that of magnesium today. About 1900, it dropped to the present price level, and while it sold in 1909–1911 for about half its present price, for the last seven years it has stuck at 23–28 cents per lb., now being around the lower end of that range. The price of ingot magnesium for the last 10 years has run from 70 cents to $1 per lb.

The price of what little beryllium has been produced, has been around $200 per lb. When the time comes that one can buy beryllium at all, it is expected to start in at say $50 per lb., and then fall. Optimists look for a $5 price some day, and superoptimists for a price of the order of the present price of magnesium.

The probable world production for the present year appears to be somewhere about 250,000 tons of aluminum, 2500 tons magnesium, and 2.5 tons of beryllium. Knowledge of the alloys of aluminum, magnesium, or beryllium is in inverse proportion to their present price, and in direct proportion to the present tonnage.

Only one designer,[11] among those who replied to the questionnaire sent out by *Aviation*, mentions beryllium at all in discussing materials for aviation engines. Rosenhain,[12] however, takes an optimistic attitude in regard to the probable utility of beryllium in aircraft.

Alloy Steels

Strong, heat-treated alloy steels, and the strong light alloys compete with each other for aircraft construction. Alloy steels heat-treated to around 200,000 lb. per sq. in. have a somewhat better strength-weight factor than the wrought strong light alloys, though the strongest magnesium alloys are about equal. The alloy steels heat-treated to 125,000 lb. per sq. in. have a somewhat poorer strength-weight factor.

On a yield-point-weight basis, the steels are superior because the yield point is much nearer the ultimate. Although the yield point in both the light alloys and in heat-treated steels is more or less a matter of definition, on almost any basis of allowable permanent set the steels have the edge. Stream-line wire, control cables, etc., are therefore never made of light alloys.

From the point of view of the modulus of elasticity, the steels are three times stiffer than the aluminum alloys, and five times stiffer than those of magnesium, while an alloy high in beryllium will have almost the modulus of steel. One does not make springs of the light alloys, but a beryllium spring could be made. On the other hand, the greater bulk of the light alloys gives a tube or an I-beam of a given strength a greater stiffness as a structure when made from light alloys than from steel. Even when one draws a steel tube so thin that it has the same weight as a given light-alloy tube, it would not have the same resistance to crumpling, though it might have identical tensile strength.

The exigencies of manufacture require certain minimum dimensions. A casting can be made only so thin. A boss must have a certain thickness to have enough thread area for a cap screw to hold, and so on. The new rigid airship in which the metal skin is the gas container, and transmits some of the stresses, uses aluminum-alloy sheet 10 mils thick. This serves the purposes better, and is easier to fabricate than would be the case with the excessively thin stainless-steel foil that would give the same strength-weight ratio.

When the minimum dimensions for fabrication give sufficient strength in the light alloys, the light alloys replace the heavy ones. Hence, there will be mighty few steel castings in aircraft, and it is in castings that magnesium will give the aluminum alloys something of a battle. When the minimum dimensions allow the use of either, other factors decide. The new British dirigibles use either duralumin or stainless steel in much of their frame work, and a final choice has yet to be made. In the 12-engined, 170-passenger Dornier, the main spars are said to be of extruded magnesium alloy. That plane is described as chiefly made of aluminum alloys.

Metal Propellers

For aerodynamic efficiency, metal propellers need a more or less definite external form and size. If it were possible to make a hollow, heat-treated, steel propeller, it ought to be better than one of a light alloy. Its higher modulus would make it hold its shape better under load. Its endurance limit would be better since the endurance-limit-weight ratios of the steel could easily be made double that of the light alloy propeller, and the steel would have a real endurance limit while there is a question whether the light alloys do have a true endurance limit. Between the heat-treated 96 per cent Al, 4 per cent Cu forging alloy and the heat-treated 95½ per cent Mg, 4 per cent Al, ½ per cent Mn forging alloy suggested for propellers, there is apparently not much choice in actual endurance limit, but the endurance-limit-weight ratio is probably in favor of the magnesium alloy. Endurance data on the magnesium alloy are as yet none too conclusive.

But, as a matter of fact, whether the propeller is steel, aluminum alloy, or magnesium, it has to be, so far, a solid forging. Built-up propellers using a high-tensile steel framework inside, and a welded light-alloy covering outside, have been used, and some work is being done on welded, hollow-steel propellers. The hollow-type propeller has theoretical advantages, but one hesitates to put any sort of joints in a propeller. That being the case, the light alloy is the better bet since it will stand up, and the actual weight of the solid forging is less.

Effect of Welding and Heat Treatment

On the impact-weight basis, the heat-treated steels show up better than the light alloys unless the steels are used in a very hard condition. One of the drawbacks of the light alloys is that their optimum strength is obtained by heat-treatment, or by cold working, or both. Heating in welding ruins the strength. Since welding is so important in airplane fabrication today, steel has the edge over light alloys for parts to be welded.

The light-aluminum alloys respond to heat-treatment much more readily in the wrought state, with the grains smashed up, than they do in the cast condition. Weld metal is, of course, in the cast condition. Castings must be heated many hours in order to effect solution for "precipitation hardening," while in wrought metal, far less time is required. The light alloys do not undergo a grain refinement on cooling as is the case when steel cools through the A_1 point. With carbon steel or stainless steel, while the weld may not be of just the composition desired, metal can be built up at the joint so that there is enough strength there. The weak spot is a bit away from the weld where the tubing itself is softened. Reheat-treatment of the whole welded assembly can repair this damage rather better than in the case of the aluminum alloys.

Chromium-molybdenum steel tubing has sufficient air-hardening properties so that air-cooling after welding regenerates a good grain structure, and the welded structure will be 80 to 90 per cent as good as the original heat-treated tubing. This great advantage accounts for the almost universal use of chromium-molybdenum steel tubing for fuselages.

Dirigible girders are built up in light aluminum alloys by bending and punching sheets into channels, and assembling these and the stamped cross members into box girders by riveting, not by welding. Airplane-wing spars are made either in steel or light aluminum alloys with some tendency toward a construction using both materials.[13]

One point in favor of modern duralumin is its uniformity of properties in different thicknesses. Tubes of different wall thicknesses, for example, appear to run more uniform in properties than would be expected in steel.

While magnesium alloys can be welded, it is a tricky operation, and welded-magnesium aircraft structures would be difficult to build up. Moreover, magnesium-alloy tubing is hard to make, and structural use of the magnesium alloys would have to rely chiefly on extruded shapes. Nothing is known about the weldability of beryllium alloys, nor of their ability to be made into tubing or extruded shapes.

Corrosion

The difficulties and disabilities of magnesium and its alloys in resisting corrosion where chlorides are present were mentioned above. Duralumin, the mainstay among the wrought-aluminum alloys for aircraft use, is also attacked in a fashion that is dangerous because the attack is not necessarily indicated by the surface appearance. This attack is intercrystalline in nature, and the alloy gets brittle. The attack may be greatly reduced by proper heat-treatment, i.e., cold-water quenching and the avoidance of accelerated aging at an elevated temperature. The attack is of no structural import on heavy sections like propellers. The thinner the material, the worse the damage.

[13] See footnote 10.

Thin sheet, say 10 mils, in contact only with rain water or distilled water, and with rather pure air, in locations far from the sea shore, and not badly contaminated by industrial gases, loses its ductility at an alarming rate. This trouble has been experimentally overcome through the application of thin layers of unalloyed aluminum by the metal-spray process, and practically, at least for fairly thick sheet, by casting a duralumin ingot between two unalloyed aluminum sheets to which the duralumin welds, and rolling the composite ingot. The resultant "Alclad" duralumin sheet is very resistant to intercrystalline embrittlement, and such coatings are far and away ahead of any non-metallic coating. Unfortunately, Alclad tubing has not yet become available, and outside of the metal-spray process, there seems little hope of putting an aluminum coating on magnesium alloys which so badly need protection.

The endurance limit of Alclad sheet duralumin is lower than that of ordinary duralumin, but no worse than that of duralumin that has corroded somewhat. The ductility and resistance to impact of the Alclad duralumin is far superior to that of the uncoated, somewhat corroded material. It has a slightly lower strength-weight ratio than uncorroded duralumin, but a far better toughness-weight ratio than somewhat corroded duralumin. The Alclad material starts out with certain properties and maintains them. This is one of the many cases where sustained mediocrity is preferable to shortlived perfection.

Protective Coatings

Alclad duralumin is rapidly displacing bare duralumin for wing coverings and the like, and is sometimes satisfactorily used without any sort of paint or varnish coating, though in tropical climates even Alclad is the better for some protection, and the thinner it is, the more it needs protection. Even though the thinnest Alclad sheet may not have a sufficient thickness of pure aluminum on the surface to give as much protection as is had in thicker sheets, its substitution for uncoated duralumin in the new metal-clad airship *ZMC-2* has probably materially increased the life of the ship.

That aluminum or the aluminum-manganese alloy used in making hard sheet is not materially attacked by chlorides is evident from the performance of the cooking utensils in every kitchen. But intermittent immersion in seawater is pretty severe service, and even Alclad sheet, although probably the best light material available for seaplane floats, has a limited life in such service.

The duralumin parts that cannot be given an aluminum skin, and any parts made of magnesium alloys have to be given some sort of a protective coat. To make the metal surface of such texture that coatings will stick, it is advisable to produce a matt surface. Anodic treatment in chromic acid (and recently promising use is being made of sulphuric acid) for aluminum alloys, some analogous chemical treatments without the use of electrolysis, in carbonate-chromate mixtures, or in milk of lime, and a chromate or phosphate treatment for the alloys of magnesium, produce a tough thin skin over the surface, with a matt texture that serves well as a "priming" coat for other coatings. One aircraft maker characterizes the anodic coating as of "immense benefit as a base for the lacquer or varnish." The anodic or similar skin, despite claims for inherent corrosion resistance is in itself not of very great value in presence of chlorides, according to the author's opinion. Its chief value is as a primer.

The paints, varnishes, lacquers, and what-not suggested for protection of light alloys are simply legion. Their protective value is far from perfect, and, from some points of view, largely illusory. Greasing over one of the matt "primer" skins, with constant renewal of the grease, preferably with aluminum powder in the grease, the use of a flexible linseed-oil carbon-black coating, or, under some conditions, rubber-type coatings, especially if pigmented with aluminum powder, do help. Brittle paint films that check or become pervious to moisture only localize the damage and delay it a bit. Some synthetic resin lacquers and the zinc chromate primers offer some promise among the non-flexible coatings.

Exposure tests of coated magnesium alloys in the tropics, in which the metal surface has been phosphate-treated, and a wide range of protective coatings tried, should be illuminating to those who believe that paint-and-varnish-type coatings afford true protection. If these coatings could really remain impervious, they would really protect magnesium. They do not. The coating doesn't know whether it is on magnesium or on duralumin. It is obviously unsatisfactory on magnesium because magnesium itself corrodes so rapidly. That it is really unsatisfactory on duralumin is less apparent because duralumin corrodes more slowly. That the non-metallic coatings afford some protection and that even partial protection is desirable, cannot be denied, but a non-metallic protective coating in which implicit faith can be placed for the complete protection of duralumin is still a long way off.

In Navy practice, bitumastic coatings are used where practicable, otherwise, aluminized spar varnish. Anodic treatment is required in order to secure proper adhesion.

Metallic beryllium is very resistant to atmospheric attack. It, and the aluminum alloys high in beryllium are said[14] to be more resistant to chloride attack than any other light alloys. Results of some cursory tests which the author has seen, make him want very definite proof of this before accepting the statement, though he can well believe that they will be far ahead of the magnesium alloys.

Castings

For many years, the mainstay in the aluminum sand-casting business was the "No. 12" alloy, with 8 per cent copper, which is nearly as brittle as cast iron. The alloy still serves for many purposes, but as the castings became more complicated, there was a need for an alloy less prone to cracking in the mold. The alloys with silicon then came in, and combined an almost foolproof resistance to mold-cracking, and a good ductility in the casting at room temperatures. But they had a very low proportional limit. Non-heat-treated alloys with both copper and silicon strike a rather happy medium. For aircraft use, still greater strength combined with good ductility is afforded by an alloy with 4 per cent copper given a very long time heat-treatment, or by alloys of copper and silicon, also heat-treated. In these latter, the properties can also be varied by varying the iron content. The more complex alloys with copper, magnesium, and silicon as alloying elements, are also used as heat-treatable casting alloys. They give higher strength, but lower ductility than the alloy with copper alone. A still more complex alloy, the so-called "Y" alloy, to which nickel is added as well as the other elements, finds minor use in sand castings. Rolls Royce is reported[15] as using a "Y" type alloy with high silicon which may possibly offer some of the casting advantages of the silicon alloys plus an approach to the properties of the oth r heat-treatable casting alloys when heat-treated.

Magnesium is attacked by steam so its alloys are not cast in ordinary green sand. The sand is bonded with glycerine or sulphur is added so that some other atmosphere than steam comes in contact with the hot casting. Other difficulties are present, but all have been well overcome so that almost any-

[14] See footnote 9.

[15] Some Recently Introduced Aluminum Alloys, W. C. Devereux, *Metal Ind.* (London), vol. 36, Jan. 24, 1930, p. 117.

thing that can be cast in aluminum alloys can be cast in magnesium alloys if one is willing to pay the price. On a strength-weight basis, they are superior to the best aluminum alloy castings so their increased use in aircraft is probable.

The alloys high in beryllium are not easy to cast, although sound castings of simple shapes have been made. There are no data available on the properties of such castings. Permanent-mold castings, made in an iron mold under gravity flow, are much used for pistons. Here ductility and corrosion resistance (except to exhaust gases) are not as important as strength at high temperatures, and resistance to wear. The greater thermal coefficient of expansion of aluminum alloys over cast iron is a drawback, partially cured by Invar struts, but the higher thermal conductivity is an advantage. In automobiles, many manufacturers change from aluminum to cast iron from year to year. In aircraft, the aluminum piston remains standard.

On account of the low melting point of aluminum, most of its alloys get pretty weak at engine temperatures, so the alloys have to be chosen with high-temperature strength in view. The probability of still higher temperatures focuses attention on this point.

Although magnesium pistons will work, the strength of the magnesium alloys is still lower than that of the aluminum alloys, and their thermal conductivity is lower so that in order to drain off enough heat, the piston has to have greater volume. Unless magnesium becomes as cheap as aluminum, there seems little chance for the magnesium piston as there is no real weight reduction. Attack by exhaust gases would probably be less than with aluminum.

Beryllium is of great interest here. Its thermal coefficient of expansion is not far from that of cast iron. Its high melting point encourages one to expect good strength at high temperatures, and beryllium itself is so hard that good wear resistance may result. On the important matter of thermal conductivity there seems to be no data at all on beryllium, but one would hardly expect it to be as high as in aluminum or even magnesium. It will take some time to develop casting methods that will produce sound pistons of beryllium or alloys high in beryllium.

Die Castings

Pressure die castings in aluminum alloys are useful outside of aircraft for small parts not highly stressed. They can be produced close to size and require little machining. They are likely to consist of a honeycomb of blow-holes on the inside, and a nice sound skin on the outside. As long as the part is still strong enough even though its interior is cheesy, this merely helps on weight reduction, but inspection difficulties are multiplied to be sure that each piece is strong enough. Material with internal defects such as are likely to be found in die castings, is most dangerous under repeated stress, and hence, there is almost no use of die castings in stressed aircraft parts.

There is a great difference between a die casting made by one who knows how to make it, and one who does not. The efforts of the die-casting committee of the American Society for Testing Materials are helping this situation materially, but it is doubtful if the castings can be made satisfactory for highly stressed parts of aircraft. On the whole, for aircraft use one prefers a forging to any casting, both because of soundness and because the forgings heat-treat to better properties.

Forgings

Here the aluminum alloys stand out. The technique of making heavy aluminum forgings is pretty well understood. The magnesium alloys harden up more rapidly on forging and are therefore more difficult to make. Yet, satisfactory magnesium-alloy propellers have been made experimentally, and have decided advantages over heavier alloys. They may have a future.

Beryllium-alloy forgings are still a closed book. As the metal is only amenable to hot-working, development of such forgings would be even harder than with magnesium. The high modulus of elasticity might give a material advantage to a beryllium-alloy propeller. What the endurance properties would be is entirely unknown.

Heat-treatable light-aluminum wrought alloys have all been spoken of as a class. The chief alloy, duralumin or "17 S," contains around 4 per cent Cu, $^1/_2$ per cent Mg, and $^1/_2$ per cent Si. The mechanism of heat-treatment, according to the usual theory, is to heat to about 500 deg. cent. long enough for most of the previously separated constituents to be taken into solution, and to quench, retaining the solution at room temperature. As time goes on hard compounds like $CuAl_2$ and Mg_2Si form and precipitate at room temperature in very tiny particles which strengthen the alloy. The alloy can be severely worked immediately after quenching while it is soft without making it brittle. Rivets must be driven in about $^1/_2$ hr. after quenching.

Duralumin hardens at room temperature. If copper and silicon are the only alloying elements as in the alloy "25 S," or if only magnesium and silicon are used as in "51 S," then we get, respectively, $CuAl_2$ or Mg_2Si. Without the presence of the other, these compounds do not precipitate at room temperature. Heating is required. Hence where cold forming is to be done, it can be carried out at leisure with these alloys instead of in a hurry as with duralumin. The alloys are more readily handled than duralumin in some types of hot forming. Propellers are generally made from the 25 S (copper) alloy.

The strength of these alloys is just a little below that of duralumin. Hence, when the best strength-weight ratio is needed, duralumin is used unless some problem of fabrication outweighs the need for strength.

There is naturally a desire for material of still better strength-weight ratio than ordinary heat-treated duralumin. In dirigible girders, carefully heat-treated duralumin may be slightly cold worked after aging has occurred or progressed part way, thus adding something in tensile strength, considerable in tensile yield point, and considerable in endurance limit, at the expense of some ductility. There is not so much use of heat-treated and cold-worked duralumin in airplane tubing, since the yield point in compression is not raised, and probably lowered by the cold work.

Duralumin, higher in silicon than the normal, can by aging at a slightly elevated temperature be brought up to 75,000 lb. per sq. in. with 13 per cent elongation instead of the 60,000 lb. per sq. in., 25 per cent elongation, of very good duralumin of ordinary composition. This "super-duralumin" is strong enough so it has a better strength-weight ratio than the magnesium alloys of comparable ductility. There seems to be hope of making beryllium-aluminum alloys that will have a materially better strength-weight ratio than the alloys of the better known light metals. So many factors enter the selection of a material for a given purpose in aircraft construction that in a paper of this sort, one can deal only witeh gneralities.

Conclusion

An attempt has been made in this discussion to set forth some of the outstanding drawbacks of the light alloys as well as their outstanding advantages. Competition among light alloys and with other alloys will go on. Every time a drawback is overcome, whether it be of price, of fabricability or of properties, the improved material will find wider use in aircraft. The survival of the fittest materials will doubtless bring light alloys

even more to the fore in aircraft construction. Without them aircraft could not have reached their present usefulness. Aeronautics owes much to the science of aerodynamics and to engine designers, but it also owes much to metallurgy. Metallurgical research has provided materials with properties suitable for the service demanded. Further progress in aeronautics is closely linked with further progress in the metallurgy of the light alloys. Fortunately, so much continued metallurgical research in light alloys is in progress that one can confidently look forward to continued improvements.

Some Economical Aspects of Airplane Design

By SCHUYLER KLEINHANS,[1] CINCINNATI, OHIO

Airplane design requires a very clear idea of the duties to be performed. Specifications should include full information as to engine power, load, top speed, landing speed, climb, range of operation, restrictions of dimensions, special arrangements for docking or storing, and factors of safety desired. The paper contains computations and graphs for planes with one, two, or three engines. It shows gains in pay load with reduction of top speed and increase in power loading. The three-engined plane suffers in comparison due to greater resistance from the greater division of power.

DESIGN of modern airplanes introduces many problems of a purely economic nature. These are factors that have a profound influence on the performance of the airplane, but are not directly connected with its engineering aspects. For example, it is simple enough to design and build an airplane that will fly, but not so simple to design and build one to meet specific conditions.

For military service these conditions are so different that distinct types have been evolved for pursuit fighting, observation, photography, bombing, transport, etc. Hence the military airplane is designed for a single purpose, all conflicting requirements being compromised to meet that end best.

The commercial airplane on the other hand has not, up to the present at least, been required to meet such specific requirements, the same make and type of airplane often being used for passenger hopping, aerial taxi, commercial photography, and cross-country flying. This promiscuous use of any type of plane for any duty has been responsible for large operating costs and a more or less mediocre performance, the airplane being compromised in so many places to make it suitable for the many kinds of service.

The public attitude has contributed its bit to this haphazard procedure by hesitating to ride in certain types of planes, believing them to be less safe than some other form which may have received considerable publicity and extensive advertising. Thus the airline operator has in many cases been forced to buy equipment that he would otherwise not think of purchasing if it were not for the public sentiment involved. This has in many instances led to incorrect investment, high operating cost, and less efficient service.

While public interest was running high and almost any kind of an aeronautical enterprise could be financed, there was no particular need for the air operations companies to show a profit, but such days cannot last forever and sooner or later all users of aircraft must establish their operations on an economically sound foundation. Thus the present need of aviation, particularly the transportation companies, is to make money. To do this, they must realize the lack of suitability of much of their present equipment and purchase airplanes designed to meet their particular requirements. This leads to a study of the factors governing the design of suitable equipment.

The first important point, then, is that the designer should have a very clear conception of the duties which the airplane has to perform, and for this purpose a specification is absolutely essential. The authority for whom the airplane is to be constructed should draw up this specification from a careful study of his requirements. It should include such principal points as:

1 The engine power available for the design
2 The amount and nature of the load to be carried
3 The top speed which is required from the airplane, and more particularly, the cruising speed required
4 The landing speed required
5 The climb which is necessary
6 The range of the airplane
7 Restrictions as to overall dimensions
8 If multimotored, the performance with engines out of action
9 Any special arrangements for docking or storing
10 Factors of safety required
11 Accommodations, etc.
12 All other points that the purchaser feels need particular attention.

The specification should also include such points as type of finish, materials of construction, type of construction, and any special provisions required.

If the specification is sufficiently detailed a capable designer can study the project and decide whether he can design an airplane to meet the requirements or not. If he can, he should have no fear of drawing up a rigid contract to build to the specification or provide a forfeit. If he cannot, it is better that he abandon the project because the contractee presumably knows what he wants and is only delayed by further negotiations.

The operator may need a land plane, sea plane, amphibion, or flying boat. He may need single- or multiple-engined equipment. He may need to operate a fast schedule to make connections with other lines, or the range may be large because of the necessity for non-stop flights. Speed in the extreme may be unnecessary, but the transportation of large loads may be of paramount importance. There is no end to the cases that may possibly arise. It is, therefore, interesting to study some of the economical factors in airplane designs.

Passengers Versus Speed

A passenger is chosen as a unit of load because it is more comprehensible to the average mind. The average person has a much better idea of the load if one says 150 passengers than if one says 27,000 lb. Computations have been made, and curves drawn for installations with one, two, or three engines each of 200, 300, 400, or 500 hp.

Since each combination of engines was studied for seven different values of the speed, the results are obtained for 84 hypothetical airplanes differing only in scale, because they are assumed to be geometrically similar. That is, all the three-engined airplanes are geometrically similar, and all the single-engined planes are also, although there is, of course, no similarity

[1] Chief Engineer, Metal Aircraft Co. Mr. Kleinhans was born in Pittsburgh, Pa. He was educated at the University of California and the Massachusetts Institute of Technology. He worked with several aircraft firms on the Western Coast, and with the Keystone Aircraft Corporation and the Metal Aircraft Corporation in the East. He is now employed by the Sikorsky Aviation Corporation as a designing engineer in charge of projects designed and built for the U. S. Navy.

Presented at the Pittsburgh Aeronautic Meeting, Pittsburgh, Pa., March 12, 1930, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

between the planes having a different number of engines. This difference is weighted by the use of the appropriate constant in the speed formula.

A wing loading of 15 lb. per sq. ft. of wing surface has been chosen as a basis for these calculations, for it is considered the maximum that may be used and still give a landing speed that present airports and emergency fields will permit. With this loading an airplane with a maximum lift coefficient of $C_l = 1.40$ will have a stalling speed of 65 m.p.h. at sea level when referred to standard conditions.

It is well known that the most economical speed of operation, namely, most miles-per-gallon speed, occurs for most conventional airplanes, at approximately half their maximum lift coefficient. Thus the most economical speed is about 41 per cent greater than the stalling speed. $V_e = V_s \sqrt[3]{2}$. While this is the most miles-per-gallon speed, it is not necessarily the best

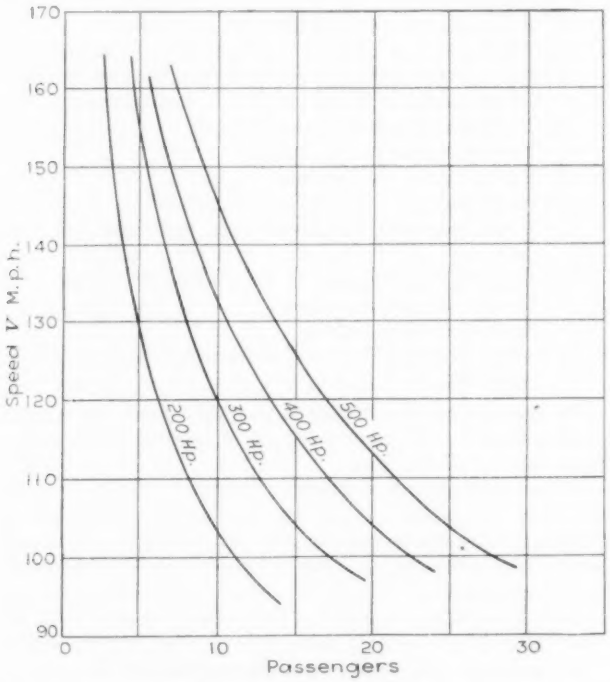

FIG. 1 RELATION OF PASSENGERS AND SPEED IN PLANES WITH SINGLE ENGINES

cruising speed for the airplane because there are a number of direct and indirect charges placed upon the airplane that have no direct connection with the plane except by the number of hours it is in the air. That these charges may be kept as low as possible, it is necessary for the airplane to complete the flight in the minimum time. Thus there are two conflicting factors which mutually affect one another and demand a compromise performance. An investigation of operating costs of a number of different enterprises seems to show that the best compromise is to operate the airplane at a speed approximately 25 per cent in excess of the economical speed. This then is the best cruising speed considering both direct and indirect expenses.

With a stalling speed of 65 m.p.h. the economical speed will be 92 m.p.h. and the best cruising speed 114 m.p.h. This speed is independent of the maximum speed or the amount of engine power installed. This is an important point which has not received the attention which it deserves. The reserve speed required of course depends upon average climatic conditions, terrain operated over, length of line, importance of schedule, etc.

Hypothetical airplane performance and characteristics were computed in the following way:

1 By assuming the top speed required

2 By solving for the area by the formula $V = k\sqrt{\frac{\text{hp.}}{A}}$

where V = maximum speed in m.p.h., hp. = horsepower of engines, A = wing area, and K = a constant. It is 140 for single-engined airplanes, 130 for twin-engined airplanes, and 125 for three-engined airplanes.

3 By solving for the gross weight by multiplying the area by the wing loading

4 By solving for the pay load which is assumed to be 25 per cent of the gross weight

5 By solving for the number of passengers, assuming a passenger and his baggage to weigh 180 lb.

The calculations are given in tabular form in Tables 1 to 12 inclusive. The results are plotted by groups in Figs. 1 to 3 inclusive. Fig. 1 is for single-engined planes, Fig. 2 for twin-engined planes, and Fig. 3 for three-engined planes.

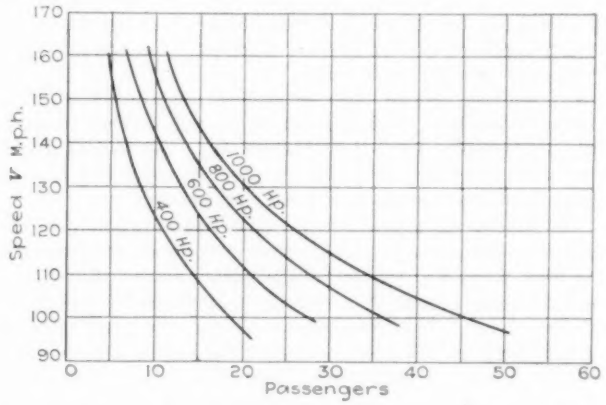

FIG. 2 RELATION OF PASSENGERS AND SPEED IN PLANES WITH TWIN ENGINES

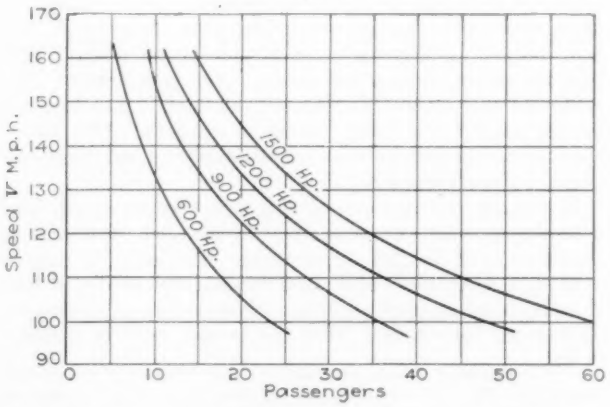

FIG. 3 RELATION OF PASSENGERS AND SPEED IN PLANES WITH TRIPLE ENGINES

As would be expected the results are very similar for the three different groups. They all show large gains in pay load with reduction in high speed and increase in power loading. The smaller pay load per horsepower for the multiengined planes is a direct consequence of the smaller constant in the speed formula. The three-engined plane suffers from a greater resistance because of the greater division of power. Thus the

speed constant for the three-engined plane is considerably less than that for a single-engined installation, and a little less than that for the two-engined plane. Most of this difference comes from the fact that engine nacelles are usually not well "streamlined," and even if artistically done are still of rather high resistance. Some of the newer cowling methods promise a large increase in the speed constant for both two- and three-engined planes.

In drawing conclusions from these curves and figures, it must be remembered that the results are no more reliable than the assumptions they are based on. It is true that some of the hypothetical airplanes analyzed are probably not capable of flight because of the extremely high power loadings. They have been included, however, because they border on the edge of practical design and fall in the class of some of the initially heavily loaded record-breaking airplanes. It should also be remembered that these results apply only to conventional airplanes of modern design, and do not indicate future possibilities. The constant reduction of resistance will gradually permit higher and higher speeds and greater pay loads. In brief, the reduction of resistance will be shown by an increase of the constant in the speed formula.

Wing Loading

From the foregoing discussion it would seem that there is no end to the benefits of increasing the wing loading. There are, however, serious drawbacks, if the loading is excessive for the size of the machine, for if the loading exceeds a particular value dependent on the size of the plane the airplane loses what might be called its more or less buoyant feeling when in a powerless glide. Another drawback is the resultant high landing speed, although this is not as serious as it seems on first thought. Briefly the advantages and disadvantages are as follows: Among the advantages are: (1) It permits the airplane to be operated nearer its economical speed, (2) it gives the pilot more control of the plane in landing, (3) the airplane is influenced less by air disturbances, (4) it reduces the structural weight, and (5) it reduces the resistance of the plane. The disadvantages include: (1) A slightly longer take-off run, (2) a longer landing run, and (3) a greater amount of kinetic energy stored when landing.

1500	160	715	15	10700	2680	14.9

The first point has been discussed in the preceding paragraphs, and needs no particular discussion here. The matter of control is simply a consequence of the fact that the air forces vary as the square of the speed while the inertia forces remain constant. The influence of air disturbances is merely one of effective incidence of the airplane. For example, suppose a lightly loaded airplane to be flying at an absolute angle of attack of 3 deg., and to meet a disturbance that increases the angle of

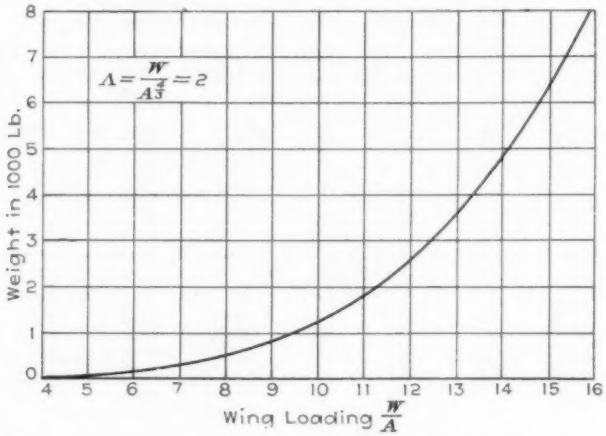

FIG. 4 RELATION OF WING LOADING TO GROSS WEIGHT UP TO 5000 LB.

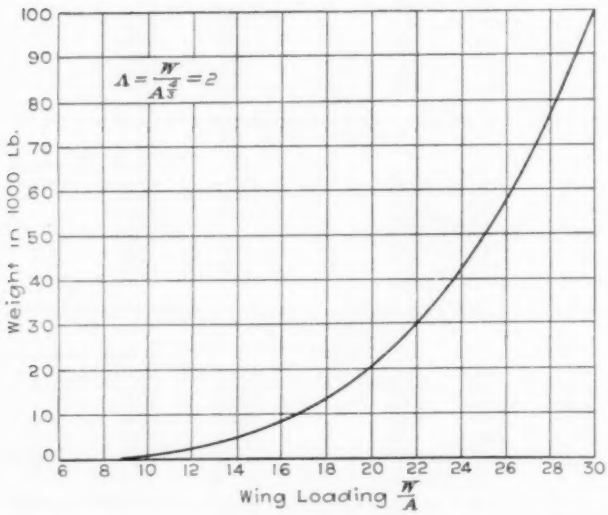

FIG. 5 RELATION OF WING LOADING TO GROSS WEIGHT UP TO 100,000 LB.

attack by 3 deg., then the lift will be doubled and the acceleration will be 2 g.

Now suppose a heavily loaded airplane to have twice the wing loading of the lightly loaded machine. The incidence will now be 6 deg. absolute angle of attack. The disturbance will again cause a 3 deg. increase in the incidence, and will result in an incidence of 9 deg. This is one and one-half times the original incidence, and will produce one and one-half times the original lift. The acceleration will then be 1.5 g. This effect is particularly noticeable when flying the same airplane, first light then fully loaded, under the same relative conditions.

The saving of structural weight is particularly noticeable where metal covering of the wing surfaces is to be used. The minimum thickness and weight of material is often the determining factor in the design so the same material in the same sizes will often carry the increased load. Also it is possible to build a structure to carry a much greater load without increasing the weight of the structure proportionately. The reduction of resistance is a consequence of the smaller wing area required to sustain the same load. The reduction in profile resistance of the wing may be a substantial saving, since the total wing profile of modern airplanes represents about 25 per cent of the parasite resistance.

The longer take-off run is serious only where the space for taking off is limited. Flying fields and airports are increasing their runways almost constantly so there will, in general, be ample space to take off with even the heaviest loaded machines. The problem of taking off from small emergency fields should not receive particular attention, for it is not the airplane's normal working environment. A railroad train may be required to run along the ties, but it certainly is not designed to do so. If it becomes necessary to take the plane off from some such limited space, it should be flown light. Geared engines are a decided help in reducing the take-off run. Their more general use seems to be merely a matter of time.

Wheel brakes are the principal mechanism used to reduce the landing run. If properly designed and installed they are very effective. Wind brakes have often been proposed, but they add complication, weight, and are effective only at the higher speeds. Since an airplane can in general land in a smaller field than from which it can take off, the provision of the ordinary wheel brake seems sufficient.

It is the author's observation that it is the way the plane lands that is much more important than the speed of the landing. A particular incident comes to mind. A small biplane, landing at about 40 m.p.h., was particularly hard to manage when once on the ground, while another larger and heavier machine landing at about 70 m.p.h. was so easy to control that it could be landed by the use of the stabilizer adjustment alone, and would roll to a normal stop without the necessity of any rudder control. This last machine although landing 30 m.p.h. faster than the first was certainly preferable even in cases of forced landings in small fields.

The kinetic energy stored in the two machines based on equal weight is more than three times as great for the fast-landing plane just mentioned than for the slower one. In case of a mishap, this most certainly would have been responsible for far greater damage to the larger than to the smaller machine, but the probability of a mishap with the small machine was out of all proportion to this difference in kinetic energy. Also, the larger machine was of such rugged construction that the final outcome would most probably have been in its favor if an accident had overtaken them both. Most certainly if the small machine had possessed the landing qualities of the larger one, the tables would have been reversed; still the heavier loaded machine will be of a more rugged construction than is economically possible in planes with relatively larger wing areas.

The point mentioned previously of the machine losing its buoyant feeling if it is excessively loaded, deserves considerable attention. The word buoyant is here used incorrectly because an airplane is sustained by dynamic forces and not by static ones as the word buoyant implies. It is, however, exactly the way the machine feels, and is used for lack of a better expression.

Early in the twentieth century it was observed by some naturalists that, although the wing loading of birds varied through quite large limits, there was a steady increase in loading, with increase in the size of the birds. Also, that sea birds had loadings much higher than did land birds of the same size. A careful investigation of the relationship of weight and area showed the land and sea birds to fall in two distinct classes, and the relationship to be

$$\Lambda = \frac{W}{A^{4/3}}$$

where W = gross weight of the bird
A = wing area of the bird
Λ = a constant
$^4/_3$ = an exponent.

When the weight was given in kilograms, and the area in square meters, the value of Λ was 7.6 and 8.4 for land and sea birds, respectively.

As birds have been man's model for flying machines down through the ages, it seemed logical to apply this relationship to airplanes as they now exist. The author has done this over a period of several years with considerable success. It was found that when the weight was taken in pounds and the area in square feet the constant Λ had values between 1 and 2 for most existing machines. The next point to determine was what was the upper limit of Λ beyond which some sort of trouble was sure to occur. Since airplanes were of much larger scale and powered mechanically and not by muscular effort, there was reason to believe that the value of Λ would be much larger when applied to airplanes than when applied to birds. This belief was justified and the upper limit of Λ was found by observations taken on a number of flight tests.

For monoplanes the maximum value of Λ was found to be very close to 2, although there was some small difference in different types and makes of machines. The limit was definitely shown by a decided change in type of airflow and a consequent loss of lift and increase in drag, although the plane had not yet reached its calculated stalling speed. It was found necessary to glide the machine at rather fast speeds to maintain the normal type of airflow. The phenomena is generally spoken of by pilots as "squashing" through the air.

At first, the results with biplanes were not so promising. The values were much lower and did not at first appear to follow the same law. It looked for a time as though extrapolation from monoplane bird to monoplane airplane was legitimate, but that extrapolation from monoplane bird to biplane airplane was not so. It was soon noticed that the results from equal-span equal-chord biplanes checked nicely with the results of monoplanes of approximately half the gross weight. This suggested the idea of considering each plane of a biplane as a monoplane and using for the gross weight the share of the load carried by each plane. When all the biplane data were reconsidered with this in mind the values checked those of the monoplane tests and were all in fairly satisfactory agreement. As is usually the case, the matter looked very simple in retrospect, and one wondered it had not been thought of in the first place.

The relationship of the equation

$$\Lambda = \frac{W}{A^{4/3}} = 2$$

is shown graphically in Fig. 4. This shows a graph with the maximum allowable wing loading plotted against the gross weight for gross weights up to and including 5000 lb. Fig. 5 is a graph of the same equation, but to a different scale and shows the maximum permissible wing loading, plotted against the gross weight for weights up to and including 100,000 lb.

It must be remembered that for biplanes the weight is not the gross weight but the weight carried by the wing in question. Some sesqui-planes by disregarding the small lower wing may reach values approximately those of monoplanes.

Conclusion

In conclusion it is well to mention the necessity of designing the airplane as a finished piece of machinery equipped with all manner of devices designed to minimize the maintenance, and keep the machine in the air long hours each day so that it has some chance of paying its way and eventually taking its stand along with other more highly developed means of transportation. In this paper it is seen

1 That very high speed is not economical for weight-carrying airplanes
2 That the pay load is greatly increased by the use of high power loadings with its resultant decrease in maximum speed
3 That high wing loadings accompanied by high landing speeds are not objectionable if the plane is designed to land properly.
4 That the maximum permissible wing loading is given by the equation $\Lambda = \frac{W}{A^{4/3}} = 2$
5 That biplanes must be treated as monoplanes each plane carrying its share of the weight.

And it should be remembered that he who undertakes a careful and rigorous analysis of the problems at hand, and designs accordingly, will eventually be rewarded with success.

AER-52-18

Airplane Servicing From the Operator's Point of View

By RICHARD C. MARSHALL,[1] CLEVELAND, OHIO

The necessity for periodic overhauls of equipment and the large financial outlay necessary to do this work properly form one of the operator's greatest problems. The author tells why centrally located shops equipped to do this work at lowest possible prices constitute the answer to the problem. This is an able and well-informed paper on airplane servicing, drawn from actual experience, and should be helpful to airplane operators.

THE difference between profit and loss, all other factors being equal, depends upon the efficient operation of the equipment involving the investment. In the case of the airplane, from a commercial viewpoint, it becomes primarily a question of ship air hours. A ship on the ground is not earning anything unless it is on display in a show or in a salesroom. It was built to fly and to carry a certain pay load, at a certain average speed, with a certain degree of safety. It behooves every operator, whether he operates one or more planes, to minimize his ship ground hours and to maximumize his ship air hours. Inasmuch as efficiency and ship air hours are in direct proportion to the condition of his equipment, it is of vital necessity that he maintain his mechanical equipment at the highest possible state of efficiency.

The problem of airplane servicing from the operator's viewpoint has grown in many instances more or less like Topsy. By the word operator is meant the air-transport operator of the mail, passenger, and express varieties, as well as the fixed-base operator, be he large or small.

It has been the author's experience that the first requisite of knowing what the equipment is doing is that there be kept an accurate log of each plane, each motor, and each propeller. The planes and motors are kept track of rather easily, but one is forced to number the propellers as to the hub and the individual blades. It is essential that a complete inspection chart be used each time a plane is flown and that each space on the inspection chart be used each time a plane is flown and that each space on the inspection chart be initialed by the mechanic who makes the inspection. Log books, too, are a source of worry. All log books are kept by the field clerks, who are responsible for their correctness.

The length of time that an airplane motor should be run is debatable, for even the manufacturer says that, with the different types of work, in the various climates the motor will function satisfactorily for varying lengths of time.

We began with using Whirlwind J-5 motors, which we ran 225 hours, including the ground time for running up and for idling for other purposes in the 225 hours. Then we raised the maximum time to 250. Experience teaching us that we were still far on the safe side, we made the maximum limit 275 hours and cut off the idling or running-up time entirely. As this time on our run amounts to about 10 per cent of the total time, as the log books were formerly kept, we have been able to boost our motor time in perfect safety from 225 to over 300, using the original method of computing the time.

The operator, again, is faced with the question of how long he shall run his plane before he has it completely overhauled and recovered. There does not seem to be any definite time at which one can say this work should be done. However, we have a number of planes that have been in constant service for two years and which are just now being completely overhauled. They have an average flying time of about 1400 hours.

One of the major problems of the operator is that of keeping his ships at peak efficiency through the periodical overhauling of planes and motors. The climate, of course, has a great deal to do with this, as stated before. However, the maintenance is much more important. The little things done from day to day in the way of maintaining the plane and motor, if done correctly, will do more to lengthen the life of the plane and motor than will any other one thing. We will take a Whirlwind J-5 Wright 225-hp. motor as an illustration.

After the engine has attained the age of 250 to 300 hours since its last overhaul, it is again in need of a complete tear-down and inspection. However, it may be true that the engine is functioning perfectly and turning up as well as ever. Nevertheless, certain vital parts have had considerable wear and, if not replaced, may cause motor failure at a critical time. Then, too, a more or less insignificant trouble may have been developing, which in a short time may turn into a major disability.

Because of this need for frequent overhauls on planes and motors, it is necessary for the operator either to maintain his own overhaul and service shops or to send his planes or engines back to the home factories, or to depend upon some other aeronautical organization which operates airplane- and motor-overhaul bases. It is the author's belief that the last-mentioned method is the most satisfactory one for the smaller operator to follow. Inasmuch as the smaller operators are greatly in the majority now and probably will be for a long time to come, the need for well-equipped, dependable, and economical repair bases for the general public's use has become imperative. Very few operators can afford to maintain their own overhaul shops and obtain satisfactory results; first, because of the large investment necessary in maintaining a fireproof building, in having specially designed equipment, in maintaining a large corps of technically trained mechanics, re-coverers, and ship builders, and then in the need for carrying costly inventories of parts and supplies. Perhaps it is just as well that the cost of the establishment of overhaul bases is well-nigh prohibitive, for the advantages offered by a few conveniently located, highly dependable aero repair depots, owned and operated by organizations of sound reputation, outrule whatever advantages a small operator might find in maintaining his own shops.

---

[1] Vice-President and General Manager, Thompson Aeronautical Corporation. Mr. Marshall became a pilot and built his first plane in 1914 in Dallas, Texas. He was test pilot of the Thomas-Morse Aircraft Company, Ithaca, N. Y., from 1916 to 1919. For seven years he was a transcontinental air-mail pilot. As Vice-President of the T.A.C. he established the first completely equipped airplane repair depot for overhaul of motors and planes for all operators.

Contributed by the Aeronautic Division and presented at a meeting in New York, N. Y., May 8, 1930, of the Metropolitan Section of The American Socety of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

One of the most important advantages is that the larger aeronautical repair-depot operator who has a constant stream of work going through his shops can effect many economies due to this large volume of business. He can cooperate closely with the Department of Commerce and with the manufacturers of planes and motors. He can afford to employ a higher salaried and more skilled type of workman. He can afford to carry a complete stock of parts and supplies at all times, thus eliminating the time that is lost by the average operator who often has to send to the home factory for the parts needed because he cannot afford to carry them in stock. These parts and supplies can be purchased in larger quantities and at a greater discount and are always of the latest production types and materials. And, too, the operator who specializes in overhaul work can so standardize all operations through the use of specially designed equipment that the repair costs are cut to the lowest possible figure. By adopting a bonus

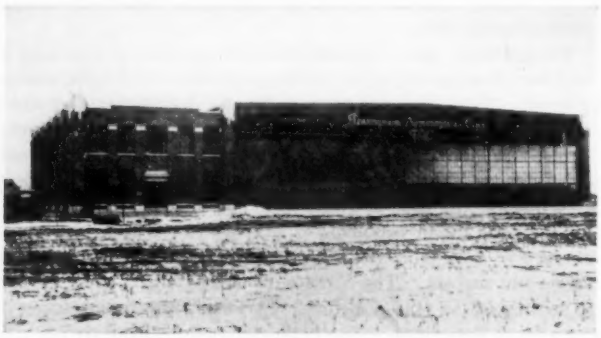

FIG. 1 AERO REPAIR DEPOT AT PONTIAC, MICH.

system, put in operation through a close study of time, prices, and labor, the charges can be lowered greatly without lowering, but even by constantly raising, the standard in workmanship. The cost can be made lower than could be secured at the factory where the original products were manufactured, due to the specialization of the man in this one line of work at the aero repair depot and the non-interruption in production by manufacturing operations, as usually happens at the home factory when outside overhaul work is taken in.

The Thompson Aeronautical Corporation, having its activities spread over four states, was faced with this problem of servicing its equipment. We found that our biggest problem was the question of how, when, and where to do this all-important major overhauling. So we established two aeronautical repair depots, one in Pontiac, near Detroit, and one at Cleveland. (See Fig. 1.) Then, we thought, if we could do our own work satisfactorily, we could lower our own costs and other operators' costs by doing as large a volume as possible, and so these depots were built to handle efficiently a large quantity of just this kind of work. Since these are excellent examples of the large overhaul bases which we believe the industry needs, it would perhaps be helpful to describe these bases and to outline the procedures followed in servicing planes and motors.

At both bases there are well-lighted buildings of brick and steel construction, because without the proper temperature and the proper lighting, the workman cannot do his best. Only the highest trained mechanics are allowed to work on motors and planes brought into these shops, because we have found that there is real economy in employing the higher class of workmen rather than having more lower-paid workmen supervised by a few experts.

Over a long period we have been taking as a beginning point or basis the time allowed by the manufacturers in various operations on their equipment and then having a time-study expert check each operation, and thus we have arrived at a constantly lowered number of hours needed to do a given job. This means, of course, economy.

Let us follow a motor through one of our depots and see just how we have tried to create efficiency and a saving in money for operators and how we have tried to solve our own problem of the greatest safety and reliability at the smallest cost per flying hour.

Again we will take the Whirlwind type of motor as an example. When the motor is brought into our depot, the first step is to receive the authorization to perform the necessary work from the owner or his representative. This is done by securing the owner's signature on a "request for repair" blank. This form, which serves as a contract is turned over to the service clerk, who in turn makes out a "job card." After these are filled out, the motor is placed in the shop. The foreman fills out a "receiving report," in which he lists all parts received and missing. After this has been done, the engine is turned over to the mechanics for dismantling. The Thompson Aeronautical Corporation has found that the greatest efficiency is obtained in tearing down or in assembling the motors by having two mechanics work together.

These workmen first place the motor on a stand and wash it down with a gasoline spray gun, to remove all grease or dirt that has collected on the outside. As the engine is disassembled, the parts are laid out on a specially constructed triple-decked parts rack, which has compartments so arranged for each group of engine parts that they can be found easily and quickly. These racks are on castors, which permit them to be wheeled over to the washing stand, the inspector's bench, and along the assembly line as the motor is being reassembled. Special tools have been developed which make a comparatively simple matter of the assembly or the taking apart of such a finely finished and accurately fitted mechanism as an aviation motor.

Following the initial tear-down, such integral parts as the front section, rear section, intermediate section, oil pump, fuel pump, and carburetor are taken apart.

Before the various parts can be inspected they receive a thorough cleaning. Therefore the parts rack is wheeled over to the washing stand, where each piece is sprayed with a gasoline air gun and cleaned with a stiff brush. Many of these parts can then be buffed and scraped to remove carbon deposits, in order that the inspection may be more accurate.

The inspector, who, like the other men, is a specialist in his line, goes over each part separately, checking for marks, crystallization, cracks, and excess wear. Practically all parts are checked carefully with a 30-diameter microscope. Many gages and micrometers are used in checking for excess wear. All parts found to be defective or worn beyond the toleration allowed are branded with red paint by the inspector to forestall any chance of their being used again. The inspector makes out an "Inspection Report," listing all machine work to be done, parts to be replaced, and component sections to be overhauled. (See Fig. 2.) Of course, such parts as the carburetors and magnetos are taken apart by men who specialize on these parts, with the special equipment necessary to inspect and thoroughly check and test them. These men must take a special course of training at the home factories of these assemblies and have all the equipment furnished by the home factories so that the job may in truth be as good as new when they are through repairing it. Nowhere in our shops do we use any equipment or parts for replacement not authorized by the maker of the original machine.

The machine work is given to the machinists. The cylinder barrels have previously been checked for tolerance, wear, etc., by the inspector. If the cylinders are beyond the toleration al-

lowed by the maker of the motor, the cylinders then are ground and honed in the machine shop.

It may be interesting to note that few operators who do their own overhaul work and maintain shops manned by skilled mechanics do their own cylinder grinding and honing, preferring to send this work out to regular machine shops. The main reason for this is the large investment which must be made in equipment and the expense of carrying an experienced grinder and honer, as there is a limited amount of this work in the average operator's overhaul requirements.

In connection with the honing process, the Thompson Aeronautical Corporation experienced considerable difficulty during the latter part of 1928, when it first started honing air-cooled motor cylinders, due to the cylinder walls being of a different texture after several hundred hours' use. It took several months of close cooperation with the makers of honing stones and the honing machine to get the right composition in the stone and the right speeds for the machine to prevent the pulling or "ringing" of the cylinders. The first stones we attempted to use made the metal ridge up or cut deep marks in the cylinder barrel. However, a satisfactory stone was developed, and for the past year and a half no trouble has been experienced.

Of course, if the cylinder is of the type that has a steel barrel and an aluminum head shrunk or screwed on, and the walls of the cylinder barrel are so badly marked or worn that the barrel cannot be used again, it must be removed and a new sleeve inserted in the aluminum head, if the owner so desires; otherwise a complete new cylinder is necessary.

Another problem which we have solved since entering the overhaul and service business was that of removing the cylinder head in the composite type of cylinder, without damaging it, from the steel barrel. The Thompson Aeronautical Corporation overcame this problem by developing a special gas furnace, in which the cylinder head alone is heated. The principal reason that this has been a difficult task is because of the improper control of the heat used; and, too, there has resulted the pulling up or wrinkling of the aluminum head when an attempt was made to remove the steel insert or sleeve.

Another operation that has caused an excessive amount of trouble and loss of time, but which has been solved, has been the removal and proper replacing of valve seats in the aluminum heads of the modern air-cooled cylinder. Previously, all of this work was done at the home factory of the motor builder, and many of the operators still send work of this nature to the home factory, but because of the great amount of this type of work that was coming to us, we had to develop equipment to do the job ourselves.

It might be asked why we did not secure the same type of equipment employed by the motor manufacturers. The reply is that we did not consider their methods satisfactory or fast enough, as they usually had very little of this kind of work to do. The loss of material which was injured and thereby lost was too great in most cases, due to the damage which resulted in attempts to remove the worn valve seat.

With cutters and jigs designed for the job, we use a large drill press to ream out the old valve seat. The cutters are designed to leave 0.002 to 0.003 in. of stock of the old seat, which can be easily removed with a sharp-pointed tool. This does a quick clean job. After the seat has been removed, the aluminum part of the cylinder head is placed in the gas furnace, and a stopper, which our mechanics have developed, is inserted in the barrel so that it is in line with the top of the steel barrel. Thus the heat is kept from the inside of the cylinder and therefore is prevented from distorting or damaging it.

When the aluminum head has been heated to the proper temperature, the cylinder is removed from the furnace, and the valve seat is quickly dropped in place in the expanded aluminum head. A tool, also of our own development, is then used to expand and roll the seat firmly into place. Through this equipment we are able to save 30 minutes on a cylinder, or $4^1/_2$ hours on a nine-cylinder motor. This of course is a big saving to the operator whose motor we are overhauling.

While the parts are being machined and reconditioned, a "material requisition" blank is filled out by the shop foreman, who lists all the new parts necessary to complete the assembly of the motor. This is turned over to the stock room, where the new material list is made up. This eliminates delay, and work can proceed without loss of time.

In the assembly operations, the greatest care is taken to keep all clearances at the precise exactness necessary. The assembly of the motor is done in the most practical and well-proved method, each case depending upon the motor type and size. Each operation is passed on by the shop foreman or an equally competent man. When completely assembled, the engine is washed down with a gasoline spray gun and dried, in order that any oil leaks developing during the block test may be positively detected and identified. The engine is then mounted on a test stand, located in the test building. This building is arranged so that the engines run under "outdoor conditions" at all times.

A mechanic, usually the foreman or the chief mechanic, watches the engine at all times while it is on the test stand, from a point in a room adjoining the test room where he can observe the engine and put it through various tests. Before him is an instrument board most completely equipped. Among the instruments on this board he has an oil-pressure gage, an oil-in and oil-out temperature gage used for indicating the temperature of the oil as it enters and leaves the motor, a recording tachometer which registers the r.p.m., a carburetor air-intake thermometer, and a thermometer to show the temperature of the water through which the oil coils pass. He also has a thermometer on the oil tank and a clock and a stopwatch at hand. Conveniently located at the bottom of the board is the throttle, spark, and switch control of the type employed in an airplane.

The test stand is built to withstand a 1000-hp. motor, and there is a practically complete absence of vibration. With the aid of a four-bladed calibrated propeller, the conditions are ideal for testing.

The standard block test for the Wright Whirlwind, Cyclone, Kinner, and other popular makes of motors in their class includes a four-hour run-in. The run-in consists of one hour at 700 r.p.m., increasing the speed by 100 r.p.m. every fifteen minutes thereafter, until the engine has reached the speed at which it is developing nine-tenths of its full rated horsepower.

During the run-in, readings are taken at the start of each change in speed of the oil temperature in and out, the oil pressure, the manifold vacuum in inches of mercury, and the carburetor air temperature in degrees fahrenheit.

Readings are taken and recorded every ten minutes during the nine-tenths full-rated-load test, as during the run-in, to observe the fuel and oil consumption.

Fuel-consumption tests are made at nine-tenths full rated load and at full rated load with mixture control at full-rich and at best setting. Two pounds of fuel are used in computing the fuel consumption. Oil consumption is figured on the same basis as the gasoline and at the same time the gasoline consumption rating is being taken.

In addition to the time required to make these tests, the engine is run at full throttle for a sufficient length of time to determine the maximum horsepower, with the mixture control at best setting.

The motor is given an idling test and an acceleration test. The idling test consists of running the motor for five minutes at 300

r.p.m., recording the time of start and finish for this run, the r.p.m. and the oil pressure. The acceleration test consists of opening the throttle slowly to idling speed and then quickly wide open, noting whether the engine accelerates satisfactorily.

When the run is completed, a careful inspection of the engine is made before removing it from the test stand to detect any sign of oil leakage or loosening up of any parts.

All test data are listed on the standard test sheets, together with information concerning any leaks or peculiarities that might be noted.

The engine is then dismounted and cleaned up. All exposed parts are greased and various other parts oiled and given a final check. The motor is now finished.

Of course, it is necessary thoroughly to calibrate each metal propeller each time the motor is completely overhauled, or about every 300 flying hours. We have in our aero-repair depots propeller-balancing stands and mandrels for the more popular propellers and hubs.

The propeller is first put on a pitch-setting table, and the pitch of each blade is checked, and it is then inspected for cracks or other flaws. It is then carefully balanced and polished, and it is ready for service again. Once every 1000 hours we have the blades pickled, or put in a solution that will show up any defects in the metal. This is a precaution against failure.

It is a fairly well-accepted rule that at about every 1000 hours of running time or 18 months of elapsed time a fabric-covered plane needs a general overhauling and checking up. For the average operator this is indeed a problem, because to do this work he needs blueprints of the airplane from the manufacturer. He needs to maintain a well-heated and well-ventilated dope

WORK TO BE DONE LISTED ON BACK OF PAGE

FIG. 2 INSPECTION REPORT OF THOMPSON AERONAUTICAL CORPORATION

room, with the latest type of spraying and painting equipment. He also needs a welding room where the most difficult jobs can be done by experienced welders, because most of the modern planes are of tubular-steel construction. And then, of course, the average airplane mechanic is not competent to do a ship rebuilding job satisfactorily.

It is possible for the aeronautical repair-depot operator to secure from the various manufacturers blueprints of their types of machines and to arrange for the frequent inspection by the Department of Commerce inspector, so that the work will not be held up during process, as in our motor-overhaul jobs we have endeavored to cut down the man-hours on each plane rebuilding job.

In our aero repair depots the procedure in completely overhauling a plane is as follows, the routine changing very little, regardless of whether the ship is a monoplane or a biplane:

When the plane is brought into the ship rebuilding department, it is carefully checked over by the expert ship builder, and a "work order" is made out for the job, on which is itemized as nearly as possible all work to be done. The work is then planned accordingly. The first work, of course, consists of completely dismantling. The wings and all control surfaces are sent to the wing room for stripping and careful inspection of the structures. Here all repairing and truing-up that are necessary are performed.

Following the dismantling, the fuselage is taken into the fuselage department, where it is stripped. All bearings are examined and repaired, and replaced if necessary. The struts and members are cleaned, and a minute inspection is made so as to locate cracks, damaged parts, or structural defects. If of dural construction, it is sandpapered and cleaned up completely, following which it is moved into the paint shop, where a coat of clear weatherproofing protective material, such as Lionoil, is sprayed on.

If the fuselage is constructed of steel welded tubing, it is thoroughly cleaned, and two coats of anti-rust material are sprayed on. On some members it is necessary to apply several coats of enamel over the priming paint.

Members of the steel fuselage are drilled at points where the structure will not be weakened, and a special preservative liquid, usually some sort of oil, is forced into the interior of the tubes. The holes are then closed by welding. In addition to serving its purpose as a preservative, this liquid, when forced into the tubing, will disclose defects in the welding.

By this time the linen covering has been fabricated in the cover department, and as soon as the paint shop is through with the bare fuselage, the upholsterers are busy with the interior finish and the recovering is done.

The next step is doping and finishing the fuselage. In this work six coats of dope are applied, followed by two or three finishing coats of paint or lacquer, if desired. In the meantime the upholstering is also being completely renovated or made new as is required.

The control surfaces are completed, together with the wings, and are brought into the dope room for weatherproofing by using varnish or anti-rust paints. The wings and control surfaces are then covered and returned to the dope room for final finishing.

The plane is then reassembled, and while the riggers are busy, the upholsterers are completing their ork in the cabin or cockpit.

It is understood that only the highest grade of materials is employed in all work done. The reasons for this are obvious. It has been found that only the best dopes and paints should be used, the small additional cost being many times offset by the long life given to the plane in protection and appearance. It is the same with the linen and with any other materials.

The Department of Commerce inspectors have been making various inspections as the plane has progressed from dismantling to reassembling, and they are present or in the plane when it is test-flown and finally pronounced satisfactory.

The building and its arrangement are such that work can be moved from point to point with a minimum amount of lost motion, which is very important, more so in this particular kind of work than it is in the manufacturer's home establishment.

Usually the plane is called upon by its owner to fulfil a definite job, and when it is not in use it is a loss to its owner. Consequently, every effort must be made to expedite the work on it.

The procedure and methods used in overhauling motors and planes have been discussed at length, but one of the major items to an aircraft operator is the complete servicing of his aircraft. The line operations or day-by-day maintenance problems are not nearly so difficult to the operator as are his overhaul problems. The solution of the operator's problem along these lines is, as stated before, the providing of reliable, competent aero repair depots, located at convenient points, so that through the volume of work which they do they are enabled to keep the cost down to the minimum and which are every day striving to lower their own costs, so that they in turn may lower the cost to the airplane operator.

Discussion

D. W. Tomlinson.[2] From the standpoint of the large air-line operator it is essential as well as desirable that maintenance work of motors and planes be an integral part of the operations department of the organization. Usually in air-lines operations of any consequence there is a sufficient amount of motor and plane overhaul to justify shops for that purpose. When such work is done within the organization, the work can be better planned and executed in such a way that the entire plan of operations is most efficiently served.

Log books, both plane and motor, are in this organization, kept up by a chief clerk at division headquarters. Each plane carries an inspection form on which is recorded in abstract form the total time of the plane and all motors, with any other special information the log books contain on that particular ship or its motors. In addition we employ in our hangar a motor board. This is a large blackboard on which is kept up to date the total number of motor hours since overhaul of each engine then in service. With this data there is also recorded for each motor the time it has run since the several routine operations required in service have been performed, such as oil changed, valves checked, pushrods greased, magnetos checked, strainers cleaned, etc. This provides a visible record, which may be seen at a glance, of the status of all engines in active service.

Regarding the number of hours which any engine may safely be run, the writer believes it depends, as the author states, on the conditions under which that particular engine operates. The greatest factor in the operating life of the modern engine is the care with which it receives its routine service checks. This assumes, of course, that the engine at its initial point of operation was in perfect condition. Experience has shown us that engine wear, and the resulting life of the engine between overhauls, depends also on the amount and kind of dirt which goes through the engine with the fuel; in other words, dust off the field. If present-day engines could be assured of a fuel supply free of grit, their operating life would in many instances be practically double. Up to certain limits the writer does not believe in dismantling an engine for inspection and overhaul so long as it is functioning perfectly. Invariably a motor will give timely and sufficient warning of wear due to use. We have found it practicable to run Wasp engines 500 hours between overhauling.

[2] Manager of Operations, Western Division, T.A.T.-Maddux Air Lines, Los Angeles, Calif.

The points brought out by the author in detailing the procedure followed in the motor-overhaul shops are excellent. The routine outlined is basically that employed in our own overhaul department.

The author makes one point that is well worth consideration by all operators, which is that it is far more economical to employ only higher-paid skilled mechanics than to carry one or two such men with a larger number of helpers. In our shops we use only the most experienced and reliable men. The only place where we have found it advisable or economical to employ helpers is for such work as changing oil in ships at night, fueling planes, running oil in the cleaning machine, cleaning the motor parts in the teardown room, etc.

Only all-metal Ford monoplanes have been used so far in our operations. As yet there has been no necessity for major overhauling of any of these planes. Routine maintenance and incidental repairs are made by a special metal force. Planes are very carefully inspected as soon as they arrive at the base field. An inspector goes through the interior of the wings and examines the ship generally for any defects. The life of these planes before an overhaul would be a debatable question, and resolves itself down to the life of the metal of which the planes are built. We have several planes with well over 2000 hours of operation. These planes have, to date, shown no indication whatever of any failure or deterioration. Unless crystallization or fatigue of the metal develops it is the writer's opinion that these ships may give perfect service without major overhaul for some five to ten years. This presupposes painstaking routine maintenance throughout this period.

The problem of renewing cylinder heads, valve seats, and regrinding cylinder barrels has been taken care of by us in returning the parts to the factory for such operations, with the exception of cylinder regrinding, which is done locally, the volume of motor overhaul not having developed to the point at which it would be economical for us to perform these operations in our own shop.

To facilitate the testing of motors we have employed a test stand mounted on the rear end of a truck. All test instruments are mounted on a board between the driver's seat and the motor mount. This instrument board, with all engine controls, is closed for the convenience of the mechanics making a test. This stand has been found very satisfactory. It greatly simplifies the mounting and dismantling of the engines from the test stand, as the engine is backed up to the motor overhaul shop itself. As minor failure occurs during the test the motor can be brought without delay directly to the overhaul shop for the adjustment or change of parts.

Alfred C. Hurlbut.[3] Maximum performance at a minimum maintenance cost is becoming one of the most important factors in the aircraft industry. A manufacturer can design a ship so that all parts can be easily serviced, but the ship must be inspected and serviced constantly to insure continuous dependable performance.

Like any other piece of machinery, an airplane must have constant care and cleaning to keep it functioning properly. However, it differs in that the need for repairs must be anticipated before they become serious. This, of course, emphasizes the need for trained airplane mechanics who know what parts are most likely to show excessive wear, how to look for them, and how to repair them.

For example, the bolt holes in certain places may become elongated due to vibration. It is an easy matter to enlarge these holes and put in a larger bolt, and this is often done, with the result that sometimes there is not enough stock left in the member so drilled to give it sufficient strength, and it gives way. If this member had been filled, and then drilled to its original size, it would have been as good as new.

Another example is improper cleaning. Many ships are cleaned with gasoline, as it is the quickest way, or they are cleaned with nothing but water. Either of these methods will cut the life of the finish in half. The ship should be thoroughly scrubbed with castile soap and water, and then carefully rinsed to remove the soap. If the ship is finished with lacquer, it should be gone over with a good lacquer polish to bring the life back. Thorough cleaning is also important, because only when the ship is clean can small cracks or failures be discovered and repaired before they become serious. These are only two of the many examples which show the importance of good servicing.

Airplane operators are demanding planes that can be kept in the air a maximum number of hours per year and a ship that is designed so that inspection, lubrication, and replacement of parts may be easily accomplished. Such ships can usually be operated at a lower cost than a plane of more complicated construction. The Detroit Aircraft Corporation realized this fact, and all models are so designed that there are a minimum number of working parts, and all of these are easily inspected and serviced by removing several cotter keys from an inspection plate or opening a zipper fastening. This enables the pilot to make his own inspections or to have them made quickly at a minimum cost.

The service departments of manufacturing concerns, operating lines, and general service hangars are faced with problems which in most cases are similar. Through years of experience, we have evolved service departments which operate smoothly and efficiently.

Any ship coming up the runway to the hangars is met by a representative of the service department with his order pad and pencil in his hand, who takes the customer's signed order for any work he wants done and who is held responsible for the ship until it leaves. He makes out the order, sees that all jobs are done, that they are paid for, and that the customer is satisfied. Anything which he can do personally for the pilot, such as arranging hotel accommodations if the pilot is staying overnight or getting weather reports, is gladly done.

The personnel of the service hangar must comprise experienced mechanics not specialists in one line, but men who can do various kinds of work. The service hangar is continually running into new problems which a crew of skilled mechanics can solve and repair with a minimum amount of lost motion. Many times the service department is called upon to do work in a field miles away from the hangar, and usually the telegraph or telephone call which orders them out to the job does not give complete information. Upon arriving at the scene, the mechanic may find that, besides the broken parts he is prepared to replace, he must also patch fabric or splice a control cable. Valuable time is lost and extra expense to the customer is incurred if the service department does not realize these possibilities and anticipate them by sending an experienced man and necessary materials to take care of any damage which might be caused by such an accident.

For example, the Ryan Division service department in St. Louis received a long-distance call for service. The pilot reported an axle washed out in overshooting a field and running into a ditch, and asked that a mechanic be sent out with a new axle by airplane at once, as they must get the ship in the air as soon as possible to fill an important engagement. He stated nothing else was needed. The mechanic and axle were sent in an airplane, along with some extra parts which might possibly have torn loose. Upon arriving at the scene of the accident the mechanic discovered the fuselage axle fittings badly bent and the bottom fairing broken, but he was able to make the necessary repairs because

[3] Service Manager, Ryan Division, Detroit Aircraft Corporation, St. Louis, Mo.

the possibilities had been anticipated. If he had not taken these parts along, an important engagement would have been unfilled and an additional expense to the customer incurred by ordering more parts shipped.

Too often ground crews lose sight of the responsibility they undertake when servicing a ship; therefore, the mechanics should be under the direction of a foreman who understands the problems which face a pilot and who realizes his responsibility when he inspects the finished work and approves the ship for flight.

A service hangar should have a machine shop, a dope shop, a sheet-metal shop, welding equipment, woodworking tools, and miscellaneous equipment necessary for checking pitch, balance and track of a propeller; vises, jacks, hoists, and all the special tools required for a particular motor. A manufacturing plant has an advantage in this respect, as many of the departments can be used for service work without duplicating equipment in the service hangar.

If the service hangar is specializing in the maintenance of any particular type of ships, a supply of the parts which need replacing from time to time should be carried in stock. It is our policy to carry in stock a supply of parts for all models, obsolete and present, to enable the service department to make immediate delivery of any part. This policy saves much time and money for customers.

If a service station is connected with a sales agency, it can be of great value through its contact with visiting pilots who often furnish leads which result in the sale of new ships. If it is connected with a manufacturing plant, it can be of assistance in many respects. It is a great help to the production and engineering departments, as reports on how various parts perform or stand up will help the engineering department to design many improvements.

Our service departments are operated with the fact in mind that a satisfied customer becomes a booster and that operating at a profit, although important, is a secondary consideration.

We feel that when a ship is sold, our responsibility is just beginning. The customer is given help and advice on the care and maintenance of the ship and an invitation to write or come in for suggestions at any time. He is particularly asked to come in for an inspection before his ninety-day guarantee on defective parts runs out.

AER-52-19

Vibration Characteristics of Aircraft-Engine Crankshafts

Report on a Series of Tests in Which a Recording Torsiometer Was Used

By FORD L. PRESCOTT,[1] DAYTON, OHIO

IT HAS long been realized by designers of internal-combustion engines that calculation of stresses in crankshafts was incomplete without an investigation of the torsional-vibration characteristics of the engine. Marine designers have been compelled to take this phase of design into account because of the nature of the drives used and the extremely favorable conditions for large-amplitude torsional vibrations. It is only because of the shorter drives and the comparatively stiffer crankshafts used in aircraft engines that the torsional periods have not forced themselves on the designers of such engines at an earlier stage. There has also been a feeling among those actively engaged in such work that calculation of torsional period was too involved and complex and too little was known of the phenomenon to make it worth while to take account of it. As a result, engines are built and run regardless of critical periods, and when a "rough spot" is observed in the operating range, the engine speed is varied to avoid running at that particular point. An example in point is the Liberty-12 aircraft engine. Calculation of crankshaft stresses does not reveal any marked weakness and yet there are speeds within the operating range where crankshaft failures occur. It has been found by numerous tests that there are three critical speeds at or near which torsional vibration is encountered. These speeds, as will be pointed out in connection with test records, are 1000, 1333, and 1715 r.p.m. with a frequency of 100 vibrations per second. Two of these periods, most unfortunately, occur at speeds which are encountered in operation. The normal rated speed of the Liberty-12 is 1700 r.p.m., and when fitted with a propeller for supercharging, but taking off without supercharge, the speed is pulled down to 1350 or 1400 r.p.m. A consideration of this design from the torsional-vibration standpoint would have indicated the desirability of removing these periods to a little-used part of the speed range. Because of the smoothness of operation of the Liberty-12 at 1450 to 1550 r.p.m., the pilot prefers to use this speed range at the expense of output. Another design of large 12-cylinder Vee engine has a critical period of vibration at 1800 r.p.m., its rated speed. The roughness of this engine, which was partially due to poor distribution, caused numerous failures of pipes, accessories, and water joints. To remedy this serious defect, a spring coupling was incorporated in the geared models. This seems to have the effect of making all speeds about equally bad in respect to torsional vibration. (See Figs. 11 and 13.) The coupling did, however, reduce the impact load on the teeth of the reduction gearing.

It would appear to be ideal to design a crankshaft so that no torsional periods would occur within its operating range. This is readily done in the case of the radial engine because of the short, stiff crankshaft used. In the case of the 4- or 6-cylinder line engine and the 8-cylinder Vee, it is still possible to avoid the primary critical period. The 4- and 6-cylinder line engines, however, will have torsional periods at one-half the primary critical speed by reason of the double-frequency inertia torque which is characteristic of these engines.

The inertia torque characteristics of a number of engine types have been computed and published in the *Automobile Engineer*, September, 1929. In the curves, the fact is brought out that the torque due to inertia is, in the 4- and 6-cylinder arrangements, greatest in the propeller-end crankcheek and main journal. In the 12-cylinder Vee, the stress due to this factor is greater in the journal between cylinders 5 and 6. This would seem to explain why the Liberty crankshaft almost always breaks at one of the cheeks between 5 and 6 instead of at the last cheek. In the case of the radial engine, inertia torque is a negligible factor.

In the case of the 8-cylinder and 12-cylinder Vee, the frequency of the inertia torque is equal to that of the power impulses. This frequency is too high in the 12-cylinder Vee to permit of designing the crankshaft so as to eliminate torsional vibration even up to a speed of 2000 r.p.m., since the equivalent flywheel effect of the necessary reciprocating and rotating parts combined with that of the crankshaft itself would make necessary a stiffness which cannot be incorporated in a practical design. It therefore appears that the best that can be done is to place the rated speed just below one of the critical ranges. This allows a considerable throttling range before the next lower period is reached. The reduced torque impulses at this latter period are not sufficiently serious to cause dangerous torsional vibration.

The study of torsional vibration by the Power Plant Branch, Matériel Division of the U. S. Air Corps, began at McCook Field prior to July, 1927. It was not, however, seriously undertaken until the summer months of that year. The project was carried through the summers of 1927 and 1928 and from June, 1929, until the present. It is felt that there is still much to be learned in spite of the mass of data already taken.

Instrumentation

The question of an instrument suitable for recording the vibrations actually encountered proved to be a serious one. Many types were considered and discarded as impractical for various reasons. The electromagnetic type of instrument gives a beautiful record of the relative velocity of the crankshaft and some uniformly rotating reference member. This record must be integrated in order to show the displacement record and of course does not give the amplitude of vibration. In the case of a vibration of harmonic form, the velocity record also gives the frequency, but the rather complicated displacement curves observed are not readily studied by any record other than the displacement-time record. It was therefore decided that the desired instrument should draw a graph of torsional displacement against time. An ingenious electrical device has been developed by Dr. H. Thoma, Karlsruhe, Germany. The novel feature of this instru-

---

[1] Senior Mechanical Engineer (Research) Matériel Division, Air Corps, Wright Field. Associate Professor of Mechanical Engineering, University of Florida (on leave).

Presented at the Fourth National Aeronautic Meeting, Dayton, Ohio, May 19 to 22, 1930, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

ment was the use of toothed condenser plates, one attached to the crankshaft and the other to a uniformly rotating member. The variations of capacity of this condenser were used as in the condenser microphone to modulate a vacuum-tube circuit, the plate current of which passed through an oscillograph. This arrangement is capable of being calibrated and gives a displacement-time record. Another device which has been used successfully is Dr. Geiger's well-known torsiograph. It was by means of these instruments that the failures of the power plants on the *Graf Zeppelin* were analyzed.

An early design of torsiometer used by the Matériel Division incorporated links and pins to impart motion to an indicating hand. The latter moved over a scale graduated in degrees and was read by means of a neon stroboscope. Rapid wear proved to be fatal to this type of instrument, in spite of case-hardened

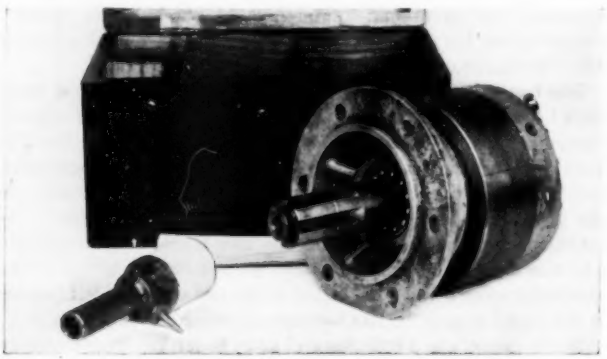

FIG. 1 VIEW OF INSTRUMENT SHOWING METHOD OF ATTACHMENT TO ENGINE-STARTER MOUNT

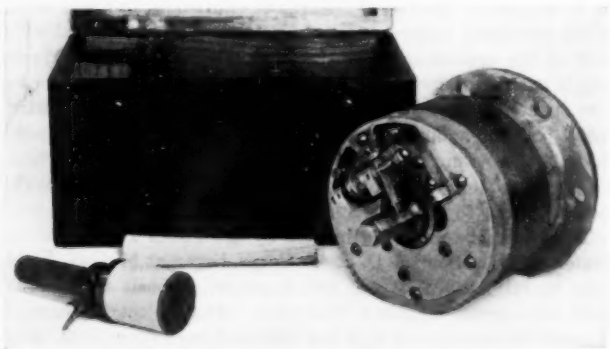

FIG. 2 VIEW OF INSTRUMENT SHOWING DETAILS OF RECORDING MECHANISM

parts. In the spring of 1928, the idea occurred to the author that a flexible cable of small size could be used, and this was accordingly incorporated in the instrument used during the summer of 1928. Figs. 1 and 2 show general views of the instrument. The arrangement makes use of pulleys and a drum on the shaft carrying the pencil. This has proved very successful and is quite free of backlash. The cable eventually wears out but is readily replaced and, under the severest conditions so far met with, the life of the cable is several hours of continuous operation. The record is made on ordinary indicator paper. A drum is provided which retains the paper, and since the pencil revolves with the instrument, the drum is held in the hand, inserted over the pilot provided for it, and quickly pressed in and withdrawn. The last $^1/_{32}$ inch of motion of the drum operates a bell-crank system and presses the pencil against the paper. A pointer is provided on the drum, and with the engine set on top center of one cylinder, the beginning of the card is lined up with the pencil, the pointer being vertical. This serves to locate the crank positions on the records. The two revolutions in the engine cycle are superposed, hence the complete cycle crosses the card twice before it repeats. In the present design, the records show a displacement of $^1/_8$ inch for each 1 deg. of torsional displacement of the crankshaft. The natural frequency of the spring-driven flywheel is 10 to 12 vibrations per second. This frequency is necessitated by the high accelerations to which aircraft engines are subjected. Fig. 3-*d* shows the calibration record obtained at a speed of 30 r.p.m. The flywheel was plucked and released to obtain a record of the damped vibration of the spring-driven flywheel.

TEST RESULTS ON VARIOUS ENGINES

A number of records from various engines are presented in Figs. 4 to 18. In Fig. 4 is presented a series of cards taken with a standard Liberty metal propeller with blades set at an angle of 25 deg. at 42-in. radius. This held the full-throttle speed down to 1330 r.p.m. Two synchronous periods are evident, one at 1000 r.p.m., card (*c*), and one at 1330 r.p.m., card (*j*). In both cases, the frequency is very close to 100 vibrations per second.

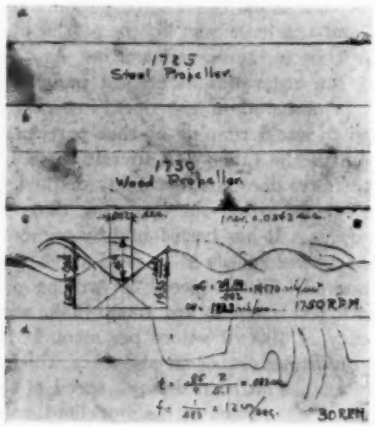

FIG. 3 (*a*) AND (*b*) RECORD OF TORSIONAL VIBRATION AT NOSE END OF LIBERTY CRANKSHAFT WITH METAL AND WOOD PROPELLERS. (*c*) METHOD OF DETERMINING ACCELERATION FROM RECORDS. (*d*) RECORD OF NATURAL VIBRATION OF FLYWHEEL OF INSTRUMENT

At 1000 r.p.m. there are 12 vibrations corresponding with the 12 power impulses per cycle or 6 per revolution. At 1330 r.p.m there are 9 vibrations per cycle, or $4^1/_2$ per revolution. These two periods would be accounted for by the presence of twelfth and ninth harmonics in the single-cylinder torque curve. Cards (*l*) and (*m*) show the effect of cutting out one set of plugs. In the Liberty, both plugs were near the center of the combustion space, hence little effect is observed other than the loss of r.p.m. Card (*n*) shows the effect of retarded spark at full throttle. The speed dropped to 1000 r.p.m., but since maximum pressure was reached later in the cycle, the deflections were greater than those in card (*c*). Vertical lines were drawn indicating approximately maximum torque (20 deg. after top center) on the cylinders marked at the bottom. It is observed that all 12 vibrations at 1000 r.p.m. and 6 out of 9 at 1330 r.p.m. show maximum acceleration at about the time of maximum torque.

Fig. 5 presents the records taken on the same engine with a propeller setting of 17 deg. at 42-in. radius. Here the maximum speed was 1700 r.p.m., the rated speed of the Liberty-12. In this set of records, three resonant periods are observed. That at 1000 r.p.m. is of small amplitude, due to the small power impulses.

The period at 1330 is apparent in cards (*g*) and (*h*), followed by a comparatively smooth range, cards (*i*) to (*l*). The third resonant period occurs at about 1700 r.p.m., as shown in cards (*o*) and (*p*). The frequency is the same as at the two lower periods. It is to be noted that 6 out of 7 of these vibrations show maximum acceleration close to points of maximum torque. This period would indicate a seventh harmonic in the resultant torque curve. No records have been taken at speeds in excess of the third resonant period on a 12-cylinder Vee engine.

Fig. 6 shows a set of cards taken on a 12-cylinder Vee engine of about 1150 cu. in. displacement. These were taken on the dynamometer using a rather heavy thermoid coupling. The compression ratio of this engine was 7.3 to 1 and the engine was operated at the maximum load it was believed safe to carry at each speed up

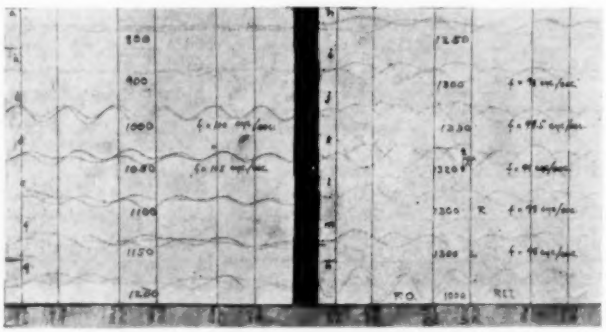

FIG. 4 TORSIONAL VIBRATION IN LIBERTY-12, WITH PROPELLER SET FOR 1330 R.P.M. AT FULL THROTTLE

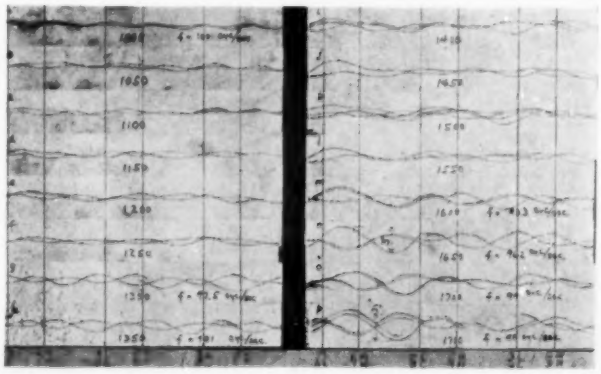

FIG. 5 TORSIONAL VIBRATION IN LIBERTY-12, WITH PROPELLER SET FOR 1700 R.P.M. AT FULL THROTTLE

to 1800 r.p.m. From this point, cards were taken at full throttle up to 2700 r.p.m. This was done in order to record the worst conditions obtainable in normal operation. Vertical lines indicate cylinders at top center. It is observed that definite resonance appears at 1600, 2100, and 2700 r.p.m. These periods bear the same relation to each other as did 1000, 1330, and 1700 r.p.m., in the case of the Liberty-12. If the frequency is accurately 160 vibrations per second, these resonance points should occur at 1600, 2130, and 2740 r.p.m. It is evident from the records that 2500 r.p.m. should be an excellent full-throttle speed, since this would allow a throttling range of 400 r.p.m. before encountering resonance, reducing the power output on propeller load to 59 per cent of that at 2500 r.p.m. It is doubtful if the effect of the resonant vibrations at 2100 r.p.m. could be felt at this reduced output. In climbing, the engine might be called upon to operate within this critical range at full throttle, but the duration of such full-throttle operation would not be great enough to cause crankshaft failure. Unfortunately, no records are available on this engine with propeller load. It will be pointed out in connection with another set of cards that it is unsafe to draw conclusions from dynamometer records, because of the effect of the coupling used. In order to approximate propeller loading, the moment of inertia of the coupling should be large.

Fig. 7 presents a very interesting record of a 6-cylinder line engine of about 470 cu. in. displacement. In this engine, resonance with the power impulses could not be observed, since it would not occur until speeds in the neighborhood of 3200 r.p.m.

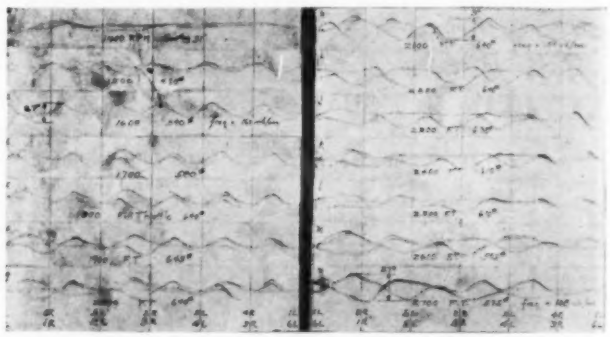

FIG. 6 RECORDS FROM ENGINE NO. 2, TABLE 1, TAKEN ON DYNAMOMETER COMPRESSION RATIO 7.3 TO 1, FULL THROTTLE, FROM 1800 R.P.M. TO 2700 R.P.M.

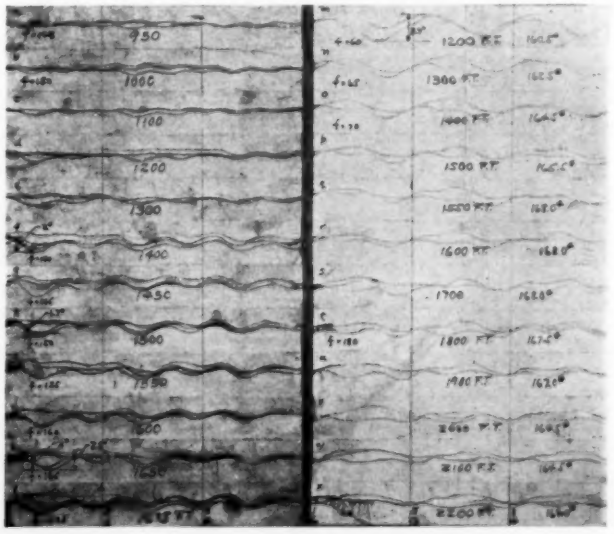

FIG. 7 RECORDS FROM ENGINE NO. 4, TABLE 1, TAKEN ON PROPELLER LOAD, IN THE AIRPLANE (*a*) TO (*l*) AND ON DYNAMOMETER, USING THERMOID COUPLING (*m*) TO (*x*)

were reached. This is far beyond the operating range of the engine. There should also appear a range of resonance at a speed of about 2130 r.p.m., but the available propellers would allow the engine to turn up only to 1875 r.p.m. Cards (*a*) to (*l*) were taken on propeller load in the airplane, while cards (*n*) to (*x*) were taken on the dynamometer. In the latter case, a thermoid coupling was used to couple the engine to the dynamometer. Since it was of small size, its effect as a flywheel was negligible and the actual crankshaft vibration was only slightly apparent in the records. These cards would seem to indicate that a coupling with appreciable hysteresis, such as that offered by the thermoid disks, might be a desirable type to incorporate in a geared engine. The chief objection to the thermoid coupling would be, of course, its size.

Figs. 8 and 9 show cards taken on a large 9-cylinder radial engine. Fig. 8 is from the direct-drive engine and Fig. 9 is from the 2 to 1 geared engine. The gearing is of the Farman type and does not incorporate any type of spring coupling. There is, however, indication of a considerable amount of flexibility in the reduction gearing, since the resonance period is lowered from about 2100 r.p.m. to about 1450 r.p.m. Assuming the same moment of inertia in both engines, the ratio of torsional stiffness from center of cylinders to edge of propeller in the direct engine is to that of

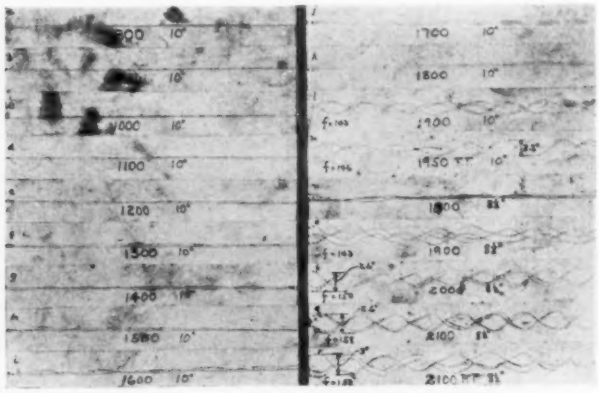

FIG. 8 RECORDS FROM A LARGE DIRECT-DRIVE 9-CYLINDER RADIAL ENGINE, ON PROPELLER LOAD, WITH TWO PROPELLER SETTINGS, 10 DEG. AND 8½ DEG. AT 42-IN. RADIUS

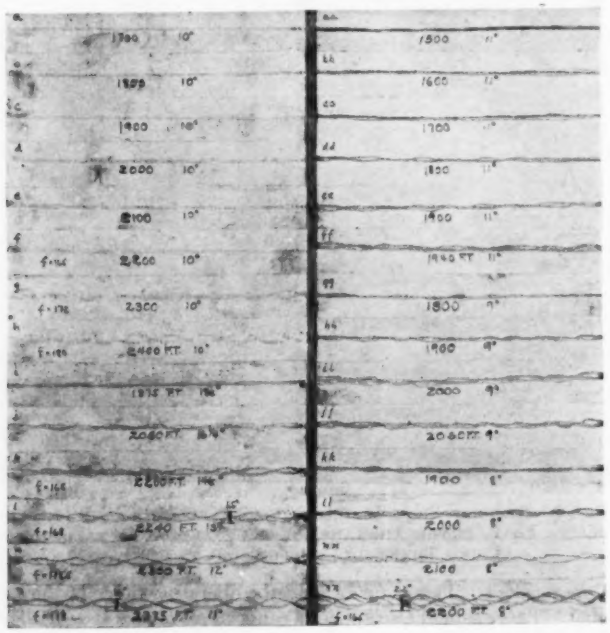

FIG. 10 (*a*) TO (*n*), RECORDS OF LARGE RADIAL ENGINE (DIRECT DRIVE) CHOSEN FOR SAMPLE CALCULATION OF RADIAL ENGINE, (*aa*) TO (*nn*), RECORDS OF ANOTHER LARGE RADIAL ENGINE OF 9 CYLINDERS

the geared engine as 2100^2 to 1450^2, or 2.1 to 1. It is hard to say where this flexibility is introduced, as this type of reduction gear is very much like an automobile differential in which the spider drives the propeller and one of the bevel gears is held stationary, the other being driven by the engine. The frequency of the direct crankshaft is about 158 vibrations per second, while that of the geared shaft is reduced to about 109 vibrations per second. It is observed that torsional vibration occurs in the direct engine at normal operating speed of 1900 r.p.m., while in the geared engine, the operating range from 1600 to 1900 r.p.m. is free of resonant vibration. The range from 1300 to 1550 r.p.m. is practically never used. Hence, this condition is satisfactory in the geared engine. In the case of the direct engine, however, stiffening of the crankshaft is indicated in order to eliminate possible trouble due to critical crankshaft vibration.

Fig. 10 shows records from two other large 9-cylinder radial engines, both of them direct drive. Both are free of critical vibration up to about 2100 r.p.m., which is in excess of normal rated

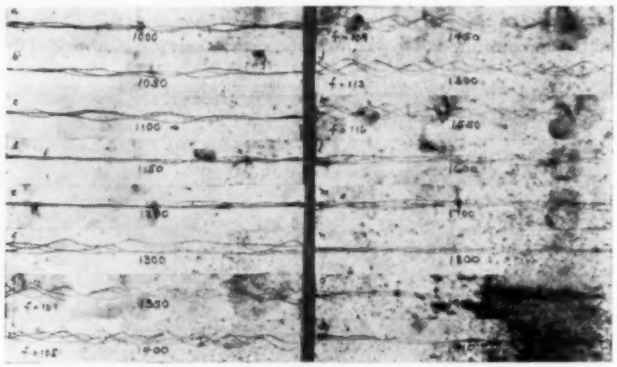

FIG. 9 RECORDS FROM ENGINE SAME AS IN FIG. 8, BUT WITH 2-TO-1 FARMAN TYPE REDUCTION GEAR

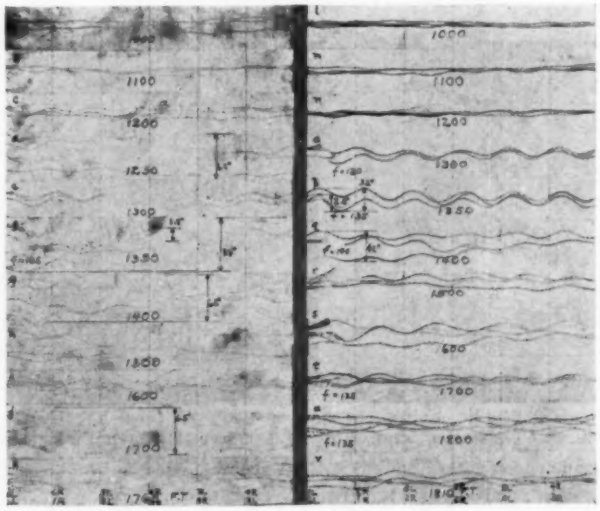

FIG. 11 (*a*) TO (*k*), ENGINE NO. 6, TABLE 2, ON PROPELLER LOAD, SHOWING EFFECT OF BAD DISTRIBUTION. (*l*) TO (*v*) SAME ENGINE WITH CASINGHEAD GASOLINE TO SMOOTH OUT DISTRIBUTION

speed. The critical frequency of the first appears to be about 175 vibrations per second and of the other, about 165 vibrations per second. These records constitute proof that the large radial engine can be so designed as to be free from trouble due to torsional vibration up to a speed as great as can be utilized before valve-gear trouble makes itself felt, and where inertia loading of the crank bearing becomes excessive.

Fig. 11 is an interesting set of records from a large 12-cylinder Vee engine. Cards (*a*) to (*k*) were taken, using domestic aviation gasoline and 5½ cc. of ethyl fluid. It is to be noted that while the period of the crankshaft is apparent at 1350 r.p.m., the variations from cycle to cycle are much greater in amplitude.

This was thought to be due to faulty distribution, hence the fuel was changed to highly volatile casinghead gasoline and cards (*l*) to (*v*) were taken. The engine operated much more smoothly on this gasoline, showing that a large part of the roughness of the engine was due to poor carburetor and manifold arrangement. It is to be observed here that the crankshaft has a distinct torsional period at 1350 r.p.m. and another at 1800 r.p.m. Both of these show a frequency of 135 vibrations per second, there being

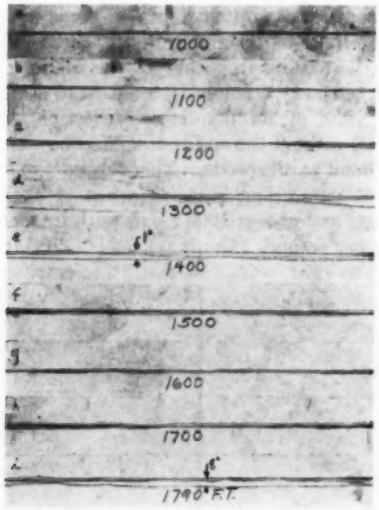

FIG. 12 SAME ENGINE AS IN FIG. 11, BUT RECORDS TAKEN FROM NOSE END OF SHAFT

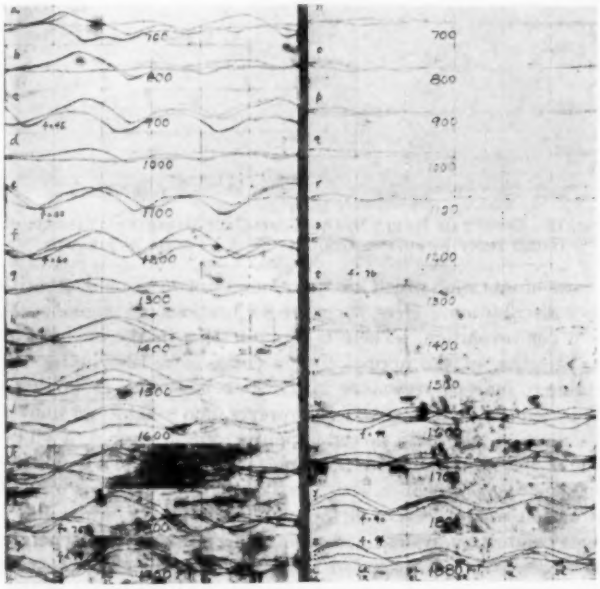

FIG. 13 (*a*) TO (*m*), ENGINE NO. 7, TABLE 1, SAME ENGINE AS IN FIGS. 11 AND 12 BUT WITH REDUCTION GEAR INCORPORATING A SPRING COUPLING. (*n*) TO (*z*), SAME AS (*a*) TO (*m*) BUT WITH RIGID-GEAR DRIVE

12 vibrations per engine cycle at 1350 r.p.m. and 9 at 1800 r.p.m. Since the rated speed of this engine is 1800 r.p.m., the engine is called upon to operate for extended periods within this second critical range. Fig. 12 shows a set of records from the propeller end of the engine, using the same fuel as was used in cards (*a*) to (*k*), Fig. 11. These records show quite definitely that deflections occurring at the rear end of the crankshaft do not indicate accelerations of the shaft and propeller as a unit. In resonant vibration, the shaft probably deflects according to an elas-

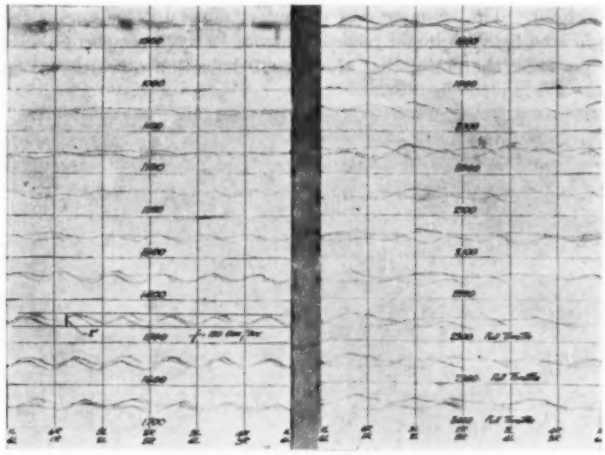

FIG. 14 ENGINE NO. 3, TABLE 1, ON DYNAMOMETER. DIRECT DRIVE THROUGH HEAVY THERMOID COUPLING

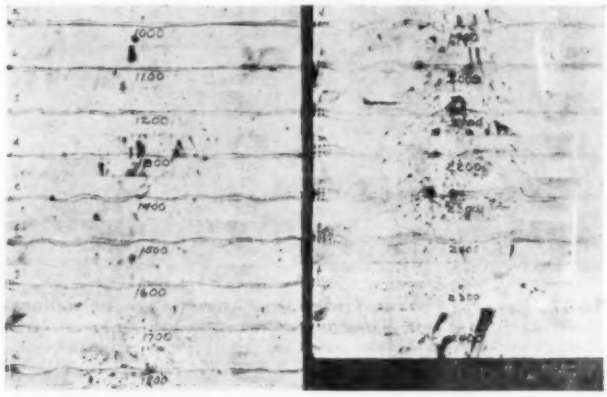

FIG. 15 ENGINE NO. 3, TABLE 1, ON PROPELLER LOAD, CRANKSHAFT CRACKED AT MIDDLE MAIN JOURNAL

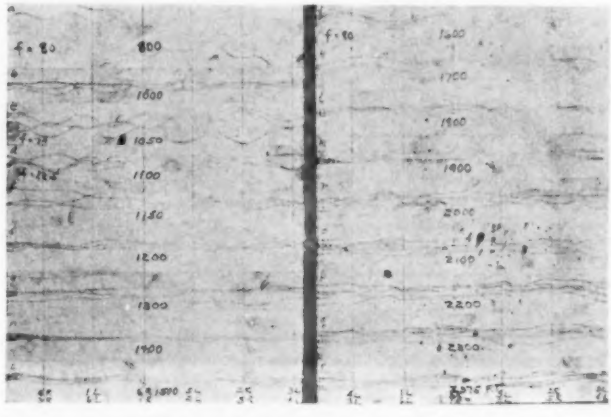

FIG. 16 SAME ENGINE AS IN FIGS. 14 AND 15, EXCEPT INCORPORATING 7-TO-5 REDUCTION GEARS AND A UNIQUE TYPE OF SPRING COUPLING. RECORDS TAKEN ON PROPELLER LOAD

tic curve, showing one node at a point close to the edge of the propeller hub. In this case, the torque on the most stressed section is nearly double that which, applied at the rear, would pro-

duce the same angular deflection as observed in operation. The large asynchronous deflections due to distribution may or may not follow this same type of elastic curve, depending on which cylinders receive the surges of pressure, or ramming effect of the manifold. The frequency of the latter effect in this engine, as indicated by vibrometer records, is from 12 to 21 per second. It is possible, therefore, that the actual deflection of cards (*a*) to

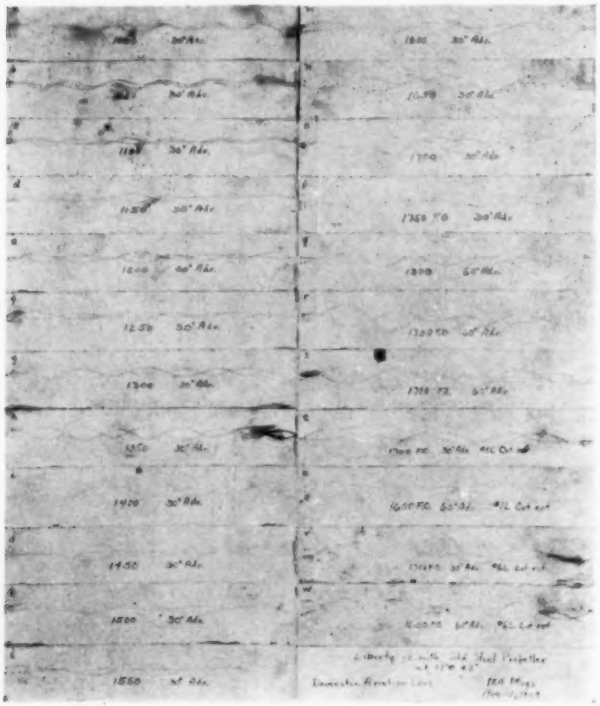

FIG. 17 EFFECT OF SPARK TIMING AND CUTTING OUT OF CYLINDERS ON TORSIONAL VIBRATION

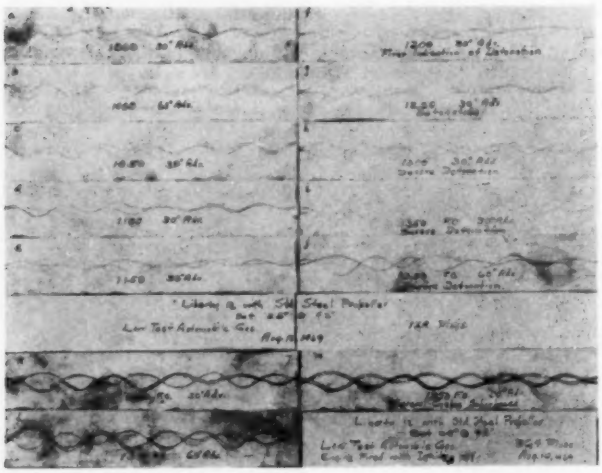

FIG. 18 EFFECT OF DETONATION AND PRE-IGNITION FROM HOT SPARK PLUGS ON TORSIONAL VIBRATION

(*k*), Fig. 11, were even greater than shown by the records, since the instrument frequency was about 10 vibrations per second.

In connection with this test, a second engine was available, which incorporated a reduction gear and a generally accepted type of spring coupling. It was also possible to replace some parts of this reduction gear with others, and run without any spring coupling. Fig. 13 cards (*a*) to (*m*) show the records obtained with the spring coupling, while (*n*) to (*z*) show those obtained with the solid-gear drive. These later records should bear some relation to those shown in Fig. 11, (*a*) to (*k*). The fuel was the same, and aside from the gearing, the engines were alike. Little can be said as to frequency of vibration with the spring coupling, except to again observe that all speeds from 700 to 1900 r.p.m. were about equally bad in respect to vibration, with no apparent tendency to damp out oscillations, as was observed in the case of the thermoid coupling, Fig. 7, cards (*m*) to (*x*). It appears that the natural frequency of the coupling is about 55 vibrations per second, although it could have a variety of frequencies, in view of its non-linear deflection characteristic. Cards (*n*) to (*z*) without the spring coupling show that much less vibration is found at all speeds. There appears to be some resonance at about 1800 r.p.m. at a frequency of about 90 vibrations per second and also at 1600 r.p.m. with frequency of about 99 vibrations per second. Cards (*c*), (*e*), (*f*), (*y*), and (*z*) show

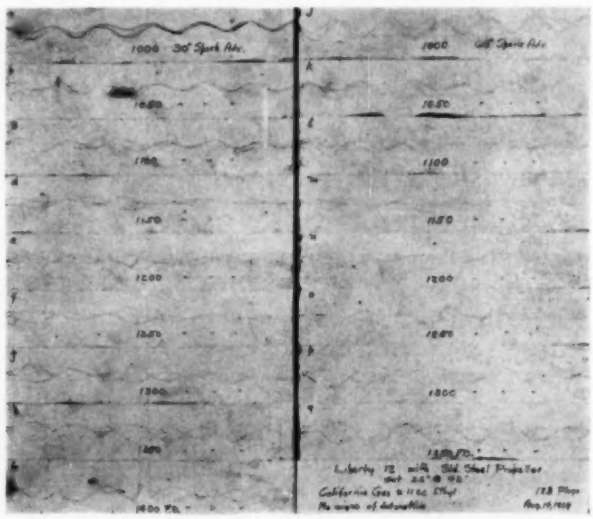

FIG. 19 EFFECT OF EARLY SPARK TIMING ON TORSIONAL VIBRATION, USING BEST FUEL AND COOLEST SPARK PLUGS AVAILABLE

a form of vibration which has been found in two Vee engines with poor distribution. Here, there are 6 vibrations per engine cycle, or 3 per revolution. There is no indication in the analysis by A. Stieglitz, of the normal torque curve of a 12-cylinder Vee engine to indicate resonance with a sixth harmonic, as would be indicated by these records. If, however, due to faulty or uneven distribution, alternate power impulses were abnormal, a vibration of this type would occur, much as is observed in a 6-cylinder line engine at resonance with the sixth harmonic. This form of vibration was observed on the air-cooled Liberty, which has a rotary induction system and plain gallery manifolds. There is no reason why the air-cooled Liberty should differ greatly from the water-cooled in character of vibration with the exception that pressure surges in the gallery type manifold are undoubtedly present, due to overlap of suction strokes. This form of vibration is not found on engines using four carburetor barrels, so that each barrel supplies three cylinders at 240-deg. intervals.

Fig. 14 is the record of another large 12-cylinder Vee engine. Here resonance occurs at about 1550 and 2000 r.p.m. On the basis of a frequency of 155 vibrations per second, resonance would occur at 1550, 2060, and 2660 r.p.m. This engine passed a 50-hour full-throttle test at 2400 r.p.m. but was found to have a cracked crankshaft at the conclusion of the test. Fig. 15 is a

set of records on the engine at conclusion of the test. The character of vibration is different from that observed with a perfect shaft, as might be expected. An attempt to run 50 hours at 2600 r.p.m. terminated at 12½ hours with a broken crankshaft.

Fig. 16 shows a set of records on the same engine as in Figs. 14 and 15, but with 7 to 5 reduction gears of the spur type. A spring coupling is incorporated in which coil springs are under an initial compression and no motion of the coupling occurs until a definite torque is exceeded. The rate of increase of torque with deflection is also different after the coupling starts to yield than before. The torsional rigidity of the propeller-crankshaft system is very greatly reduced, giving a natural frequency of only about

In Figs. 17 to 19 are presented some records taken on a Liberty-12 engine to study the effect of fuels, detonation, and pre-ignition on crankshaft torsional vibration. Fig. 17 shows the effect of changing the spark advance from 30 to 60 deg. This was undoubtedly accompanied by severe detonation, since the fuel was domestic aviation gasoline. Cards (*o*) and (*s*) serve to show the effect of premature ignition. Cards (*t*) to (*w*) show the effect of cutting out cylinder No. 1 or No. 6 combined with 30 deg. and 60 deg. advance. It appears that No. 6 (nearest the propeller) is the more serious loss, giving greater deflections than when cylinders near the rear end of the shaft are cut out. It was then decided to try the worst fuel obtainable—low-test automobile gaso-

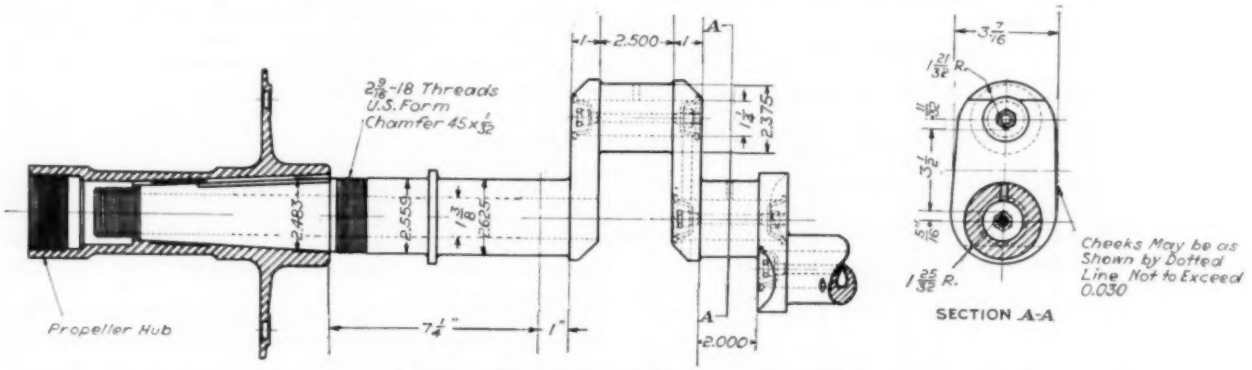

FIG. 20 DETAIL OF IN-LINE-ENGINE CRANKSHAFT

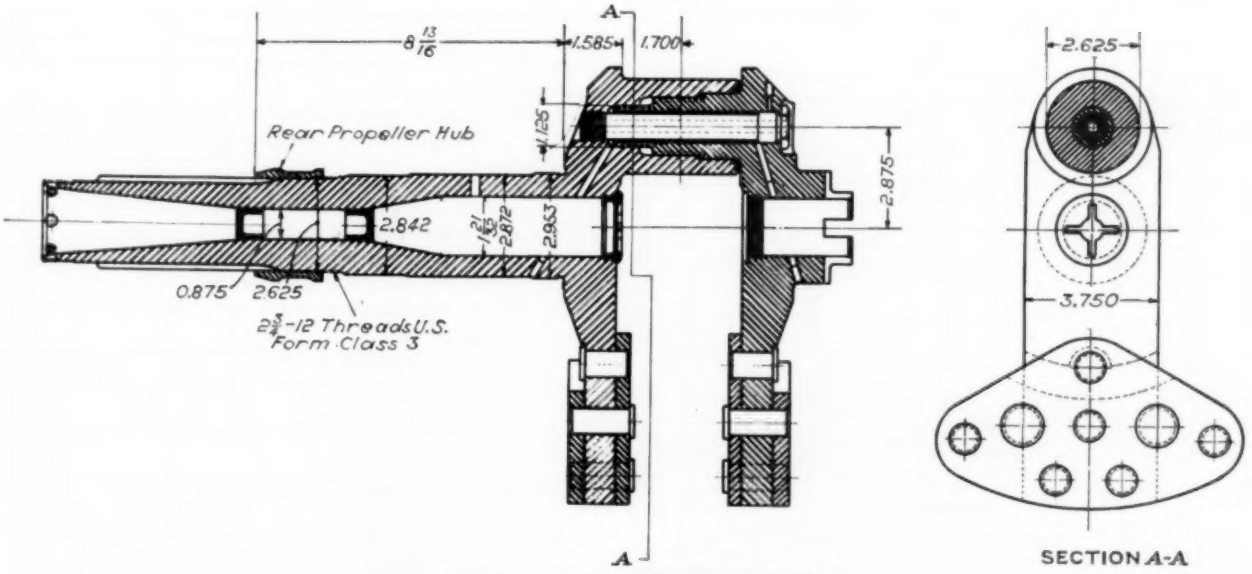

FIG. 21 DETAIL OF RADIAL-ENGINE CRANKSHAFT

80 vibrations per second. This frequency indicates the first torsional period at 800 r.p.m., the second at 1070 r.p.m., the third at 1370 r.p.m., and the fourth at 1600 r.p.m. The third period at 1370 r.p.m. does not appear in the records, but the fourth shows plainly at 1600 r.p.m. This period with three vibrations per revolution is not caused by distribution, since this engine is particularly good in this respect. It would indicate a sixth harmonic for a 12-cylinder Vee engine, contrary to the analysis previously referred to by A. Stieglitz and reproduced in Fig. 22*a*. This engine, however, has the articulated-rod construction whch may cause the torque curve from one bank to differ from the other.

line such as is used for washing purposes. To make matters as severe as possible, the plugs used were the hottest obtainable and cards were then taken at 30-deg. and 60-deg. spark advance. The detonation must have been terrific as evidenced by dense black puffs from the stacks. It is interesting to note, however, that no one was able to hear detonation above the other noises present. At another time, silencers were fitted to a Liberty in the effort to make detonation audible, but without success. These silencers were effective enough to make unnecessary the use of ear defenders and the fuel was low-test gasoline. However, no one could be sure he could detect detonation audibly. When a Liberty single is running, exhausting into an exhaust duct, deto-

nation may be heard for half a mile. In Fig. 18 are shown several cards taken under various conditions. These serve to show that premature ignition does increase the amplitude of torsional vibration, while detonation at normal spark advance does not affect torsional vibration. In case, however, of extended periods of detonation, hot spots may appear and cause pre-ignition, and thus indirectly cause increased vibration. Fig. 19 shows the best conditions obtainable. California gasoline was used with 11 cc. of ethyl fluid and cool plugs were installed. There were no visible signs of detonation, even with 60 deg. spark advance. The surprising feature of this run is that the amplitude of torsional vibration is greater for a given spark setting and power output than when using low-test gasoline with pre-igniting spark plugs and extreme detonation.

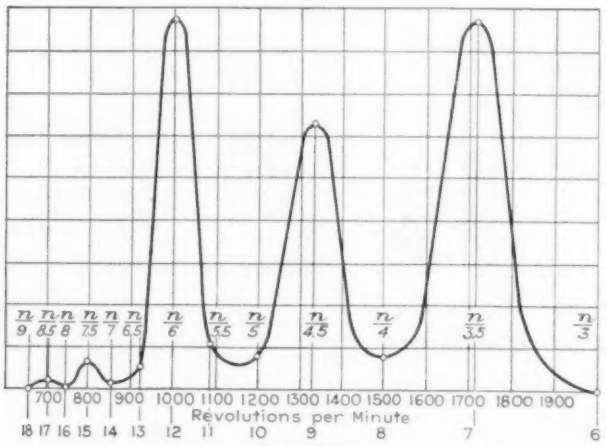

FIG. 22a

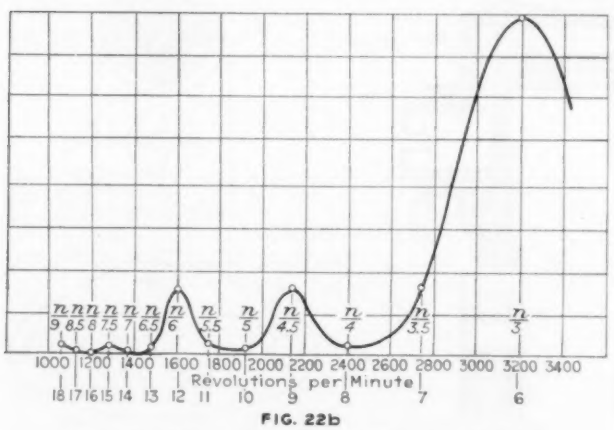

FIG. 22b

FIG. 22 HARMONICS OF SINGLE-CYLINDER TORQUE

(Fig. 22*a* Comparative resonance deflections—12-cylinder Vee, $f = 100$ vibrations per second, $n = 60f$; Fig. 22*b* Comparative resonance deflections —6-cylinder line, $f = 160$ vibrations per second, $n = 60f$.)

Figs. 22*a* and 22*b* show comparative resonance deflections for 12-cylinder Vee and 6-cylinder line engines. Fig. 22*a* is calculated on a frequency $n = 6000$, as found in the Liberty-12. These periods check with great accuracy the observed periods as indicated in Figs. 4 and 5.

Fig. 22*b* shows the 6-cylinder resonance curve on the basis of $n = 9600$ as found in the engine which gave the records shown in Fig. 7. Unfortunately, only one of the periods predicted in Fig. 22*b* could be observed.

These curves are reproduced from a paper on "Torsional Vibrations in Vertical Engines," by Albert Stieglitz, published in *Luftfahrtforschung*, July 24, 1929.

METHOD OF CALCULATING FREQUENCY OF TORSIONAL VIBRATION

Several methods of attacking the problem of torsional vibration have been proposed and two of these in particular have given excellent results. B. C. Carter, in *Engineering*, July 13, 1928, has given an empirical formula based on numerous experiments. In his method the crank is reduced to a torsionally equivalent length of shaft of the same cross-section as the main journal. S. Timoshenko in his book, "Vibration Problems in Engineering," has given a rational method of reducing all cranks to a length of shaft having one torsional rigidity. Once having the crank replaced by a uniform shaft, and the inertia masses reduced to an equivalent flywheel system, the frequency of vibration is readily calculated. In aircraft work, the moment of inertia of the propeller is from 10 to 20 times the total equivalent moment of inertia of the engine. It is therefore permissible to consider the nodal point as being located at the edge of the propeller hub. It could hardly be taken at the center of the hub, since the hub reinforces the shaft end and prevents it from deflecting. In the case of the radial engine, the equivalent moment of inertia of a given number of cylinders is approximately twice that of the line engines, because of the necessary balance weights. However, it is found that little error is introduced in considering the propeller moment of inertia as infinite, that is, assuming a node at the edge of the propeller hub.

Professor Timoshenko has stated in his book, "Vibration Problems in Engineering," that little error is introduced in calculating the primary or fundamental frequency, if all the equivalent flywheel masses at the crankpins are considered as adding together at the longitudinal center of symmetry of the engine. The problem is therefore reduced to that of finding the torsionally equivalent length of shaft from the edge of the propeller hub to the center of symmetry of the engine, and the equivalent moment of inertia of the crankpin systems.

A typical aircraft-engine crankshaft is shown in Fig. 20. The notation used is given below substantially as used by Professor Timoshenko.

a = actual length of crankpin, in.
a_1 = effective length of crankpin $= a + 0.9h$ in.
$2b$ = actual length of main journal, in.
$2b_1$ = effective length of main journal, $= 2b + 0.9h$ in.
B_2 = flexural rigidity of crankpin $= I_2E = 1.474 \times 10^6 (D_2^4 - d_2^4)$
B_3 = flexural rigidity of crankcheek $= I_3E = 2.5 \times 10^6 hw^3$
C_1 = torsional rigidity of main journal $= J_1G = 1.178 \times 10^6 (D_1^4 - d_1^4)$
C_2 = torsional rigidity of crankpin $= J_2G = 1.178 \times 10^6 (D_2^4 - d_2^4)$
C_3 = torsional rigidity of crankcheek $= J_3G = 3.33 \times 10^6 w^3h^3/(w^2 + h^2)$
D_1 = outside diameter of main journal, in.
d_1 = inside diameter of main journal, in.
D_2 = outside diameter of crankpin, in.
d_2 = inside diameter of crankpin, in.
E = Young's modulus of elasticity for steel $= 30 \times 10^6$ lb./in.^{2}
F_2 = cross-sectional area of crankpin $= \frac{\pi}{4}(D_2^2 - d_2^2)$
F_3 = cross-sectional area of crankcheek $= hw$
G = modulus of elasticity in shear or torsion $= 12 \times 10^6$ lb./in.^{2}
h = thickness of crankcheek, in.
I_1 = moment of inertia of main journal section $= \frac{\pi}{64}(D_1^4 - d_1^4)$ in.^{4}

I_2 = moment of inertia of crankpin section = $\frac{\pi}{64}(D_2^4 - d_2^4)$ in.^{4}

I_3 = moment of inertia of crankcheek section = $hw^3/12$ in.^{4}

J_1 = polar moment of inertia of main journal section = $2I_1$ in.^{4}

J_2 = polar moment of inertia of crankpin section = $2I_2$ in.^{4}

J_3 = polar moment of inertia of crankcheek section = $w^3h^3/3.6(w^2 + h^2)$ in.^{4}

K = factor of complete constraint by main journals (Timoshenko) =

$$\frac{\frac{R(a+h)^2}{4C_3} + \frac{aR^2}{2C_2} + \frac{a^3}{24B_2} + \frac{R^3}{3B_3} + \frac{1.2}{12 \times 10^6}\left(\frac{a}{2F_2} + \frac{R}{F_3}\right)}{\frac{aR}{2C_2} + \frac{R^2}{2B_3}} \text{ in.}$$

L = length of connecting rod, in.

l_1 = equivalent length of shaft from edge of propeller to first crank throw minus b

l_2 = equivalent length of shaft, center to center of main journals if shaft is unconstrained = $2b_1 + a_1 \frac{C_1}{C_2} + 2R\frac{C_1}{B_3}$ in.

l_3 = equivalent length of shaft, center to center of main journals if shaft is constrained by main bearings = $2b_1 + a_1\frac{C_1}{C_2}\left(1 - \frac{R}{K}\right) + 2R\frac{C_1}{B_3}\left(1 - \frac{R}{2K}\right)$ in.

L_f = $l_1 + \frac{n}{2}l_2$ (unconstrained) in.

L_c = $l_1 + \frac{n}{2}l_3$ (constrained) in.

m_1 = rotating weight per crankpin, lb.

m_2 = reciprocating weight per crankpin, lb.

n = number of crank throws

R = crank radius, in.

w = width of crankcheek, in.

The equivalent moment of inertia of one crank system is, according to Professor Timoshenko:

$$i = \left[m_1 + \frac{m_2}{2}\left(1 + \frac{R^2}{4L^2}\right)\right]R^2 + i_c$$

Since the average ratio of crank to connecting rod is about 1/4, this value of R/L may be used, making the term $\frac{1}{2}\left(1 + \frac{R^2}{4L^2}\right)$ equal to 0.508. This may be used for all practical purposes, hence we may take for the whole engine

$$I = n[(m_1 + 0.51m_2)R^2 + i_c] \text{ (lb-in.}^2\text{)} \ldots\ldots [1]$$

in which i_c is the calculated or experimentally determined value of the moment of inertia of one crank, about the main journal center, lb-in.^{2}

The frequency of oscillation of a torsion pendulum is $f = \frac{1}{2\pi}\sqrt{\frac{C}{I}}$ in which C is the torque in pound-feet per radian, required to deflect the torsion member, and I is the moment of inertia of the pendulum in slug-ft.^{2} In design calculations, it is convenient to use C_1 in pound-inches per radian per inch length and I in lb-in.^{2}, in which case $C = \frac{C_1}{L}$ and $f = \frac{1}{2\pi}\sqrt{\frac{12 \times 32.2 \times C_1}{IL}}$ or $3.125\sqrt{\frac{C}{IL}}$

For the unconstrained case, $f_f = 3.125\sqrt{\frac{C_1}{IL_f}}$ . . . . . [2]

For complete constraint, $f_c = 3.125\sqrt{\frac{C_1}{IL_c}}$ . . . . . [3]

Major Carter's method, see *Engineering*, July 13, 1928, is purely an empirical one, and is given only for the case of the shaft in its bearings. The equivalent length of shaft from center to center of main journals is given as

$$l_3 = (2b + 0.8h) + \frac{3}{4}\frac{D_1^4 - d_1^4}{D_2^4 - d_2^4}a + \frac{3R}{2}\frac{D_1^4 - d_1^4}{hw^3} \ldots\ldots [4]$$

in which the symbols have the same meaning as before

The above methods will now be applied to the Liberty-12 engine, where

a = 2.5 in.

a_1 = 2.5 + 0.9 × 1 = 3.4 in.

$2b$ = 2 in.

$2b_1$ = 2 + 0.9 × 1 = 2.9 in.

B_2 = $1.474 \times 10^6(2.375^4 - 1.25^4) = 43.1 \times 10^6$

B_3 = $2.5 \times 10^6 \times 1 \times 3.4375^3 = 101.2 \times 10^6$

C_1 = $1.178 \times 10^6(2.625^4 - 1.375^4) = 51.8 \times 10^6$

C_2 = $1.178 \times 10^6(2.375^4 - 1.25^4) = 34.5 \times 10^6$

C_3 = $3.33 \times 10^6 \times 3.4375^3 \times 1^3/(3.4375^2 + 1^2) = 10.6 \times 10^6$

D_1 = 2.625 in.

d_1 = 1.375 in.

D_2 = 2.375 in.

d_2 = 1.25 in.

F_2 = $\frac{\pi}{4}(2.375^2 - 1.25^2) = 3.2$ sq. in.

F_3 = 1 × 3.4375 = 3.4375 sq. in.

h = 1 in.

w = 3.4375 in.

m_1 = 6.3 lb.

m_2 = 12.4 lb.

i_c = 92.5 lb-in.^{2}

n = 6

R = 3.5 in.

$$K = \frac{\frac{3.5(2.5+1)^2}{4 \times 10.6 \times 10^6} + \frac{2.5 \times 3.5^2}{2 \times 34.5 \times 10^6} + \frac{2.5^3}{24 \times 43.1 \times 10^6} + \frac{3.5^3}{3 \times 101.2 \times 10^6} + \frac{1.2}{12 \times 10^6}\left(\frac{2.5}{2 \times 3.2} + \frac{3.5}{3.44}\right)}{\frac{2.5 \times 3.5}{2 \times 34.5 \times 10^6} + \frac{3.5^2}{2 \times 101.2 \times 10^6}} = 9.35 \text{ in.}$$

l_1 = 7.25 in. (actual) or 7.6 in. (equivalent length)

$$l_2 = 2.9 + 3.4\frac{51.8 \times 10^6}{34.5 \times 10^6} + 2 \times 3.5\frac{51.8 \times 10^6}{101.2 \times 10^6} = 11.58 \text{ in.}$$

$$l_3 = 2.9 + 3.4\,\frac{51.8 \times 10^6}{34.5 \times 10^6}\left(1 - \frac{3.5}{9.35}\right) + 2 \times 3.5\,\frac{51.8 \times 10^6}{101.2 \times 10^6}\left(1 - \frac{3.5}{2 \times 9.35}\right) = 9 \text{ in.}$$

$L_f = 7.6 + 3 \times 11.58 = 42.36$ in.
$L_c = 7.6 + 3 \times 9 = 34.6$ in.
$I = 6\,[(6.1 + 0.53 \times 12.4)\,3.5^2 + 92.5] = 1482$ lb-in.^{2}

$$f_f = 3.125\sqrt{\frac{51.8 \times 10^6}{1482 \times 42.36}} = 90 \text{ vib. per sec.}$$

$$f_c = 3.125\sqrt{\frac{51.8 \times 10^6}{1482 \times 34.6}} = 99.5 \text{ vib. per sec.}$$

According to Major Carter,

$$l_3 = (2 + .8 \times 1) + \frac{3}{4}\,\frac{2.625^4 - 1.375^4}{2.375^4 - 1.25^4}\,2.5 + \frac{3 \times 3.5}{2}\,\frac{2.625^4 - 1.375^4}{1 \times 3.4375^3} = 11.53 \text{ in.}$$

$L = 7.6 + 3 \times 11.53 = 42.19$ in.

$$f = 3.125\sqrt{\frac{51.8 \times 10^6}{1482 \times 42.19}} = 90 \text{ vib. per sec.}$$

The observed value is about 100 vib. per sec. as shown by the records, Figs. 4 and 5.

Table 1 shows the calculated and observed frequencies for several engines.

TABLE 1

Engine	Timoshenko: Unconstrained	Timoshenko: Constrained	Carter	Observed: Freq.	Observed: Crit. R.p.m.		
(1) Liberty 12.5-in. × 7-in. Vee	90	100	90	100	1000	1330	1715
(2) 12-cyl. 4½-in. × 6-in. Vee	147.5	161	152	160	1600	2130	2740
(3) 12-cyl. 5⅛-in. × 6¼-in. Vee	139.3	153	149.5	155	1550	2070	2660
(4) 6-cyl. 4½-in. × 5½-in. Line	151	161	155	160	1600	2140	3200
(5) OX5, 8-cyl. Vee	132	135.5	133.5	Not obs.	2036	(Not observed)	
(6) 12-cyl. 6⅜-in. × 6½-in. Vee	129	137	138	135	1350	1800	2320
(7) 12-cyl. 6⅜-in. × 6½-in. Vee (Geared)	70.5	71.8	71.8	Ext. vib.	700 to 1900		

In applying the foregoing calculations to radial engines, it is found that Professor Timoshenko's unconstrained case applies with sufficient accuracy. This is probably because in the usual radial engine designs the after crank throw is supported by only one bearing and the shaft has a certain degree of freedom. The equivalent shaft length is calculated only to the center line of the engine, hence the after crankcheek need not be considered. The crankshaft is counterbalanced in all single-row radial engines, hence its moment of inertia may readily be found by treating it as a compound pendulum, the only data necessary being the crank radius, reaction of counterbalances at crank radius and time of one swing right to left about the main journal axis. The moment of inertia of the shaft is then

$$i_c = W_c R t^2\,\frac{144g}{12\pi_2} = 39.2\,W_c R t^2 \text{ lb-in.}^2 \quad \ldots\ldots\ldots [5]$$

where W_c = weight of counterweights at crank radius, lb.
R = crank radius, in.
t = time of ½ vibration (one swing), sec.

No appreciable error is introduced in thus including the shaft end which projects into the hub.

$a^1/2 = 1.78 + 0.45 \times 1.475 = 2.44$ in.
$b = 0.4375$ in.
$b_1 = 0.438 + 0.45 \times 1.475 = 1.098$ in.
$B_3 = 2.5 \times 10^6 \times 1.475 \times 3.75^3 = 194.3 \times 10^6$
$C_1 = 1.178 \times 10^6(2.874^4 - 1.656^4) = 71.7 \times 10^6$
$C_2 = 1.178 \times 10^6(2.685^4 - 1.125^4) = 59.1 \times 10^6$
$D_1 = 2.874$ in.
$d_1 = 1.656$ in.
$D_2 = 2.685$ in.
$d_2 = 1.125$ in.
$h = 1.475$ in.
$w = 3.75$ in.
m_1 (rotating weight of master and link rods) = 19.8 lb.
m_2 (reciprocating weight of pistons and rods) = 56.55 lb.
W_c = weight of counter weights at crank radius = 48.27 lb.
$R = 2.875$ in.
t = time of one swing of crankshaft = 0.517 sec.
$i_c = 39.2 \times 48.27 \times 2.875 \times 0.517^2 = 1460$ lb-in.^{2}
$i_p = (19.8 + 0.51 \times 56.55)\,2.875^2 = 402$ lb-in.^{2}
$I = i_c + i_p = 1862$ lb-in.^{2}
l_1 (actual, since torsional rigidity approximately uniform) = 8.4 in.

$$L_f = l_1 + b_1 + \frac{a_1}{2}\,\frac{C_1}{C_2} + R\,\frac{C_1}{B_3} = 8.4 + 1.098 + 2.44\,\frac{71.7 \times 10^6}{59.1 \times 10^6} + 2.875\,\frac{71.7 \times 10^6}{194.3 \times 10^6} = 13.56 \text{ in.}$$

The equivalent moment of inertia of the rotating and reciprocating parts is, as in the line engine

$$i_p = (m_1 + 0.51\,m_2)R^2, \text{ lb-in.}^2 \quad \ldots\ldots\ldots [6]$$

Fig. 21 shows the crankshaft of a very successful 9-cylinder radial engine of 1340 cu. in. displacement, in which

$a/2$ = (center of engine to crankcheek) = 1.78 in.

$$f_f = 3.125\sqrt{\frac{71.7 \times 10^6}{1862 \times 13.56}} = 166 \text{ vib. per sec.}$$

The critical speed, therefore, will be for nine cylinders,

$$N = \frac{166 \times 60}{4.5} = 2210 \text{ r.p.m.}$$

Fig. 10, (*a*) to (*n*), shows the torsiometer records on this engine at throttling loads from 2400 r.p.m.; also full throttle from 1875 r.p.m. to 2375 r.p.m.

Fig. 10, (*aa*) to (*nn*), shows the records of a large 9-cylinder radial engine of 1860 cu. in. displacement on propeller load. The calculated frequency is 180 vibrations per second and the critical speed

$$N = \frac{180 \times 60}{4.5} = 2400 \text{ r.p.m.}$$

A similar calculation on a small 5-cylinder engine of 370 cu. in. displacement shows the frequency to be 156 vibrations per second and critical speed

$$N = \frac{156 \times 60}{2.5} = 3750 \text{ r.p.m.}$$

No test records are available on this engine.

Fig. 3 (*a*) and (*b*) show torsiometer records of the nose end of a Liberty-12, using two types of propeller, metal, and wood. A small displacement undoubtedly occurs, but due to the relatively large moment of inertia, it is insignificant; hence in aircraft work it appears sufficiently precise to record only the motion of the rear end of the crankshaft. These records also serve to show the desirability of driving accessories, and particularly superchargers, form the propeller end of the shaft where torsional vibrations are of low amplitude. Slipping clutches, spring couplings, etc., could then be omitted, making a saving in weight. Ignition and valve timing would also be more uniform, resulting in smoother operation of the engine.

Card (*c*), Fig. 3, shows a method of arriving at the accelerations which occur in actual accessory drives, using the conventional rear-end drive.

From the foregoing it is seen that calculation of torsional periods from design data is sufficiently precise to make such a study worth while in any new design as well as in existing engines. Data are not available on all types of engines, but the leading types have been covered by experiment so that the character of vibration to be expected is fairly well established. It is the aim of the Power Plant Branch to continue this study until all types of engines and reduction gears have been analyzed.

Discussion

J. P. DenHartog.[2] Vibration troubles occurring in the rotating parts of machinery can be grouped in two distinct classes, (1) torsional and (2) flexural or whirling vibrations. In most types of machines the whirling vibration causes most grief while the torsional type is comparatively unimportant. Exceptions to this are the gas and Diesel engines, where due to the great non-uniformity of torque the torsional vibrations are more important than the flexural.

The present state of the art of predicting by calculation the behavior of a machine in this respect is in quite different stages of development for the two types of vibration. As regards the determination of the frequency or the "critical speeds," this can be done in the torsional case with an error of 5 per cent or less. In the flexural case, however, the frequency depends on the flexibility of the bearings and the frame, so that in a complicated machine errors of over 50 per cent are not uncommon.

Determination of the amplitude of vibration at a critical speed is possible in the torsional case with an accuracy, making such calculations practically useful. The methods for this have been worked out by Holzer, Wydler, and Lewis, and are described in S. Timoshenko's book mentioned in the paper. For the flexural case, however, a determination of amplitudes is as yet not possible.

The present paper gives a rather rough method of precalculating the frequency of torsional vibrations. The author reduces an engine with many cranks and pistons to a system with a single equivalent inertia in the center of the engine. This introduces an inaccuracy which in practical cases runs up as high as 10 per cent.

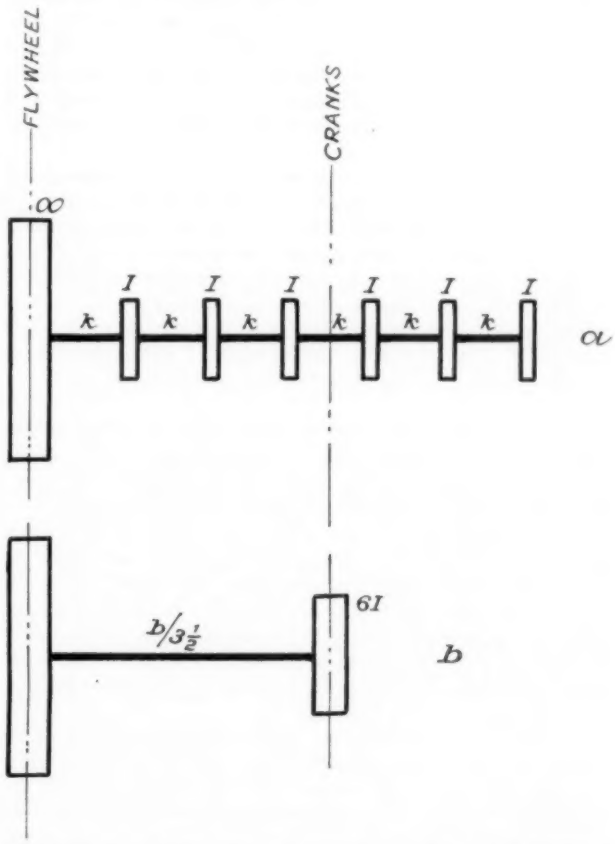

Fig. 23 System With Heavy Flywheel and Six Equal Inertias

For instance consider a system consisting of a "heavy" flywheel, and six equal inertias I connected by six pieces of shaft all of the flexibility k lb-in. per radian. (Fig. 23*a*.)

The exact calculation (for instance by means of Holzer's method[3]) gives:

$$f = \frac{1}{2\pi}\sqrt{0.0580\,\frac{k}{I}}$$

while the author's approximation as shown in Fig. 23*b* gives

[2] Research Laboratories, Westinghouse Electric & Manufacturing Co., East Pittsburgh, Pa. Assoc-Mem. A.S.M.E.

[3] "Vibration Problems in Engineering, by S. Timoshenko, pp. 150 and 151.

$$f = \frac{1}{2\pi}\sqrt{0.0476\,\frac{k}{I}}$$

being about 10 per cent smaller. In case a coupling of great torsional flexibility is inserted between the engine and the flywheel the error becomes less. It is seen in Table 1 of the paper that the observed frequencies are between zero and 10 per cent greater than the ones predicted by calculation by means of Timshenko's unconstrained or Carter's formulas. This discrepancy is due to the lumping of all masses into a single one. It again can be regarded as a confirmation of the experience that the effect of constraint of the main bearings does not play an important part.

In the paper the author states that certain of his test results seem to contradict the analysis by Stieglitz shown in Fig. 22a. However, it seems that the engine tested is not exactly like the one analyzed, and since the amplitude in the third order vibration ($n = 3$) for a 12-cylinder engine depends on the crank-shaft structure and on the firing order of the cylinders, no comparison is justified.

The author does not give any calculations of the amplitudes of vibration at the critical speeds. It would be of considerable interest to do this yet and to compare the calculated results to the observed ones. In this manner the accuracy of calculations of this type can be improved. In cases where thermoid couplings are used, first a test has to be run on the coupling by itself to determine the energy absorption as a function of the amplitude and frequency. With this data a calculation of the amplitudes of torsional vibration at the critical speeds can be carried out.

Melvin Price.[4] The author shows some vibration records taken from a crankshaft with a reduction gear with a spring coupling interposed between them. In his comment he applies the adjective "bad" somewhat, it seems, to the disparagement of the spring coupling. The use of the word "bad" in this connection seems a trifle harsh. The spring coupling is one of the devices often used to protect toothed gears from shock. This use seems a legitimate one. The investigations undertaken by the author are of particular value in the detection and avoidance of resonance. There is nothing in the records to show that resonance is produced by the spring coupling or, if initially present, that it is aggravated by the coupling.

In other records a relatively large torsional deflection is attributed to the Farman reduction gear used in one of the tests. The large decrease in the critical speed as a consequence of the insertion of this gear is one of the surprising results of his investigation with the torsiometer. While not as "springy" as the spring coupling the effect is much the same in making all speeds more or less "equally bad." Yet in such theoretical treatments the geared systems are treated as though the gears were rigid. The Farman assembly shows the possibility of considerable elastic distortion on account of the variety of shape and the arrangement of the members connecting the power with the work.

The experimental determination of torsional deflection in toothed gearing brings to mind the other machine elements in a drive-shaft assembly and makes one reflect on how best to estimate the torsional behavior of such things as bolted, flanged hubs—whether in ring-gear assemblies or flange couplings—and also of other types of shaft couplings, especially where hollow shafts are used, and these are common in aircraft. This at once raises the question of the efficacy of the "equivalent-length" method of locating the node points in the determination of critical speeds. It would seem to revert to the old question of what is easiest to judge or to estimate in the furtherance of a solution of a vibration problem. Professor F. M. Lewis prefers to use, instead of "equivalent lengths," a "rigidity factor" for each element interposed between the power and the work. It seems that this simplifies the solution somewhat, and makes it possible to apply the judgment to the rigidity factor with somewhat greater accuracy than is possible in the "equivalent length" analysis.

W. Klemperer.[5] Have experiments with the torsiograph also revealed any two-noded vibrations, that is to say, with one node in the crankshaft in addition to the one node next to the hub, or are the more-noded modes in heavier-than-aircraft engines of too high a frequency to be causing any trouble? This question is, of course, mainly of interest in connection with large 12-cylinder V-type engines.

Roland Chilton.[6] The author is to be congratulated on the development of a satisfactory torsional-vibration recorder for aircraft engines and for the excellent presentation of the results obtained. A glance at the curves shows that the resonance occurs in most engines at two, three or four different speeds due to different harmonics from the explosion impulses, and it appears to the writer that a very serious limitation in engine usefulness is involved in the attempt to keep the operating-speed range of the engine away from all of the possible zones of resonance.

Certainly, in specific cases, the limitation to increased engine speed is definitely that a period of resonance will be encountered and the redesign of the crankshaft to lift the period by only 200 r.p.m. necessitates enlarging the journals, including the connecting rod, which in turn may require a larger crankcase. The result will often be that the next lower period will be sufficiently raised to be encountered at cruising speed.

One of the most interesting points brought out in the paper is illustrated in Fig. 7 comparing cards *a* to *l*, with a rigidly attached propeller, with cards *m* to *x* taken with a thermoid coupling driving to a dynamometer. The writer has previously suggested that a coupling with appreciable hysteresis will suppress torsional vibrations, and it is hard to see why its usefulness would be limited to a case of a geared engine.

The automobile industry several years ago realized that many of its troubles were due to torsional vibrations and for a time most manufacturers tried to cure this condition by making the crankshafts heavier and heavier. Finally they were forced to the use of a damper which eliminates all periods at all speeds instead of merely locating the several synchronous points at somewhat higher speeds. Aircraft-engine builders have probably suffered more from failed crankshafts and crankshaft gears than any others, but they seem slow to take advantage of the experience already gained in other lines. The automobile designers took precisely the same attitude several years ago, but have now practically all been forced to some form of damper, of which there are now several different types giving satisfactory results.

When it is seen that a typical engine has vibration periods at 1550, 2060, and 2600 r.p.m., it is not obvious how the crankshaft stiffness can be juggled to bring all the new periods outside of the operating range. If the engine is already in production, the changes would be of an extremely far-reaching nature compared to which the installation of one of the several types of dampers already developed for automobiles would be relatively simple.

In face of the fact that the mere inclusion of the simple thermoid disc suppressed high-amplitude vibrations at all speeds, it seems that some such device should be investigated immediately in an aircraft-engine installation. It is not thought that the cou-

pling will have to be larger than the spinners now in use. It should be noted that the Packard Diesel engine is already using rubber blocks to drive the propeller.

Author's Closure

Mr. DenHartog brought up the question of the firing order of line engines. All the line engines with 6 or 12 cylinders have only two firing orders which are practicable from the standpoint of distribution and smoothness. These are 1, 5, 3, 6, 2, 4 and 1, 4, 2, 6, 3, 5. There are other possible firing orders, but with the manifold system arranged with cylinders 1, 2, 3 and 4, 5, 6 of each bank fed by separate venturii, the other arrangements do not give uniform intervals between suction strokes on each carburetor, thus interfering with distribution. It is possible that another firing order could be used, which would eliminate one of the critical periods, but in aircraft work, odd-firing intervals, and balance masses would be objectionable from the standpoint of magneto ignition, which requires uniform firing intervals, and from the standpoint of added weight, were balance weights required.

It should be possible to calculate the "damping factor" for several engines, from torsional vibration records. If the damping were known, the amplitude of vibration could be calculated from the torque curve of the engine.

Mr. DenHartog called attention to the possibility that card *f*, Fig. 11, could be explained by the fact that the frequency was roughly 10 times the fundamental of the instrument. However, the same objection should apply to card *p* taken at the same speed, but with better fuel. There was no difference in the two runs other than the use of highly volatile fuel. Hence, it would seem hard to explain the difference, except on the basis of distribution.

It is realized that the approximate solution of grouping all the crank inertia masses at the center of symmetry of the engine is not exact, but the complete solution by the method of determinants complicates the calculations considerably. The close agreement between the constrained case (Timoshenko) and the observed frequencies, shown in Table 1, is gratifying, to say the least. Calculations show that the stiffer the crankpin and the shorter and stiffer the crank cheeks, the nearer are the constrained and unconstrained cases to each other. This may partially explain why, in Diesel work, little evidence is observed of constraint by main bearings. In most aircraft engines, the crankpins are not as stiff as the main journals, and the assumption of constraint is probably not far from the truth.

Professor Price objected to calling the records of Fig. 13(*a*) to (*m*) "bad." Let us call them equally good, but the fact remains that cards *n* to *z* are quite definitely better. It would appear that spring couplings need damping and freedom from backlash to make them entirely satisfactory. It has been found by deflection tests that some of the flexibility, in reduction gears, is in the gear case, although there is, of course, actual deflection of the gears themselves. Where drive shafts are used, it should be possible closely to approximate the torque per radian for the entire drive from propeller to center of the engine. The fundamental frequency of the crankshaft will then not enter into the calculations, since the entire drive will have a lower frequency than that of the crankshaft itself. In complicated drives, it would be necessary to deflect the system, and thus obtain the stiffness for calculation of frequency. The Matériel Division has not experimented with any drives other than propeller reduction gears with and without spring couplings, but in automobile drives the period of the propeller shaft bears no relation to that of the crankshaft.

Doctor Klemperer inquired as to evidence of higher frequencies than the primary. No evidence has yet been found of vibration with two nodes. It may be that such vibration will be encountered as engine speeds are increased, but to date the Matériel Division has no engines capable of operating at speeds high enough to make possible such higher frequencies. The Matériel Division's torsiometer has not been applied to the study of vibration in long shafts. Some form of belt drive would have to be resorted to, and such drive must be viewed with suspicion. Doctor Thoma's electrical device should be well adapted to such use.

Mr. Chilton has brought up a very interesting field for investigation. There is, however, some question as to the effectiveness of a damper, and there is the question of possible failure of the damping device to function. Is it not true also that a damper, while suppressing torsional vibration at one frequency, introduces another frequency at which vibration may occur? A case in point is a recently developed fluid friction damper of European make. Curves were shown, representing the amplitude of vibration versus speed in r.p.m., and were made on two 6-cylinder line engines. The two critical ranges due to the twelfth and ninth harmonics appeared at 980 r.p.m. and 1290 r.p.m., but the third, and by far the most serious, would be that due to the sixth harmonic, occurring at 1960 r.p.m. The latter period was, however, out of the speed range since the normal speed of these engines was about 1500 r.p.m. This would mean that the engines would cruise at about 1300 r.p.m., or in the second critical range. By the use of the fluid-friction damper, the critical ranges were lowered to about 850 r.p.m. and 1170 r.p.m., the third occurring at 1700 r.p.m. This arrangement undoubtedly improved conditions in the cruising range, but brought the third critical r.p.m. uncomfortably close to the normal speed of the engine, as evidenced by increased amplitude of vibration at 1500 r.p.m. The test curve of the engine, with and without damper, is reproduced in Fig. 24. It would appear that a better solution in this case would have been to raise the frequency of the crankshaft by design, from 98 vibrations per sec. to 125 or 130 vibrations per sec. Critical ranges then would have been 1200 to 1300 r.p.m., 1600 to 2730 r.p.m., and 2400 to 2600 r.p.m. This would not introduce a crankshaft of unduly large dimensions since there are 12-cylinder Vee engines whose crankshafts have frequencies above 160 vibrations per sec. The larger and stiffer shaft greatly decreases the alternating stress due to vibration and also the stress due to torque. A damper then becomes unnecessary, since an engine can operate continuously while in critical vibration, provided the combined torsional and alternating stress is low enough. This is evidenced by a recent test on the radial engine whose torsiometer records are reproduced in Fig. 8 of the paper. One of these engines passed 100 hours at 1900 r.p.m. and another 150 hours at the same speed without any indication of crankshaft failure. The first 50 hours in each case was at full throttle. The author did not believe these engines would go 25 hours at full throttle.

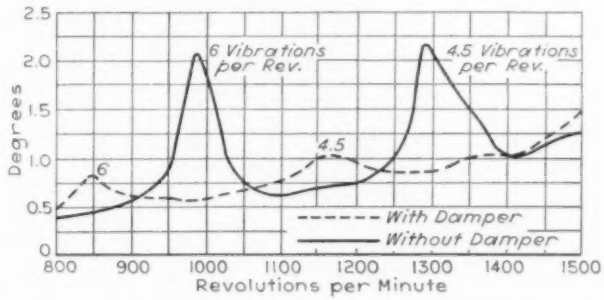

Fig. 24 Test of Engine With and Without Damper

It is, of course, true that a redesign of the connecting rods and crankcase follows an increase in crankpin diameter, but this has to be done only once, and the saving in service and increased reliability would appear to warrant such a change. In a new design, there would be no reason to incorporate a shaft whose vibration characteristics had not been investigated. It is worthy of note that a low-priced 6-cylinder automobile is said to have a crankshaft stiff enough to remove all torsional periods from the driving range, or up to a speed of about 60 m.p.h. This is without any form of damping device. Such a condition would, however, be impossible in an 8-cylinder, 9-bearing crankshaft, hence the damper becomes necessary. The use of a coupling with damping characteristics offers a field of great interest, as evidenced by the records of Figs. 7 and 16 of the paper.

AER-52-20

New Developments in Airport Lighting

By H. C. RITCHIE,[1] SCHENECTADY, N. Y.

The principles of airport lighting have been covered in many papers which have varied slightly and only in details, says the author, these principles now having been standardized through the medium of the Department of Commerce. These requirements are stated, and then the author points out some new developments which make it possible for airports to obtain maximum ratings for lighting equipment and also some of the new systems or devices brought out to supplement these requirements.

THE subject of airport lighting has been covered by many articles in the trade journals and in engineering magazines and also has been the title of many papers before engineering and commercial societies. The principles of airport lighting as propounded in these articles and in these papers have been practically the same and have varied only slightly in details.

These principles have been standardized through the medium of the Department of Commerce, Aeronautic Branch, by the publication of Airport Rating Regulations in Aeronautics Bulletin No. 16. These regulations, particularly referring to lighting, have been prepared by the Department after a comprehensive study of the lighting requirements and the recommendations of manufacturers of lighting equipment. The bulletin, published over a year ago, gives in detail the minimum requirements for lighting equipment for the different classes of airports.

It is intended to give briefly these requirements, and then to point out some of the new developments which make it possible for airports to get maximum ratings for lighting equipment, and also to state some of the new systems or devices which have been brought out to supplement these requirements.

Before a rating will be given to any airport there are certain minimum basic requirements which must be met. These are:

(*a*) A suitable landing area, described as a firm, smooth, well-drained plot of ground substantially level, without obstructions which would be hazards in taking off or landing, and with suitable approaches.

(*b*) Freedom from obstructions within the gliding angle to the field—namely, 7 to 1.

(*c*) The airport shall be situated on a good road leading to the nearest city or town.

(*d*) The airport shall be equipped with an approved type of wind-direction indicator.

(*e*) The landing area shall be marked, not only with a 100-ft. circle on the field, but the name of the city or town should be placed near the marker circle or on a building roof in letters visible from an altitude of at least 2000 ft. The outline of the landing area shall be marked with either sheet-metal cones or 4-ft. white circles placed not more than 300 ft. apart.

(*f*) If runways are used, they shall be constructed of a suitable material.

(*g*) The landing area shall be adequately drained so that the entire field is available for landing and taking off.

(*h*) The airport shall be provided with facilities for supplying aircraft with fuel, oil, and water, also drinking water shall be available. There must be dependable communication with the nearest city or town, as well as transportation facilities. Personnel shall be in attendance throughout the day or readily reached by telephone.

[1] Aeronautical Specialist, Lighting Section, General Electric Company.

Presented at the Joint Meeting of the A.S.M.E. Aeronautic Division with the Engineers Society of Western Pennsylvania, Pittsburgh, Pa., March 12, 1930.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

The complete rating symbol of an airport consists of a letter, a numeral, and a letter. The first letter signifies the general equipment and facilities which are available; the numeral indicates the size of the field; and the second letter the night-lighting equipment.

To receive the highest, or "A," rating on night-lighting equipment, the airport shall have the following:

(*a*) An airport beacon, the type of which is described in full in Airport Rating Regulations.

(*b*) An illuminated wind-direction indicator.

(*c*) Boundary lights placed around the border of the usable landing area to indicate the extent of the field.

(*d*) Obstruction lights placed on all obstructions within gliding angle of the field.

FIG. 1 GENERAL ELECTRIC NOVALUX SERIES AIRPORT LIGHT (This is mounted on a Curtiss boundary cone; at Schenectady, N. Y., airport.)

(*e*) Hanger floodlights and roof marking must be such as to give the pilots a true picture of the airport buildings at night.

(*f*) A ceiling projector for determining the height of the ceiling at the airport must be provided.

(*g*) Landing-area floodlight system must be such that there shall be a minimum intensity of 0.15 foot-candle vertical or normal to the beam at all points of the landing area.

(*h*) The airport beacon, wind-direction indicator lights, boundary lights, obstruction lights, and roof-marking lights shall be kept burning all night and every night, and there must be sufficient personnel in attendance throughout the night for the proper operation of the other lighting equipment.

The lower ratings on night-lighting equipments require less equipment, but all except the lowest rating require all-night operation of the lighting equipment.

It will be seen that these requirements enable the pilot to find the port by means of the beacon, to see the extent of the landing area and the obstructions around the port, and the direction of the wind, and that they provide for illumination of the landing area so that he can make a safe landing.

During the last year several new types of beacons have been put on the market, and in addition improvements have been made in the Department of Commerce airway beacons.

FIG. 2 A 24-IN. ROTATING BEACON FOR AIRPORTS AND AIRWAYS

All probably are familiar with the design of 24-in. revolving airway beacons (Fig. 2) being installed by the Aeronautic Branch of the Department of Commerce on the National Airways. This consists of a 24-in. parabolic mirror, at the focal point of which is placed a 1000-watt, 115-volt incandescent lamp. This lamp is installed in a lamp changer, which, upon failure of the first lamp, automatically throws a second lamp into position. The front door of the beacon is fitted with a 25-deg. upward-reflecting cover glass which directs 10 per cent of the beam in an upward direction as an additional aid to the pilot when he is close to the beacon. The drum is also fitted with four zenith panels so that he can locate the beacon when almost directly over it.

On-course lights (Fig. 3) are provided at the beacon, one pointing each way along the airway. These are flashed by means of a cam and contact-making mechanism in the base of the beacon.

Improvements which are incorporated in the beacons now being installed by the Aeronautic Branch are the substitution of a spherical mirror in front of the lamp for the louvers or stray light shields formerly used. The louvers merely shielded the light so that the immediate area surrounding the beacon was not illuminated. The principal reason for this was to avoid annoying those living near the beacon location. The spherical mirror, however, not only cuts out this light, but it redirects a portion of the light back into the mirror and adds to the strength of the beam. This is not strictly a spherical mirror, but is really two halves of a hemisphere between which is placed a cylindrical section. This has the effect of lengthening the secondary image of the filament, and without detracting from the strength of the main beam gives additional light from the beacon to a wider angle. Adjustment is provided on this mirror to enable it to be focused with the lamp.

The flashing of the on-course lights is now accomplished through mercury-tube connectors rather than through air-break contactors. The signals are determined by means of a cam which is attached to the central revolving shaft of the beacon.

No change has been made on the design of the 18-in. course lights installed with every beacon, but the use of amber at intermediate fields has been abandoned and green substituted. The system now is to use red on-course lights at isolated beacons and green at intermediate fields and airports.

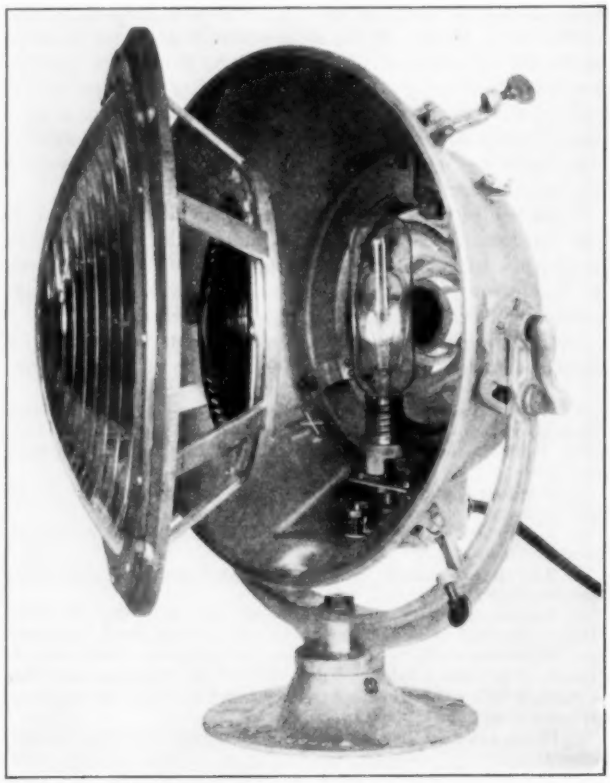

FIG. 3 AN 18-IN. ON-COURSE PROJECTOR
(The doublet lenses swing outward.)

At several places along some of the airways it has been found necessary to have small wattage beacons installed at closer intervals than is usual with the 24-ft. revolving beacons.

For this purpose there was designed the electric code beacon (Fig. 5), which consists of Fresnel-lens lanterns with two lamps, each of 200 watts. The lamps are flashed by the flasher with a

definite code signal, and while they are of much lower candlepower than the 24-in. revolving beacons, this code beacon has been found of considerable benefit in certain locations. This beacon also has other uses, and the equipment is now available for commercial application. It may be fitted with a green color shade and with 500-watt lamps instead of 200-watt lamps and used as an auxiliary beacon at an airport, being flashed by the revolving beacon, with the code letter giving the airport designation. This would mean that the approaching pilot would not only know that there was an airport close at hand, but would be able definitely to identify the airport. It has been recommended that the auxiliary beacons be installed directly above the revolving beacon.

This lantern may also be used and is recommended for the marking of towers of transmission lines crossing navigable rivers.

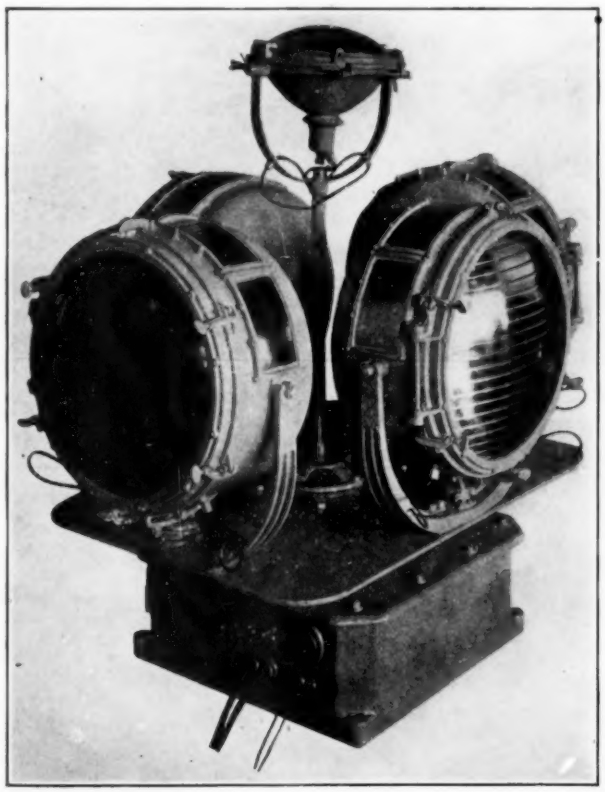

FIG. 4 QUADRUPLE AIRPORT BEACON

In this case the lantern is fitted with a red color screen and is not flashed.

Another type of airport beacon lately put on the market is enclosed with a large glass dome which covers the revolving mirror and lamp. This beacon has the advantage of giving full zenith indication, with the necessary eclipse period. Another great advantage is that there are no revolving portions exposed to the weather or to the wind. It has been found on the 24-in. revolving beacons that there is an uneven torsion on the center shaft and on the worm gear and worms caused by the non-symmetrical shape of the beacon drum. It has also been found that the presence of snow and sleet on the base of the beacon retards the rotation and in some cases damages the mechanism.

The glass dome is mounted in a cast frame which is hinged at the bottom, allowing the dome to be lifted for inspection of the beacon and for lamp replacement. The large covers in the base

FIG. 5 AIRWAY ELECTRIC CODE BEACON

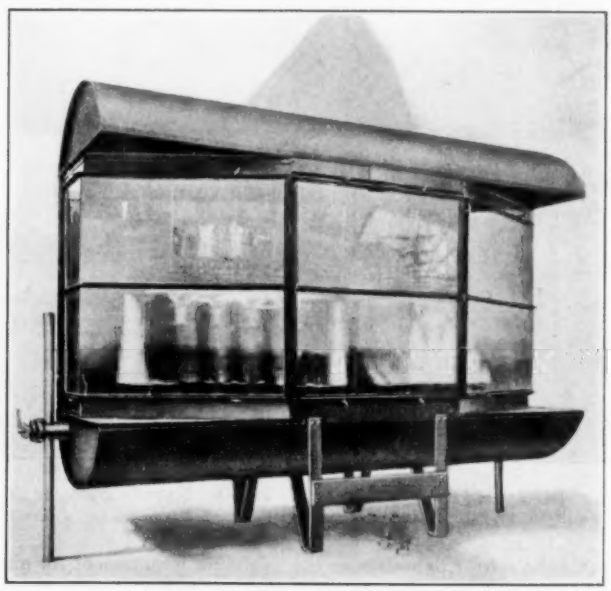

FIG. 6 A 24-KW. AIRPORT FLOODLIGHT

give easy access to all parts of the mechanism and allow easy replacement or adjustment of any parts.

The beam candlepower of this beacon, which uses a 20-in. deep parabolic mirror, is well over the minimum requirement for airport use and has the advantage also of giving a wider beam than the more shallow standard 24-in. parabolic mirror.

As a distinctive beacon for airports there has been designed the quadruple beacon (Fig. 4), which consists of four of the 24-in. Department of Commerce type drums fitted with front-door glasses of several color combinations, these four drums being surmounted by a floodlight with a diverging lens. One has been in use at Cleveland Airport for over a year and has been found

FIG. 8 ILLUMINATION OF MURFREESBORO AIRPORT AT NIGHT
(One 24-kw. General Electric floodlight is used.)

of great value to approaching pilots. Its red and white flashes definitely distinguish Cleveland Airport from airway beacons or other lights in the vicinity, and its wide vertical spread enables it to be picked up at any distance within its range.

The airport rating regulations recommend the use of sheet-metal cones with boundary lights to serve principally as daylight markers. A cone (Fig. 1) has been developed which supports the boundary-light fixture, the base of the cone resting directly on the ground,over a disconnecting pot-head cutout. The fixture is connected by flexible cable to the plug portion of the cutout, and in case the boundary light is knocked over or dragged across the field by either a plane or an automobile, the plug is pulled from the receptacle and the series is completed by means of the spring clips in the receptacle.

The receptacle is provided with a spring cover which upon the pulling of the plug closes the opening against the entry of foreign matter. This cutout is not waterproof, but provision is usually made to so mount these receptacles that they will be above any water which may stand on the field.

While the airport rating regulations of the Department of Commerce limited the voltage of series circuits for boundary lights where insulating transformers were not used, they have permitted the use of any voltage on the boundary circuits where these disconnecting pot-head cutouts are used with each boundary light. Replacement of the plug in the receptacle is made easy by means of a large handhole and cover in the cone.

For floodlighting large landing areas one manufacturer has introduced an incandescent lamp unit which has a total capacity of 24 kw. (Fig. 6).

Differing from previous designs of large capacity floodlights, the wide horizontal angle of spread of the beam is obtained, not by lenses or front-door strips, but by the mirror arrangement. All are acquainted with the property of a parabolic reflector whereby a light source placed at the focal point of the reflector produces a beam with approximately parallel rays. A new type of mirror was designed for this floodlight which has a parabolic section in the vertical plane and is a straight line in the horizontal plane. A light source placed on the focal line of this mirror produces a beam in which the rays are parallel in the vertical plane and diverging in the horizontal plane. The best arrangement which has been found for this large floodlight has been of two banks each with three mirrors and four 3-kw., 32-volt lamps. The two banks are placed at an angle to each other to obtain a total horizontal spread of approximately 180 deg. The photometric curve shows a very even distribution and is especially arranged for very large landing areas. Smaller angles of horizontal spreads with corresponding increase in beam candlepower may be obtained by putting the two banks of mirrors in line. It is very seldom, however, that a spread of less than 180 deg. is considered advisable. Each one of the lamps in this floodlight is fitted with a spherical reflector which not only acts as a louver, to cut out stray light and to shield the light source from the approaching pilot, but redirects a considerable amount of light back into the parabolic mirror. The large mirrors are adjustable so that they may be perfectly lined up with each other and with the lamp.

One very important requirement of airport rating regulations is that all equipment shall be so operated and maintained at all

FIG. 9 NIGHT ILLUMINATION OF BOLLING FIELD AT WASHINGTON, D. C.

times as to meet at least the requirements of the regulations for the particular rating issued.

This applies particularly to lighting equipment which can be permitted to deteriorate in efficiency. One of the great problems at an airport has been the collection of dust on the lighting equipment, and in the case of floodlights which are ventilated, this dust is drawn into the floodlighting fixture and deposited on the reflecting surfaces and on the lamp. The large incandescent 24-kw. floodlight which has been described is enclosed as completely as possible, and no natural or forced ventilation is provided. As a substitute the volume and radiating surfaces of the floodlight are so proportioned that the 24 kw. of energy is readily dissipated by the external surface. This leaves only the problem of cleaning the covered front glass of the searchlight, which can readily be made a matter of daily routine.

As a supplement to the requirements of the Department of Commerce, a new system of airport lighting has been installed on several airports and gives promise of being of considerable assistance to the pilot when landing or when taking off at the airport.

By means of lighting units set flush with the surface of the ground and arranged in rows over the landing area, the pilot is given definite lanes on which to land. These lights are 100 ft. apart and mark quite definitely the surface of the field. Marker lights placed at the ends of each row indicate the direction of the prevailing wind, these lights being controlled automatically by a wind vane.

It is not proposed that this system should be a substitute for field floodlighting, but only as giving additional information to the pilot.

AER-52-21

Automotive Methods and Practices Involved in Aircraft Engines

By O. E. SZEKELY,[1] HOLLAND, MICH.

The author draws a striking comparison between the cost of standard parts in automobile manufacturing and the cost of parts in airplane manufacturing. Iron and steel and other metals that enter in automobile manufacturing can be secured in the market at apparently a very much lower price than when it is known they are intended for use in airplanes. Although airplane making is a new industry, most of the principles involved in aircraft-engine manufacturing have long been practiced in the internal-combustion engine industry.

VAGUE as this subject may seem, yet it is felt, from the point of view of general economics and from the public interest manifested, that it is a major factor.

At first the intention was to make it a purely technical paper in order that its discussion might bring out definite and distinct points of interest to members; however, in the end it seemed more timely and advisable to have this topic receive the cloak of generalities under which the various details may be discussed by those who wish to enter into this problem from a deeper and purely technical angle.

The aeronautic industry did not spring up uncalled for. Necessity and the demand of the present-day methods of doing things and arriving at results brought about ideas of inventors and activities of engineers, designers, and, finally, business men endeavoring to solve locomotion in a manner different from that available.

The ground has been exploited in a rather generous manner—first, the coolie carriage; then, animal-drawn vehicles such as wagons and stages; later on, steam and electrically propelled and rail-guided trains and cars; recently, the automobile, truck, passenger bus, and in the last few years elevated lines and subways.

While it is true that room is still available and that prairies cover territories infinitely greater than are covered by cities, yet because of geological, intercommunicating reasons and proximity to raw and finished materials for the sustenance of our daily lives, cities and towns are located within reach of one another.

Traffic in the last few years has grown out of all proportions to the space in which it performs; therefore, the conquering of the air started to materialize as a natural result. From the point of view of transportation, it is boundaryless and magnificently unrestricted as to speed, territory to be covered, distances in any direction, and the manner in which it is accomplished; from that of the general public, it is already a marvelous achievement; but from the point of view of the engineering profession, we know it is in its infancy.

For comparison between the automobile and aircraft, may not a distinction be made between the two, and this is that, with the advantages of the automobile running on terra firma on four wheels, it is only natural that one feels a certain comfort in knowing that by following the rules and regulation of common sense in the maintenance of speed and direction, no mishap will occur; while in flying, even under the most careful piloting of the craft, the element of danger is present.

Let us now discuss the motive power or power plant of an aircraft and make it the subject, both from the point of view of interest to engineers and that of the public in general. It must not be forgotten that without public acceptance of public demand, or without public absorption of the things that engineers develop or produce, there would be no incentive for further developments or further production.

The second move in this direction should be the possibilities of producing something at a rate and under conditions consistent with the present knowledge of proper design and production, coupled again and unforgettably with the economics of the world, in order that no failure shall come on part of the public in using up the energy so expended in the form of a product, thereby offering additional incentive for additional and better, more developed, and still further improved articles.

One might say, of course, that this is a vicious circle. And that is true and should be, because the moment that complete satisfaction is manifested in what we already have, then all ideas and progress will have ceased. Public demand interpreted in the sense of human endeavor will always try to produce a need for more.

This may be brought down to human effort in producing a mathematical formula. Let human experience, knowledge, and endeavor combined equal "effort" and call it Y, against which there is public consumption, public demand, and repetition of

---

[1] President, Szekely Aircraft and Engine Company. Mem. A.S.M.E. Mr. Szekely was born and educated in Hungary, with a year of post-graduate course in Germany, practicing analytical engineering under the leadership of Professor Steinruech and at the engineering laboratories of Koerting Brothers in Vienna. He came to America in 1910. He was employed in the Experimental Department of Pierce Arrow Motor Car Company and with the old Thomas Motor Car Company, working on the Thomas Flyer. From there he went to the Western Mott Axle Company in Flint, Mich., as designer, and to the Velie Motor Car Corporation, Moline, Ill., serving as checker, chief draftsman, experimental engineer, and chief engineer and works manager for the truck, tractor, and engine division. During the war he was with the Rock Island Arsenal, Velie Motors Corporation, Holt Caterpillar Company (small tanks), and heavy fuel-burning generator developments. Since then he has been occupied as consulting engineer, in designing the front-drive principle and cars, in designing and producing tools, jigs and fixtures, and special equipment for International Harvester Company, Yellow Sleeve-Valve Engine Works, Cushman Motor Works, and Sumner Iron Works. He established the engineering, mechanical and physical, and automotive-testing laboratories for the Ramsey Corporation, completing a series of tests on 27 different makes of engines. He did all of the design, development, and production, with necessary tools and special equipment, for the Velie Tractor and its four-cylinder and six-cylinder automobile engine. In 1927 Mr. Szekely entered the aircraft industry through the development of the first American three-cylinder 40-hp. air-cooled radial engine while president of the O. E. Szekely Corporation of Holland, Mich. His present company manufactures the Flying Dutchman, single-seater low-wing monoplane of the SR-2 two-cylinder, SR-3 three-cylinder, and SR-5 five-cylinder radial air-cooled aircraft engines. Mr. Szekely also did the design and development of the Davenport locomotive and its engine for mining and industrial locomotives.

Contributed by the Aeronautics Division and presented at the Semi-Annual Meeting, Detroit, Mich., June 9 to 12, 1930, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

public desire for more and better products and make them equal "usefulness," and, for the purpose of mathematics, call it X, and it will be found that the growth of one is relative to the growth of the other. If X is to grow in some proportion and Y is to follow, one can set up an equation in which can be found the resultant and the ratio offered by the two, thus:

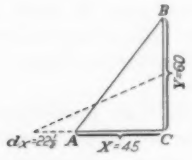
If X is to grow at the rate of dx and Y is to grow proportionately at the rate of dy, it is only necessary for us to find the value of dy/dx.

For example, $Y = X^2$ (assuming that public demand is in such proportion to effort)

then: $Y + dy = (x + dx)^2$

$Y + dy = X^2 + (2X \times dx) + (dx)^2$ [$(dx)^2$ is so small, it is negligible]

$$dy = (2X \times dx)$$



$$\frac{dy}{dx} = 2X$$

There is practically double the amount of public demand relative to engineering skill and available effort. This alone necessitates constant development and, mathematically solved, gives you a differential formula as to the manner in which effort must grow to the ratio of usefulness.

It behooves all to remember that an internal-combustion engine in any shape is still an internal-combustion engine, and while it is also true that on account of its peculiar characteristics it may be proportionately more expensive from the point of view of actual dollars expended in the manufacture and production of same, still there are limits set by public demand and by public absorption.

This, necessarily, brings about the question of cost. The circumstances must be mitigated by the fact that costs can only be reduced by mass production. Tools and operations assist only to the limit of their expediency; from which point, then, number of pieces per unit of time controls production costs. In the comparison, attention is called to the fact that a six-cylinder automobile engine produced at the rate of 60 per day involves a $45 net labor and material of approximately $40, or a total of $85.

Assuming that the material in an aircraft engine must have, say, 50 per cent higher quality of materials, therefore, a 50 per cent higher cost, a 50 per cent greater labor expenditure, this would relatively change the net production of aircraft engines to 33 per day. This is shown in the following formula:

$X = \$45$

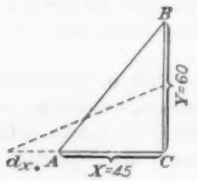
$Y = 60$ engines

$dx = \$22.50$ or 50 per cent

$AB = \sqrt{(AC)^2 + (BC)^2}$

$AB = \sqrt{(45)^2 + (60)^2} = 75$

$(y - dy)^2 = (75)^2 - (67.5)^2$



$= 5625 - 4556.25 = 1069$

or

$$y - dy = \sqrt{1069} = 32.6 \text{ or } 33 \text{ engines per day.}$$

Assuming now that, instead of 60 engines, there are only 5 engines per day produced—the cost of operations is increased relative to the 60 engines, and the labor cost on 5 engines per day to $74.83.

Reversing the formula to prove the cost per engine on the basis of 5 per day, it is as follows:

$AC = 45$

$BC = 60$

$AB = 75$

$Y = 60$

$X = 45$

$dy = 55\ (y - dy) = 5$

$dx = ?$

$(Y - dy)^2 = (AB)^2 - (X - dx)^2$

$(X - dx)^2 = (AB)^2 - (y - dy)^2$

$= (75)^2 - (5)^2$

$= 5625 - 25 = 5600$

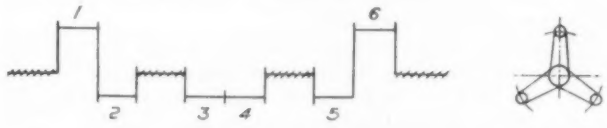
$X + dx = \sqrt{5600} = \$74.83$

The cost of materials, as mentioned before, is 50 per cent greater or $42.50, or a total of the two of $119.83. Add to this the original cost of $85, or a grand total of $204.83, and taking advantage of any possible scrappage at the rate of 10 per cent, or $20, the total gross cost of manufacturing such an engine would still be around $225. At the rate the industry is at the present time operating and under the conditions in which the various parts are being manufactured, the price of a six-cylinder aircraft engine in comparison with that of an automobile engine is approximately five times the price of an automobile engine.

It is a well-known fact that a six-cylinder 75-hp. engine can be purchased in the automotive industry for approximately $250, yet a 75-hp. aircraft engine, even to manufacturers of aircraft, ranges around $900 and with a list price of from $1400 to $1600, and on a 100-hp. engine from $2000 to $2500 for the same design.

In order now to reconcile these statements with manufacturing methods and principles, let it be stated that all materials and all labor in an aircraft engine must be beyond impeachment. Nevertheless, the same machinery and equipment at present producing automobile parts are being used for the production of aircraft engine parts; therefore the primary investment did not change.

It is hardly believed necessary to propound the fact that the materials used in automobile engines are not in the least inferior in many respects to the materials used in aircraft engines, because automotive-type engines have been performing very well for a number of years, and if that is true, it is hardly reasonable to believe that the same material if properly handled and used in the proper places under the proper conditions, will not perform similarly in an aircraft engine.



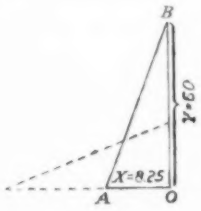
Nevertheless, an automobile crankshaft is manufactured from between 35 to 50 per cent carbon, heat-treated alloy steel. This crankshaft has six throws and not less than three main-bearing surfaces. Also, such a crankshaft has integrally forged and machined balance weight. These crankshafts are manufactured within a limit of 0.001 in. to the diameter of the crank and bearing pins. This is as close a limit as is absolutely necessary for the proper performance of a crankshaft, and it is a commercial tolerance under present manufacturing conditions. The manufacturing price of such a crankshaft is around $12. Compare this now with the same crankpin diameter single-throw crankshaft for aircraft purposes in which the material is a chrome alloy material properly heated-treated—however, without balance weight integrally forged. The purchase cost under the present production system in the aircraft industry for this single-throw crankshaft is $16, or, relative to the six-throw automotive type, eight times the manufacturing cost of the six-cylinder automotive six-throw crankshaft.

Assume a six-cylinder crankshaft, six crankpins $1^1/_2$ in. diameter, 2 in. long, and four main bearings $1^1/_2$ in. in diameter $2^1/_2$ in. long; therefore the total machined projected area would be 33 sq. in.; four set-ups are necessary. Compare the same with a single-throw crankshaft with three main-bearing contacts of 2 in. in diameter, 3 in. long, and one crankpin $1^3/_4$ in. in diameter, $2^1/_2$ in. long, or a total of approximately 22.37 sq. in. of machined surface, and only two set-ups are necessary for this purpose.

The ratio between the two set-ups will be $^1/_2$ or 50 per cent. The bearing-surface ratio will be 22.4/33.0, or approximately 0.68.

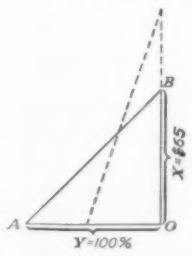
However, let it be assumed that the production ratio, on the same basis as the engines were figured, would be 60 automotive engine crankshafts against 5 crankshafts single-throw for aircraft purposes, or a ratio of 12 to 1. Also add to this the fact that the general machine work on the all-over finished aircraft crankshaft is 100 per cent more than on the automotive type crankshaft, or 2 to 1.

One can then set up the following formula:



6 crankpins $1^1/_2$ in. × 2 in. = 1.5 × 2 × 6 = 18 sq. in. proj. area
4 main bearings $1^1/_2$ in. × $2^1/_2$ in. × 4 = 15 sq. in. proj. area 60 per diem production
Total = 33 sq. in. proj. area
33 sq. in. at $0.25 per sq. in., or $8.25 labor.
$8.25 × 60 = $495 and approximately 50 per cent of forging machine finished, however, produced on four different center set-ups.

Single-pin bearing $1^3/_4$ in. × $2^1/_2$ in. = 4.37 sq. in. proj. area
3 main bearings 2 in. × 3 in. × 3 = 18.00 sq. in. proj. area
Total = 22.37 sq. in. proj. area



This shaft is machined only on two center set-ups, however, at the rate of only 5 per day; therefore the cost may be relative, thus:

$$AB = \sqrt{(OA)^2 - (OB)^2} = 65$$
$$Y = 60$$
$$X = \$8.25$$
$$(X + dx)^2 = (AB)^2 - (Y - dy)^2$$
$$= \sqrt{65^2 - 5^2} = \$64.80$$

However, for the sake of comparison, it may be admitted that the other finished surfaces will double the normal surface of an automotive crankshaft, therefore, relatively, raising the cost thus:

Finished surface aircraft 100 per cent = Y
Finished surface automotive 50 per cent = dy
Price (5 per day) automotive $64.80 = $65.

$$X = \$65$$
$$Y = 100 \text{ per cent}$$
$$dy = 50 \text{ per cent}$$
$$AB = \sqrt{OA^2 + OB^2} = \$119.26$$
$$(X + dx)^2 = (AB)^2 - (y - dy)^2$$
$$= \sqrt{119^2 - 50^2} = \$107$$

Another example is valves and valve materials. Silichrome or tungsten valves of $1^3/_4$ in. size for automotive purposes can be purchased between $0.40 and $0.80, depending upon the quantities purchased. The same valve of the same specification for aircraft purposes, manufactured under exactly the same methods of procedure, can be acquired at a price of between $2.50 and $4.50 each.

Piston pins do not break in an automotive-type engine. It is well known that the highest grade of automotive-type piston pins can be purchased at from $0.12 to $0.32, while the same size aircraft-engine piston pin is $1.25 to $3.50.

This disease has even reached the bearing manufacturers. From automotive practices, it is known that any make of S.A.E. No. 308 deep-grooved ball bearing can be purchased for around $2 each, but when an aircraft engine is manufactured the price is much higher.

Another interesting feature of the spark-plug picture is the fact that the same spark plugs which can be purchased in quantities by automotive-engine manufacturers for not over $0.10 a piece sell to the aircraft industry for from $0.50 to $1.50.

A carburetor for an automotive-type engine can be purchased by automotive-engine manufacturers at a price of between $5 and $7.50 and not over $10. Compare this same carburetor in manufacturing limits and tolerances, in economy, in durability, and in appearance and workmanship with an aircraft carburetor manufactured by the same people in which the limits and tolerances are not extremely far over those used in the automotive carburetor and in which the materials are not extremely better, yet a carburetor of the same capacity for the same horsepower is around $40 to $50.

Cast iron for cylinders in automotive-type engines has for a long time not been known to reach over $0.10 a lb., and such gray iron for internal-combustion engine purposes has been specifically defined by the service demanding 0.035 carbon, absolutely pure, less than 0.4 of 1 per cent sulphur, and very close grain, with a tensile strength upward of 30,000 to 35,000 lb. The same material for aircraft cylinders, allowing a certain margin for the quantities produced and for other necessary requirements, has not been known to be less than $0.35 to $0.45 per lb.

The aluminum industry is no exception when one considers that the aluminum alloy price per pound ranges quite a good deal higher than $1 a lb. for aircraft engines.

These conditions present problems which the public wishes to solve and puts it up to the engineering profession and, in turn, to the manufacturers, until the manufacturers themselves realize that the present-day methods are inadequate in the aircraft industry and that they must borrow knowledge from the automotive industries.

But little has been said about overhead in the aircraft line as against the overhead charges in the automotive line, but the crux of the situation at the present time can be laid, in addition to the mistaken available returns on produced pieces and parts, to that of the maintenance of overhead not tolerated nor known in the automotive industries.

The author would call attention to articles published in *Aviation* in the issues of February 15 and 22, through the efforts of Edward P. Warner, in which the majority of replies to a series of questions point toward a long-awaited realization and solution of the present problem. The exactness of the demand in the aeronautic industry has not been thoroughly answered—not because engines have not been able to withstand the punishment meted out by their use, but simply because no heed is taken of the already established principles, methods, and costs of operations readily available in the automotive industries.

The various prices and figures herein used are necessarily arbitrary and purposely outside of the limits of common knowledge and practice and are used purely for the comparison and

the reasoning established so that the results may show nothing but the proper ratio established.

As a matter of fact, so far no standards have been established, and each and every manufacturer of aircraft engines has an idea of his own as to the necessity of the parts being truly a special unit unlike any other on the market, while if, under the proper methods of production, parts were to be standardized or nearly so, the net labor cost and overhead figures in the manufacture of aircraft engines would drop to an acceptable level.

One must not forget, however, that this is a new industry, but it is felt that most of the principles involved in aircraft-engine manufacturing have long been practiced in the internal-combustion engine industry. The author, therefore, would summarize as follows:

(1) Consideration and application of automotive manufacturing principles and practices in the manufacturing of aircraft types of internal-combustion engines.

(2) The development of means and ways on an already established basis to enhance the ability of aircraft-engine manufacturing to reach mass production on a standardized basis.

(3) Let it be admitted that public demand and acceptance as well as absorption must be created; therefore the reasons for the industry's slow progress in sales could be classified as 60 per cent prohibitive cost and price and 30 per cent public knowledge of undefined character in the handling of matters, coupled with natural fear.

Truthfulness would call for taking an inventory of ourselves and answering the following questions:

(1) Are we in position to assist in stabilizing the industry through any means whatsoever?

(2) Do we realize that this industry is here to stay and that the mode of living for the future will be changed?

(3) Are we ready to accept the responsibility of facing the facts produced by the old adage of supply and demand?

(4) Are we willing to accept past experience as a teacher and use the knowledge gained to further the advantages?

(5) Are we applying our best efforts according to the responsibility placed upon us by the public in general?

(6) Knowing what we lack, are we doing our best to overcome this incompatibility?

AER-52-22

Metallizing the Airplane

By H. V. THADEN,[1] PITTSBURGH, PA.

At present there appears to be a gradual trend toward the use of metal in airplane construction. There are many design problems to be solved by research and experiments. Three basic materials or their alloys are now used in airplane construction. They are steel, aluminum, and magnesium. Extruded sections of duralumin can be formed readily and afford wide possibilities for moldings, trim, and primary structural members.

Internal cantilever wing bracing has developed to a point where it compares favorably in weight with externally braced structures. A smooth surface covering is most efficient, and rounding or filleting of corners and fairing the curves of the structure give high aerodynamic efficiency. The paper gives advantages and disadvantages of metal construction for airplanes.

PROBABLY one of the few opinions unanimously held by members of the aeronautical industry is that the airplane of the future will be all-metal. In fact, it is quite generally agreed that this is the ultimate. It is also interesting to note that prophecies of when this goal will be reached depend on the prophet's knowledge of the success of recent radical departures in metal structural design.

The advantages of metal airplanes generally conceded are (1) that their life is longer, (2) they can weather outside storage, (3) they are more fire resistant, (4) their structure is more homogeneous and crash resistant, and (5) they lend themselves more readily to mass-production methods.

There is a definite indication of a gradual trend toward the use of metal by most manufacturers. In some cases, one notes efforts being made merely to change the component wooden parts to metal. In other cases, component sub-assemblies are completely metallized, unit by unit. The latter method is decidedly better than the former, but in the author's opinion neither method is as satisfactory as going the full way and metallizing the entire structure, divorcing completely all wood or composite structural precedent. The problems involved in metallizing are distinctly different, and are most successfully solved by reverting to fundamentals rather than precedent.

The problems are not simple, and much research and experimentation are essential. The fact that so few really good metal planes exist today is proof of this. However, notwithstanding these difficulties, or possibly because of them, numerous minds are at present working on this interesting problem. In Germany, several schools of thought have reached quite successful solutions; more recently the French and English have been meeting with successful solutions; and here in America, there are a number of schools of thought just getting under way.

The attack on these problems is influenced by a number of factors, of which the business policy, the choice of material, the structural design, and the aerodynamic design are most important. Of these four, the first very largely influences the other three as it has to do with such fundamental economics as cost of production, volume, and profits.

In practically all production work, it is a well-established fact that the greater the number of similar articles produced, the cheaper they can be made because of the better production machinery which can be profitably utilized. However, production machinery, special jigs, and dies are expensive and the volume of the airplane market is comparatively small. Also, engineering obsolescence is, and will be for some time, a most serious factor. Under these circumstances, some compromise solution must first be made to determine how much money can be justifiably spent for special machinery, jigs, and dies in anticipation of a given volume of production. Even a most cursory analysis shows that airplane production is not today, nor likely to be for several years, in a class comparable to the automobile industry. In fact, a survey reveals that the aeronautical industry is comparative in size, and to some extent in market, to the present motorboat industry.

Considering all this, it behooves one to use conservative judgment for the next few years and to curb natural desires to install the most modern, or most specialized, production machinery because, obviously, the volume will not warrant such expenditures.

By this there is no implication that every effort should not be made to use existing production machinery, but merely that during the inevitable transition from small to large production, it might be profitable rather to accept higher charges for more hand labor than to lower special machine-made charges to which a disproportionately high burden must be added. The low prices of automobiles are due to the tremendous volume in which they are made and to the use of highly developed, but unfortunately costly, jigs and dies. Airplanes will never be on a comparable cost basis until they have a like volume and similar jigs and dies.

It might be well, then, so to modify present designs as to use the available production machinery, to simplify designs, and to standardize as much as possible in order to reduce the cost price. As the volume increases designs can be altered more profitably later to suit the automotive mass-production methods.

Choice of material is extremely important and must constantly be kept in mind. In these days of intensive research, a metallurgical development might well alter an entire production procedure. Lighter and stronger materials are constantly being developed as well as commercialized. There are today three basic materials, or their alloys, in use in commercial aircraft; namely, steel, aluminum, and magnesium. Of these, magnesium is still used only to a small extent, but its extreme lightness gives it interesting possibilities.

Magnesium sheet in thin gages presents certain unsolved problems of which fire resistance and corrosion are the most serious. Castings and forgings, however, have a useful field for low-stressed parts such as in secondary members. Steel has found extensive use in aircraft in various classes from the medium carbon to the high alloy. Seamless tubing in both the carbon and in the chrome-molybdenum alloy is used predominately in fuselage structures, and also to some extent in the spars of wing structures. Forgings, where a sufficient number of similar parts justify the expenditure for dies, form reliable members for the primary structure. Thin alloy-steel sheet in strip form is used in numerous places as it can be readily formed and welded. The sheet stock or the tubes, when welded and later heat-treated, develop very near their full physical prop-

[1] Vice-President, Pittsburgh Metal Airplane Co.

Presented at the Pittsburgh Aeronautical Meeting, Pittsburgh, Pa., March 12, 1930, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

erties, but in the event that length or size make heat treatment, after welding, impracticable, neither the physical qualities nor the fatigue resistance can be realized.

Aluminum is being used in increasing extent, both in the commercially pure state (98 per cent) and in various alloys such as duralumin and alclad. The latter material has particularly good corrosion-resisting qualities because of the coating of pure aluminum with which it is surfaced. Aluminum-alloy tubes, so far, have been commercially obtainable of duralumin only, but it is promised that they will also be made of alclad in the near future.

Of the aluminum alloys, probably the best known is that of duralumin which contains a small amount of copper. Under proper heat treatment this material finds very extensive use in the primary structure as well as in the covering of an airplane. The fact that it has considerable more bulk for a given weight than steel makes it more resistant to secondary failure such as the crinkling of the free edges.

Extruded sections of duralumin can be readily formed and offer wide possibilities for moldings and trim as well as for primary structural members. To date, the minimum practical thickness to which this material can be extruded is about $^1/_{16}$ in. Duralumin castings can be employed where stiffness or bearing area is required, but it seems somewhat hazardous to utilize them for tension members in a primary structure. Duralumin forgings have proved especially practicable and will unquestionably be used to a large extent. One of the advantages of aluminum alloy is the possibility of heat-treating the material, subsequently forming and shaping it to size, and still retaining the ultimate physical properties by virtue of its "aging" characteristics.

Generalizing, it would appear that these various materials could be advantageously used in some of the following ways. For pure tension, the best material from a structural and weight standpoint are the alloy steels. For pure compression, in short columns the magnesium and aluminum alloys offer possibilities except in very highly stressed members. For bending and compression, the limitations of available space for the structure determine the most practical material. In the event that steel is used, the thinness of the material would probably be the criterion; in this event, a bulkier material such as duralumin would work in more efficiently. In fact, the most serious limitation in the use of sheet metal of either duralumin or steel is the inability to use the material in the most economical sizes because of the stiffness factor.

The structural and aerodynamic design of airplanes are more or less interrelated, having their closest point of contact in such matters as weight and parasitic resistance. Some of the important factors influencing these problems are the relative merits of the monoplane and biplane types, the method of wing bracing, and the surface covering.

In the author's opinion, the monoplane makes the better commercial type of plane because of its simpler construction, the fewer number of parts, and the greater aerodynamic efficiency (some 10 per cent). On the other hand, greater maneuverability is obtained with a biplane structure due to its smaller moment of inertia. This, however, is of more importance to military than to commercial ships.

Internal cantilever wing bracing, which is of relatively recent origin, has developed to a degree where the weight involved is comparable to that in the externally braced biplane structure, or in the externally braced monoplane type. With the weights of the two types about on a par, the problem now revolves about the degree of profile resistance unavoidably present with thick-profile sections required in the cantilever type compared to the thin profile sections of the externally braced type with their extra strut braces. The trend seems to be toward the thicker cantilever wings, however, which have a higher lift permitting lower landing speeds and quicker take-offs.

In the matter of surface covering obviously the most efficient type is one with a smooth surface and conforming to a streamline shape. Rounding or filleting of the corners of structural intersections and generally fairing the curves of an airplane structure tends toward high aerodynamic efficiency. A rectangular round-cornered or elliptical fuselage is more efficient than a rectangular square-cornered type. In general, the fewer protuberances from the essential portions of an airplane, namely from the wings and fuselage, the less power is required to propel the airplane through the air. Full-scale wind-tunnel tests indicate smooth metal as having the least surface skin friction, with, however, painted metal and unpainted plywood having only slightly greater resistance. The influence of corrugating the metal, with corrugations similar to those used by Junkers and Ford, is a relatively small factor when studied from the standpoint of performance. The increase in surface area is approximately 15 to 20 per cent, and on a wing test alone, a decrease in efficiency of somewhere around the same amount is noted in the L over D between a smooth and a corrugated wing cover. However, when this loss is transformed into terms of performance of a complete airplane it is found that the horsepower required results in a loss of top speed of only 1 to 2 per cent. This loss is even more negligible at lower speeds and is practically zero at climbing speeds. This is better appreciated when it is remembered that at top speeds less than $^1/_3$ of the total horsepower is required to overcome the total wing drag. An interesting aerodynamic phenomena which is brought out by these same full-scale tests on corrugated sheet is that there is a general flattening out of the lift curve near the burble point. This has the effect of delaying the tendency of the wing to autorotate and thereby delay spinning.

Consideration of these various aerodynamic factors leads one to certain conclusions regarding the most adaptable type of structural design. It has been reasoned that if the outer cover is necessary for aerodynamic reasons, and if a structure is required to carry the imposed loads, then it might be well to design the covering to serve both purposes. This line of reasoning has brought about another principle of structural design.

At present there are two basic schools of structural design; one makes use of the conventional type of framed structure in which stresses are statically determined by well-known methods of analysis, and the other follows the "monolithic" (a term to designate single-piece construction which has recently come into use) type of structural design which in general is not amenable to conventional determinant analysis. This latter type has been generally taboo because of this fact, but notwithstanding the limitation of formal analytical analysis, it is gradually coming more and more into use. This type of structure must usually be physically tested to determine its structural strength, at least until sufficient data will have been acquired to correlate the theoretical hypothesis with the actual test structure.

Most airplanes today are designed on the basis of the first type, namely, the determinant framed structure type. Thus their design is based on fairly exact methods of calculation. The loads in each member being determinant, an economical primary structure usually results. Unfortunately, however, these structures, especially the fuselage, generally have aerodynamically inefficient cross-sectional forms and their square or rectangular, or even triangular frames have to be padded up and the corners must be rounded to give the desired streamline to the structures. This secondary structure is inefficient from a weight standpoint, besides being costly both in the initial manufacture and in field repair. On the other hand, the "mono-

lithic" or monocoque type of structure can be most easily made with rounded corners, rather than square, and the surface covering generally "streamlines" its contours naturally. As stated, this type of structure is not calculable and must be tested statistically to prove its strength. However, as the number of units of a given type increase with production, this disadvantage becomes negligible.

An important advantage of the "monolithic" type of structure is that small holes, or discontinuities in the surface, do not in general seriously detract from the strength. In a frame structure, the failure of one of the few essential structural members generally results in a total collapse. Thus from a military standpoint, shell holes would be decidedly less hazardous in the monocoque type.

One of the first structural components of the airplane in which this principle of construction was applied was the fuselage. The earliest types, and even some of today, use wood in a laminated form to make the outer contour of the fuselage. This type, however, has certain limitations because of the climatic variations to which an airplane is subject, the lack of resistance to fire, and splintering of the wood under crash loads. Likewise, this type of covering is not adaptable to mass production methods; therefore, attempts are made to metallize this type of structure. Two general types are being evolved. One uses a multiplicity of transverse bulkheads of the required aerodynamic cross-sectional shape, to the periphery of which are fastened longitudinals. The resultant "bird-cage" structure is covered with flat sheet metal. Securing the sheet to the bulk-

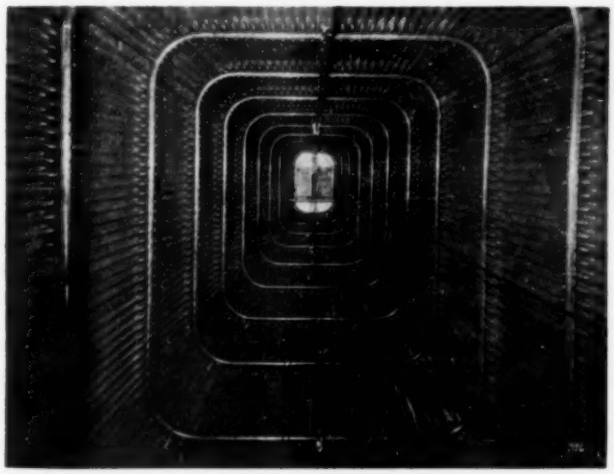


FIG. 1 INTERIOR OF MONOCOQUE FUSELAGE OF THADEN T-4 ALL-METAL AIRPLANE

heads and longitudinals has the effect of splitting the structure up into a series of small rectangular frames riveted to a flat plate skin, the flat skin acting as a shear web.

The second type of fuselage structure which is being evolved is one using a somewhat similar type of transverse bulkheads but omitting the longitudinals and replacing them with sheet metal corrugated longitudinally. This is, in effect, the equivalent of a multiplicity of very small longitudinal members fastened to the transverse bulkheads. In this case the skin takes all of the shear loads as in the flat-skin type, and also takes all of the chord loads due to the primary bending moments. The skin is truly stressed and, in fact, the bulkheads serve their chief purpose as separators constraining the sheet to its designed position. An example of this type of fuselage is shown in Fig. 1, in which the bulkheads are formed of aluminum-alloy tubes bent to the desirable aerodynamic cross-section, the longitudinally corrugated skin is riveted to the tubular bulkheads.

The wing structure is developing along much the same lines as the fuselage, but at a somewhat slower rate, chiefly because of the apparent efficiency of the conventional two-spar wooden and fabric construction. At least this is so with the externally braced monoplane and biplane types of structure. In the case of the cantilever monoplane, increasing spans and higher speeds demonstrated a serious limitation of the conventional type of wing structure. The resultant increase in torsional forces necessitated something stiffer than that obtained with the conventional wire drag bracing. Additional bracing was obtained by replacing the fabric cover with plywood. This materially increased the torsional resistance of the monoplane wing. A number of excellent examples of this type of wing are being

FIG. 2 REMOVABLE WING PANEL SHOWING INTERIOR OF MONOCOQUE CANTILEVER WING OF THADEN T-4 ALL-METAL AIRPLANE

made today, of which the Fokker is outstanding. However, wood in the wings, as in the fuselage, has serious handicaps, and hence efforts to metalize the entire structure, including the surface, is being made.

In the two-spar biplane and braced monoplane wing structures, the ribs were the first elements to be metalized. This has been done by stamped sheet-metal ribs in the small sizes and by built-up framed ribs in the large sizes. Spars were next in development, and to date, dozens of different metal types, including the welded-steel truss spars, the stamped duralumin box, extruded duralumin I-beams and high-strength alloy-steel strip spars, have been made. During the earlier stages of the development difficulties were encountered in equaling the strength-to-weight efficiency of an equivalent wooden spar. Recently, however, government experiments have met with success and duralumin box spars superior to those of wood have been constructed.

In the conventional framed type of spar-and-rib structure the cover, for aerodynamic reasons, is generally made of fabric and, therefore, contributes no strength. It is improbable that a low-cambered biplane wing can be efficiently covered with metal. In the author's opinion, a metal cover to be efficient must carry stress, and for this reason the thicker monoplane, and especially cantilever wings, are most admirably suited. Inasmuch as a stiff cover is necessary for torsional strength in the cantilever wings, the metal type can be efficiently used.

These factors are bringing about a change from the determinant type of framed-wing structure to the "monolithic" type

in which the cover is stressed. A further structural step was to increase the number of spars, giving rise to so-called multi-spar construction. In this case "I," box, or tubular beams are used. In the absence of ribs, or closely spaced bulkheads, corrugated sheet must be used to attain the required rigidity between supports. A very efficient wing of this type is the Junkers in which a multiplicity of tubes acting as chord members and inter-connected by diagonal web braces is covered with corrugated skin riveted to the tubes.

A still different wing structure, which, while not necessarily of a metal type, is being metalized, is the so-called "mono-spar" wing in which a single spar is located some 30 to 40 per cent of the chord. This spar is designed to take only the bending moments. Diagonal wires helically disposed around the spar, or an entire sheet-metal covering on profile ribs, is designed to take the torsional loads into the fuselage. The wing profile is generally one with a very small center of pressure movement. This is an interesting development, and the author only questions its practicability from a vulnerability standpoint.

FIG. 3 THADEN T-4 ALL-METAL CANTILEVER MONOPLANE

Another type of stressed-wing development is that one utilizing a large metal box or "caisson" construction to which light leading and trailing edges are fastened. The box is composed of flat metal for the shear webs and a laminated top and bottom sheet-metal chord conforming to the wing profile. Frequent transverse bulkheads are spaced along the interior.

A further development of this box type of spar, has resulted in a so-called "monocoque" wing in which the box structure extends entirely around the leading edge of the wing and an appreciable distance back along the chord of the wing. The spar chord members are tapered in plane and profile as well as in gage, making it possible to taper the strength of the spar in proportion to the air loads.

Either corrugated or flat sheets may be used for its covering, although there is a decided advantage in the use of the corrugated sheet as it greatly strengthens the chord members against buckling by secondary failures. An example of this wing construction is shown in Fig. 2.

One of the least understood and yet probably one of the most important factors in sheet-metal structural design is that of stiffness. Unless the structural member, such as a beam, the surface of the fuselage, or wing, can be constrained to remain in the position for which it was designed, little or no efficiency will be realized. This is exemplified in the tests conducted by the Army and Navy on the strength of spars as used in the conventional two-spar wing. The greatest deficiency of most of these spars was in their lateral instability. Relatively light loads would cause them to fail through lateral deflection and consequently secondary stresses. In a like manner sheet covering, unless constrained, has practically no strength. Corrugating the skin aids to a remarkable degree in strengthening the member. In fact, any curvature of the sheet about the axis of the load increases its load-carrying capacity. It is not generally appreciated by designers that corrugated sheet can also withstand quite heavy shear loads both normal as well as parallel to the corrugations.

One of the most serious limitations in the use of sheet metal, and in fact any material, is imposed by the joints. Properly made joints always result in an increase of weight and a loss of efficiency. Welding is probably the quickest method of joining metal parts, but unfortunately it cannot be entirely relied upon when done under the stress of production, since the quality of work, in production, decreases. Furthermore, to obtain full strength it is necessary to heat-treat after welding, and this becomes impractical because of limitations of size and because of warping. In a sheet-metal structure, particularly when made of aluminum alloys, riveting and bolting are the most practical methods of bonding, and in this case the chief limitation lies in obtaining sufficient bearing areas.

Another factor, having little to do with aerodynamics or structures but frequently entirely neglected by designers, is that of inspectability of the interior of the structure. This is of particular importance in the "monolithic" type of structure and has been one of the obvious deficiencies of numerous structures of this type. It will be noted that in both the fuselage structure and the wing structure, shown in Figs. 1 and 2, the entire interiors of both of these structures may be inspected by removing the panels on the lower surface of the wing. The lack of any and all bracing in the fuselage makes it easy to inspect this part of the structure. These features have two-fold advantages; first in the initial manufacture and second in maintenance and repair work in the field.

To obtain satisfactory results in the building of these monocoque structures, it is practically essential to prepare jigs in which to do the work. It will frequently be found that such preparatory work is more economical in the long run.

As a concluding comment it might be well to point out that there is no one simple type of metal structure which will satisfy all of the structural problems of a single airplane, much less the problems involved in various sizes of airplanes. The relative size of each part must be correlated not only to satisfy the requirements for the most efficient structural and aerodynamic design but also to insure a design practicable from a production standpoint. In the present state of the art it is probably true that the greatest asset of a designer of metal airplanes is a flexible and open mind.

Discussion

JOSEPH S. NEWELL.[2] For some time previous to the first of this year the writer concurred with the author that the ultimate airplane would be all-metal. He still believes that it may in the somewhat distant future, but he is of the opinion that the present trend toward all-metal airplanes will be followed by a swing back to the conventional type of the past few years, at least for the less-expensive sport and general-utility categories. After learning that one air-transport company has found it necessary to dismantle all-metal flying boats completely after each 400 flying hours in order to inspect the connections of the main hull structure and to replace the corroded skin, one begins to wonder about the longevity and the "man hours of maintenance per flying hour" of all-metal structures. After seeing an all-metal military transport with a record of some 900 flying hours during its four years of service having a skin so badly corroded that one could force the thumb through it almost

[2] Associate Professor of Aero-Structural Engineering, Massachusetts Institute of Technology.

anywhere, one wonders still more concerning the life span of present-day all-metal aircraft, and their ability to withstand outside storage. The writer concedes that these airplanes both had plain aluminum-alloy coverings, not alclad, but both had protective coatings, and as both were maintained by large and efficient organizations it is only fair to assume that the protection afforded conformed with the best practice current during the life of the airplane. A number of similar cases could be cited, but these two suffice to make one ponder the statement recently made by the chief engineer of one of our most progressive airplane companies. It was, "For durability and dependability I'll have my all-metal airplanes made of wood."

As for fire resistance, all-metal aircraft doubtless afford a smaller hazard for ground or hangar fires, but with the low melting point of the aluminum alloys it is doubtful whether or not they afford any appreciable protection during crash fires which practically always involve the intense heat of burning gasoline and oil. In such fires, at least if one is to judge from the writer's experience, the aluminum alloy structure which has been in the range of the gasoline flames has always been melted or completely consumed, and has given no more evidence of its original shape than would a spruce structure. The steel members have always been essentially intact, but one does not consider all-steel structures when speaking of all-metal airplanes. Not at the present time at least, when designers are laboring on stressed-skin or monocoque projects.

The mass production of aircraft is a thing of the future, probably 10 years at least, and its apparent advantages are to be closely scanned before being accepted as actual. For instance, it has long been assumed that wing ribs would afford an ideal subject for mass-production methods, and, with any reasonable number of airplanes involved, these methods could best be applied to stamped metal ribs. However, after ascertaining that one manufacturer of wood ribs stood ready to build and deliver sufficient ribs for more than 500 airplanes at a total cost approximately equaling the expense of making dies for stamping out an equal number of metal ribs, one wonders just where the advantages of mass production start. For the next few years, at least, it is probable that an output of 500 identical airplanes will be considered mass production for the aircraft industry regardless of size, type, or conditions of service. Analyses and comparisons based on mass-production methods in the automobile industry, where a production limited to 500 identical units a week is considered practically the equivalent of an admission that a manufacturer's existence is economically unjustifiable, must therefore be used with discretion. It appears at present to be better practice to utilize existing production machinery and design to reduce fabrication costs to a minimum rather than use special machines involving a capital investment which, in most cases, is disproportionately large compared with the "possible savings" involved.

For all-metal airplanes of the stressed-skin type it is probable that the aluminum alloys afford the best structural materials from the standpoints of strength to weight ratio and of workability. For such types, too, it is probable that the monoplane is superior to the biplane, largely because of its simpler construction and the reduction in number of constituent parts. It is doubted that an internally braced, all-metal wing can be built to have satisfactory strength and not weigh over $1^3/_4$ lb. per sq. ft. This is possible with an internally braced, spruce spar, fabric-covered type on airplanes of around 4000 lb. gross weight. The latter type may be built with no danger of flutter for speeds up to 300 m.p.h. if suitable precautions are taken, and it is interesting to note that practically the same precautions are necessary to eliminate this danger in the stressed-skin type, either plywood covered or all-metal. So it may be inferred that, for equal strengths, the all-metal wing will be heavier than the conventional two-spar, fabric-covered variety, at least for the smaller commercial types.

As for fuselages the writer has during the past two months discussed weight-saving prospects with some five or six competent engineers, and each has said he believed the all-metal fuselage could be built lighter than fabric-covered welded-steel frames, but where direct comparisons were possible each had so far found an actually greater weight in the all-metal construction. This is doubtless due to the fact that data on various types are so meager.

Several manufacturers have apparently built and tested aluminum-alloy fuselages and have back-figured the stresses occurring at failure using the standard beam formula, $f = Mc/I$, only to clothe their results with the greatest secrecy. In some half dozen cases the writer found that failure of the stiffened skin or semimonocoque fuselages occurred when the stress on the extreme fiber in compression was somewhere between 8500 and 9000 lb. per sq. in. at the critical section. The cross-sections were elliptical in shape, the moment of inertia being computed for the skin and longitudinal stiffeners combined. One or two values around 7500 lb. per sq. in. were noted, and there were a couple near 10,000 lb. per sq. in., but 8500 lb. per sq. in. appears to be a fair ultimate stress for preliminary designing at present. It is hoped that extensive research programs will soon provide definite values and will afford more rational methods of proportioning both stiffeners and skin. There are too few dependable data available at present to justify establishing any method of analysis or any set of allowable stress properties for flat sheet or corrugated covering. Such results as are available seem to indicate that analyses involving highly mathematical investigations or allowable stress properties based on the theories of applied elasticity should be confirmed by actual tests on full-size specimens in every case. For instance, theory indicates that a flat sheet 24 in. square should carry about one-sixth of the load which a 4 by 24 in. specimen would take assuming that the sheet is loaded in compression, that its column length is 24 in. in each case, and that the edges parallel to the direction of the load are stiffened to prevent localized buckling, but that either edge may rotate about an axis in the plane of the sheet and lying along the edge in question. Theory and practice appear to agree that the sheets will buckle into "squares," i.e., the 24 by 24 in. sheet will buckle to form a single square, the 4 by 24 in. specimen will buckle to form six, 4-in. squares. But as indicated by recent tests at the Bureau of Standards, the results of which are to be published shortly by the National Advisory Committee for Aeronautics, both sheets will carry the same load for stresses causing permanent set. Sufficient tests have been made by the bureau on different gages, widths, and materials to establish this rather serious discrepancy between elastic theory and practice. It appears necessary, therefore, to static-test all-metal structures for some time to come, and to coordinate and study the results with a view toward establishing workable design values.

The writer wishes to protest the introduction of "monolith" to describe all-metal airplane structures. It is true that monolith means single stone. But is it not probable that the average person will associate the characteristics of a stone with what might be described as the "falling tendency" of an airplane rather than with the integrity of its structure? It would seem that monocoque, meaning single shell, is the more logical and more satisfactory word for structures of the type in question.

In closing, the writer wishes to congratulate the author on his excellent paper. It affords a clear, rational, and well-arranged presentation of the problems of the manufacturer of all-metal airplanes, a presentation that is particularly valuable

at this time when all-metal types are being considered by a number of manufacturers as a possible cure-all for the present ills of the industry. That the writer has presented his comments from a different point of view is not to be construed as a disagreement with the author's excellent discussion, but rather as an interjection of the more somber aspects of the problem of metal aircraft construction and operation in the hope that the less experienced manufacturers may be constrained to consider the possibility that a remedy so simple and yet so powerful does not exist.

AER-52-23

Some Fundamental Economics of Aircraft Operation

By R. H. UPSON,[1] DETROIT, MICH.

The paper is intended as a sequel to the author's paper entitled, "The Airship for Long-Haul Heavy-Traffic Service," presented at the annual meeting of the American Society of Mechanical Engineers in 1922. In that paper the airship was considered mainly as an ocean-going vessel, the principal comparison being made with ocean steamships. Various design problems were also discussed and the desirability of certain improvements pointed out. The situation needs reviewing on account of the sensational bid for transoceanic service that has subsequently been made by the airplane and the fact that many of the improvements indicated as desirable in the previous paper have now been demonstrated in experimental form. Hence, this paper is devoted principally to the consideration of the relative economic fields of airships and airplanes, the attempt being made to deal primarily with fundamental characteristics rather than with current performance records.

IT SEEMS to be generally recognized that in comparison with the airplane the airship is best suited for operation over long distances. But any comparison to have much permanent value must be quantitative in character, and it must be based on characteristics more fundamental than mere types and performances of the day. In a paper given to the A.S.M.E. nearly seven years ago,[2] the author felt that it was most conservative to base comparisons on actual performances, there being insufficient aerodynamic knowledge for anything better. Now, however, the accumulation of numerous tests and their reliable interpretation by the methods of Prandtl, Glauert, and others make it possible to depend more on the real fundamentals.

Let it be assumed that the main purpose of either airship or airplane is to carry a certain load over a certain distance at a certain speed. Then the fundamental distinguishing feature of each type of craft is its lifting unit—namely, the wings for the airplane and the gas hull for the airship; and the fundamental items of performance for both are lift, drag, and speed. As the fuel consumed over a given distance is proportional to the drag, the distance pertaining to a given fuel load (as a proportion of lift) varies as lift divided by drag (L/D). Without going into detail in this paper (this having been fully covered in another paper[3]), the author will simply select the best-tapered internally braced airplane wing and the best airship hull, the latter with a drag practically equal to skin friction alone. (See Appendix.)

As a tentative approach, the airplane was assumed at constant lift-coefficient and varied in aspect and thickness ratio in such a way as to keep the weight of its main beam flanges increasing in the same proportion as those of the airship for increasing gross lifts.

As might be expected, in spite of the lower coefficient of skin friction applying to the larger sizes of airplanes, the structural requirements caused the actual L/D to drop slightly with increasing size. Therefore, the charts here shown have been drawn up on the basis of comparing a single airship hull of varying size with a multiplicity of airfoil elements at constant L/D. Assuming a minimum parasite drag of 33 per cent of the total (a figure not yet attainable except for gliders), it is equivalent to an L/D of 20 for the complete airplane.[3]

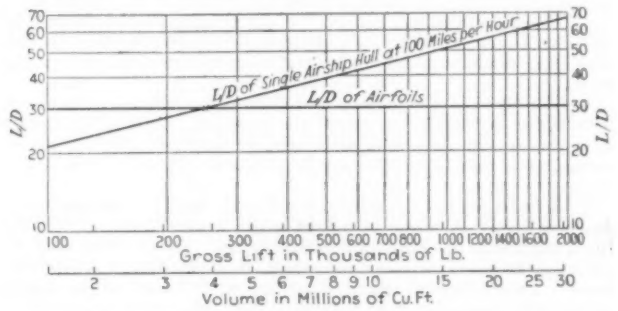

FIG. 1 COMPARISON OF L/D AT CONSTANT SPEED

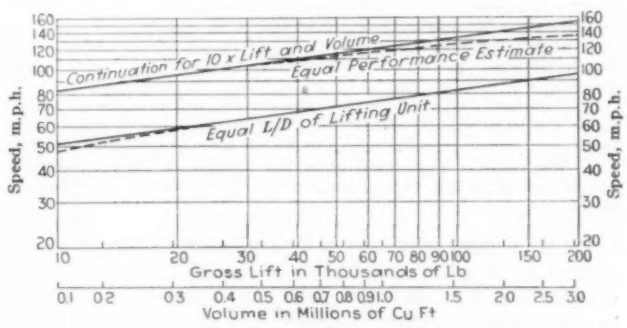

FIG. 2 SPEED OF EQUAL L/D

Fig. 1 shows the variation of max. L/D for the one speed of 100 m.p.h. This is the operating speed, the top speed being, say, 20 per cent higher for airplanes or 10 per cent for airships. Where these two curves intersect is the point where the lift, drag, and speed are the same for both airfoils and airship hull. If similar intersection points are calculated for other speeds,

[1] Aeronautical Engineer. Mr. Upson received his M.E. at Stevens Institute of Technology in 1910. He conducted research in aerodynamics and airship engineering in 1908–12. He won the International Balloon Race in 1913, and the American National Balloon Race in 1913, 1919, and 1921. Mr. Upson was chief engineer of the Goodyear Tire and Rubber Company's aeronautical department 1914–20, producing most of the American balloons and airships used during the war. As Chief Engineer of the Aircraft Development Corporation, he was responsible for the design of the Metalclad *ZMC*-2, the first successful all-metal airship. Since then he has conducted research on airplane wings, for which he received the Wright Brothers' Medal. Last year he was one of the recipients of a watch from the A.S.M.E. "in recognition of services rendered aeronautics."

Contributed by the Aeronautic Division and presented at the Akron Meeting, October 21 to 23, 1929, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

[3] "Wings—A Coordinated System of Basic Design," *Journal of the S.A.E.*, January, 1930, p. 15.

there is obtained the full line in Fig. 2 showing the speed of equal or constant L/D for different sizes of airship hull. This forms the most fundamental line of separation between the operating fields of airplanes and airships.

Of course, this theoretical curve cannot be taken as a complete answer to the question or as a substitute for good judgment. Its purpose is to make at least one important phase of the problem definite as a foundation on which to base that necessarily vague and uncertain thing called "judgment."

From a directly practical standpoint, the interest is not so much in the L/D of the lifting unit as in the ratio of useful load (exclusive of crew and ballast) to the total drag of the complete unit, which for a given speed and distance determines the pay-load capacity. The author's estimate of the curve of equal performance on the latter basis, for the best possible construction of both types, is shown by the dashed-line modification in Fig. 2. It is based on the following considerations of conditions along the equal L/D curve for both airships and airplanes:

1 The power plants are equal, due to the assumption of equal total drag and speed. This also balances out the item of distance except as it is reflected in the size and speed.

2 The stabilizing and control organs, including supporting structure, are somewhat larger in proportion for planes, but in each case their drag tends to remain a substantially constant fraction of the total.

3 The effect of size alone is to reduce the structural efficiency of both types as the size increases, the airplane a little more rapidly than the airship. But comparing the single airship to a group of planes, as is done here, the handicap of size applies to the airship alone.

4 A large part of the airship's structure, used for resisting aerodynamic forces, increases in weight as the square of the speed. On the other hand, the structural weight of the airplane is actually reduced as the speed increases, providing the lift coefficient is kept constant. Thus in larger sizes the structural efficiency of the airship suffers more markedly in proportion to the plane, not only because of the size, but because of the increasing speed.

5 The airship has an added weight of gas-holding material which is especially high in proportion for small sizes, but it is also serious for large sizes due to the apparent necessity for compartmenting.

6 Space requirements of airplanes necessarily involve more parasite resistance, especially in the smaller sizes and for the higher speeds.

7 A certain amount of water-recovery apparatus is almost necessary for a large airship, but on the other hand the use of some of the hydrogen (or fuel gas) for power tends to offset the weight involved.

8 The landing equipment of planes is more of an item in both weight and resistance than is the landing and mooring equipment of airships.

For the highest of the speeds here considered (134 m.p.h.) the assumption of a lift coefficient $C_L = 0.5$ for planes makes the wing loading 23 lb. per sq. ft., which would involve an excessive landing speed according to present American practice; but it could probably be brought within reason by a suitable use of flaps, slots, etc., which in turn must be allowed for in the weight and drag.

The whole subject of landing gear, including floats, for very large planes is a matter of considerable conjecture, and is likely to remain so, as there seems to be no fundamental factor to justify the building of sizes up to anywhere near the limit of this chart. As before noted, the "equal performance" curve represents the comparison of any large single airship with any group of medium-sized planes totaling the same carrying capacity.

The net efficiency of the airship will be considerably decreased if helium instead of hydrogen is used, but it will be increased if the aerodynamic lift can be utilized. That of the airplanes will be decreased if the wing loading is decreased. The airship, on the other hand, has certain special items of upkeep expense of which gas and gas-holding materials are the most important. The initial cost per unit carrying capacity, though much lower for the airplanes in small sizes, becomes more nearly equal in large sizes. Generally speaking, maintenance of route is more expensive for the planes, and terminals for the airship. For any specific use there are special factors to be taken into account.

The author's conclusions are:

(*a*) Airships must be used mainly for conditions below the *equal-performance line* if they are to be worth while. This applies to practically any use, military or commercial. For the latter use the *equal-economy line* would be a little further below, especially for small sizes.

(*b*) Even through a considerable range below the line, airships will be hard pressed to show an economic advantage if they are unduly burdened with extra "*parasite*" *expense* such as for helium, hangars, ground crews, perishable materials, unnecessary weight and resistance, etc. The reverse, of course, applies in so far as the airplane has to be held back by facilities such as for slow landing and seaworthiness. Some of these items are of course very good in themselves, but the extent to which they may be profitably used must be determined in every case by careful consideration of the economics.

(*c*) In view of the *meteorological conditions* prevailing over this country and the adjacent oceans, and the other means of transportation available, it is hard to believe that any aircraft with a top speed much under 100 m.p.h. can have more than a very limited use.

(*d*) From the foregoing considerations, an airship of somewhere between three and four million cubic feet seems to be about the *minimum profitable size* for commercial transport, and then only when gas and other important factors are economically favorable. (The *Graf Zeppelin*, certainly the best airship thoroughly tested to date, does not, the author believes, meet the requirements.)

(*e*) *The longer the trip, the bigger the ship.* There continues to be some gain in transport efficiency over transatlantic distances for airship sizes up to at least 30,000,000 cu. ft. But the law of diminishing returns is working so hard there that one would hardly advocate anything beyond 20,000,000 cu. ft. with the present available materials; and it would be foolish to try anything that large without further improvements in construction and more experience in operation.

(*f*) There is little change in basic airfoil efficiency for moderate changes of either *size or speed*. Thus the only object in making airplanes larger is to gain certain secondary advantages such as cutting down parasite resistance, distributing the load more equally, and gaining certain qualities of seaworthiness. Speed, however, is a great object in itself. For this reason, it is believed that airplanes will be increasingly used over nearly all routes that they can negotiate with a reasonable pay load (or military load) and at a speed probably well above the equal performance curve.

(*g*) Small airships seem to have a certain legitimate utility, for training and other special purposes, but not even that can be said for very large airplanes. It may be worth while to build planes up to the size where most useful load can be carried in the wings, or, say, 10,000 sq. ft. maximum wing area. This corresponds in lift to an airship of about 2,600,000 cu. ft. Thus the *main field of the airship* will probably begin beyond the size where the airplane, as an individual unit, leaves off.

(*h*) The dividing point in *actual distance* is harder to assign because it depends on so many other factors. For straight transportation the airplane seems generally to be more efficient than the airship up to at least 1000 miles, assuming the same relative perfection of engineering. (See Appendix.) On the other hand, no matter what the state of the art, there always will be a field for the airship beyond a certain distance, where by a suitable lowering of the speed, almost any desired L/D ratio may be had. For example, even without any further improvement there is a distinct field for the large airship in long-range naval scouting.

(*i*) At the present time, also, airships seem to be *safer* for flights at night, over rough country or long stretches of water, and in fog. Airplanes are probably safer in very rough air and near electrical disturbances (at least as compared to hydrogen-filled fabric ships).

(*j*) In respect to construction there are four main elements on which substantial progress has already been made, but which urgently need continuing attention to permit the fullest realization of aircraft possibilities, as follows:

		Airplane	Airship
1	*Form*	Highly tapered cantilever wings	Low fineness ratio (preferably not over 4.5)
2	*Material*	Substantially all-metal construction for both types, with special emphasis on economy of production	
3	*Strength*	Elimination of flutter	Greater strength and rigidity in rough air
4	*Control*	Elimination of spinning, and more positive control of landing	Positive stability, when flying and when moored

All progress has its price. Fortunately in the airplane field there have been in the past no lack of men willing to pay the price; but although development has been rapid there is still a long way to go—a fact not generally realized. Airship development, handicapped inherently by the large units involved, has been further restricted by the very limited number of organizations actively interested. The recently demonstrated Metalclad airship (built by the Detroit Aircraft Corporation for the U. S. Navy) is a significant step, but it is only a step, as it will have to be developed to much larger sizes to be commercially available.

With all the present interest in aircraft production and operation, it is to be hoped that more people will realize the dominating importance of continuing research and development along sound engineering lines, which may as well be called sound business lines, because it is the kind of business on which the entire future of the industry depends.

Appendix

Lift and Drag of Airship Hulls. Assume hydrogen gas with a mean unit lift of 0.065 lb. per cu. ft.; then the gross lift $L = 0.065$ vol. From miscellaneous tests in the N.A.C.A. variable density tunnel, the drag coefficient of the best airship hull may be closely approximated for varying size and speed by the formula:

$$C_s = 0.222R^{-0.15}$$

where R is the Reynolds number $= 9330\, v\, \text{vol.}^{1/3}$; v = speed in miles per hour; vol. is in cu. ft.

Then the actual drag

$$D = C_s\, q\, \text{vol.}^{2/3}$$

$$= 0.000144\, \text{vol.}^{0.617}\, v^{1.85}$$

Then $L/D = \dfrac{450\ \text{vol.}^{0.383}}{v^{1.85}}$

Lift and Drag of Airfoils. The general formula[3] for airfoil drag coefficient is:

$$C_D = (0.007 + 0.1t^2)\,(1 + 0.8C^2_L) + \frac{C^2_L(1 + \delta)}{\pi\, n}$$

where t is the thickness ratio; n is the aspect ratio; δ averages about 0.04.

The foregoing is for a Reynolds number of about 3,500,000.

For large changes in size, it is probable that the first coefficient (0.007), and perhaps the entire first term, should be taken to vary as $R^{-.15}$, the skin friction factor. Also, to keep on a comparative basis with airship hulls, either the wing loading W/S or the structural ratio n/t, or both, must be varied in such a way as to keep corresponding proportions of structural weight with increasing size.

If the beam-flange weight longitudinals w is taken as the criterion, it may be easily shown that for airship $w \propto W^{4/3}$, where W is the gross weight or lift; and for airplanes $w \propto W\,\dfrac{b^2}{a} \propto W\,\dfrac{n}{t}\sqrt{Sn}$, where b is the span and a is the effective wing depth.

Then if the airplane w is to vary as airship w, for equal gross weight, the condition is:

$$\frac{W}{S}\,\frac{n^{3/2}}{t}\,S^{3/2} = W^{4/3}$$

where the wing loading $\dfrac{W}{S} = \dfrac{v^2 C_L}{391}$ (v in miles per hour).

If C_L is assumed constant, this reduces to:

$$v^2\,\frac{n^{3/2}}{t}\,S^{3/2} \propto W^{4/3}$$

Even allowing for the decreased skin friction of larger sizes and a small allowance for decreased load factors and improved load distribution, the resulting L/D curve is still found to drop slightly with increasing size. Hence, it seems preferable to make the comparison on the basis of a fixed, constant L/D for airfoils. As shown,[3] the maximum L/D of "structural airfols," cantilever type, will run from about 25 to a maximum of probably 32, depending on the degree of taper and general structural efficiency.

Comparison of Airfoils and Airship Hulls. Taking for further study an airplane L/D of 30 as definitely attainable, the dividing point then between airplanes and airships will be for conditions which make the airship L/D equal to 30, or

$$v^{1.85} = 15\ \text{vol.}^{0.383}$$

from which

$$v(\text{miles per hour}) = 4.33\ \text{vol.}^{0.207}$$

This is plotted in Fig. 1.

Assume 10 per cent of the gross lift devoted to fuel = F (exclusive of reserve). Then $F/D = 3$.

Let distance = x (miles). As one hp-hr. = $33{,}000 \times 60 = 1{,}980{,}000$ ft-lb.

Fuel consumption $= \dfrac{0.5}{0.75 = 1{,}980{,}000}$ lb. per ft-lb.

assuming 0.5 lb. per hp-hr. and 0.75 propeller efficiency; then the total fuel $= F = 3D = \dfrac{5280Dx \times 0.5}{0.75 \times 1{,}980{,}000}$

or

$$x = \frac{3 \times 0.75 \times 1{,}980{,}000}{5280 \times 0.5} = 1690 \text{ miles, or } 1130 \text{ miles if } L/D = 20.$$

AER-52-24

Practical Airplane Performance Calculations

By DR. MICHAEL WATTER,[1] HARTFORD, CONN.

A design must meet the characteristics set forth in the specification if it is to warrant construction. Performance characteristics represent a most important requirement, and there are today many methods and theories of performance calculation.

The conclusion was reached to obtain simplicity even at the cost of scientific accuracy, so long as the calculations gave a correct answer. The method described is based on the evaluation of parasite resistance, wing or cell characteristics, and knowledge of engine-propeller behavior. It is intended for routine calculations, but may be extended for special cases.

TO FULFIL its purpose and to justify its construction, any given design must meet the characteristics set forth in the specification. This specification may represent the requirements of the customer or the objective which the designer must meet in order to compete successfully with other similar types in existence or in course of construction. The performance characteristics represent one of the most important requirements of an aircraft, and it is not surprising, therefore, that there are today numerous methods and theories of performance calculation. While accuracy is of paramount importance, the time factor cannot be ignored, because in a number of instances the designer is required to supply this information in comparatively short time and also to be able to revise the data for small changes in design which may be specified or found desirable. As there have been several excellent methods evolved, and numerous papers have been written on various problems of performance calculations, it therefore is with a certain hesitation that the author presents this paper.

The long-debated problems of slipstream effect, influence of the Reynolds number, coordination of wind-tunnel and free-flight data, as well as recent tests in the N.A.C.A. density and 20-ft. wind tunnels, were considered by the author. The conclusion was reached to obtain simplicity even at the cost of scientific accuracy, so long as the calculations gave a correct answer. In engineering investigations this is an age-long procedure, since all know that most of the structural problems are treated in exactly this way. The problem of strength of beams is solved by assuming that the relationship of

$$M = EI \frac{d^2y}{dx^2}$$

holds true past the elastic limit of the material, which while not being scientifically correct leads to a very easy and accurate way of proportioning the beam sizes by use of experimental values of allowable fiber stresses. Similarly, when confronted with the complexity of the aerodynamic phenomenon which takes place in flight, it is almost hopeless to attempt to evaluate all the mutual interactions and interferences when one considers how comparatively little is known of the individual behavior of wings, parts having parasite resistance, propeller and engine unit, etc.

Brief Summary of the Method

The method described is based on the evaluation of parasite resistance, wing or cell characteristics, and knowledge of engine-propeller behavior. It is intended for routine practical performance calculations, but can be extended for special cases and evaluation of influence of small changes in design.

Certain coefficients and laws of variation of resistance with change in angle of attack were obtained by the author from back-figuring the actual free-flight test of airplanes the characteristics and design of which were known. Other coefficients were obtained from different sources, and credit is given in the text.

In order to make a performance calculation, it is necessary to have the three-view drawing of the airplane, with sizes and shapes of the fuselage, hulls, floats, nacelles, engine, and radiators, and information in regard to struts, wires, wheels, armament, type of fittings, and as many of the details as it is practical to obtain—the brake-horsepower curve versus the revolutions per minute of the engine, the isolated wing characteristics, arrangement of the wing cell, and the following general data:

VL at which the isolated parts were tested
Cross-sectional areas of parts having parasite resistance
Areas of the wings
Gap
Stagger
Sweepback
Decalage
Spans
Chords
Angles of fixed incidence
Area of horizontal tail
Horizontal tail setting (can be assumed from available data)
Vertical tail area
Gross flying weight
Amount of fuel carried

The performance calculation usually consists in obtaining the following data:

Maximum speeds at sea level and specified altitudes
Stalling speed at sea level and specified altitudes
Service ceiling
Rate of climb at sea level and specified altitudes
Climb in 10 minutes
Time to climb to various altitudes
Best speeds of climb
Endurance at full throttle
Range at full throttle
Endurance at maximum range
Range, maximum

Assumptions

Before proceeding with the detailed description of the method, it will not be amiss to state and to justify certain omissions and simplifications used.

---

[1] Design Engineer, Chance Vought Corporation. Dr. Watter was educated at the Polytechnic Institute of Riga, the Imperial Technical Institute of Moscow, Russia, and received the degree of D.E. from the Royal Polytechnic Institute of Turin, Italy, in 1921. Upon coming to this country in that same year he entered the employ of the Curtiss Aeroplane & Motor Corporation at Garden City, L. I., remaining with that concern for two years. He resigned to become associated with the Chance Vought Corporation at Long Island City, with which concern he is at present connected.

Presented at the Fourth National Aeronautic Meeting, Dayton, Ohio, May 19 to 22, 1930, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

It was a standard practice in the past to take into account the slipstream effect, and certain well-known and authoritative books on aerodynamics give various methods of evaluating the influence of slipstream. The author, however, always has believed that the inclusion of the slipstream effect in performance calculations leads to an unnecessary complication without adding to the accuracy of results, as it, if anything, increases the chances of possible errors. In an article entitled "Slipstream Effect" which appeared in the February, 1928, issue of *The Aero Digest*, the author reviewed the suggested corrections for slipstream effect from a few representative articles. The following statements and conclusions are taken from that article:

The opinions of the experts on the subject are far from unanimous; the inclusion of slipstream effect in performance analysis is considered by some as indispensable for any degree of accuracy, by others as desirable for greater accuracy, while still others think it superfluous because of other uncertainties and assumptions used in theoretical calculations.

There are a few points on which all seem to agree:

(1) The slipstream effect introduces an error in level-flight analysis of such small magnitude as to be negligible.

(2) With the usual engine-propeller group, the maximum speeds can be predicted with the desired degree of accuracy neglecting the slipstream effect.

(3) The slipstream effect causes comparatively greater error in climb. The magnitude of this error, however, is difficult to ascertain, and there are other factors which may influence the analysis and yet be confused with the slipstream effect.

The slipstream effect can be considered as mutual interaction of the objects in the slipstream and the propeller proper. This mutual interaction must be considered as a play of internal forces resulting in changed condition of flow and propeller behavior and can be taken as consisting of two effects:

(1) Propeller-slip effect due to increased velocity of the air after it passes the propeller disk. The result of this is an increase in forces on the objects which are in the propeller's slipstream. This effect, however, cannot be evaluated by the customary law of V^2 for the reason given below.

(2) Obstruction effect. Since the propeller is not working in an unobstructed air, the objects in its slipstream have an effect equivalent to slowing the air down.

It must be remembered, however, that since the slipstream effect is an internal phenomenon, the final effect should be judged by combining (1) and (2).

Conclusions. There is a great deal more of experimental data and theoretical investigation published on the subject, but it is hoped that the material reproduced will bring forth some of the more important questions; namely: (1) the complexity of the problem, (2) absence of a satisfactory theoretical solution, (3) variation in experimental results. These points alone would not justify to disregard the slipstream, but the importance of the problem be rather weighed on the basis of quantitative considerations. Since it seems to be agreed by every one that the slipstream effect has little importance for level-flight condition, the problem is limited to the climbing speeds alone. Part of the resistance usually affected by the slipstream (fuselage, engine, radiators, landing gear, struts, wires, etc.) for small angles of attack constitutes 35 to 55 per cent of the total drag, while at climbing angles the drag of the wings becomes predominating, and that part of the parasite resistance seldom exceeds 35 per cent of the total drag of the machine. This explains why even a comparatively large error which the experiments do not seem to reveal would have considerably smaller importance when one considers complete drag of the airplane. Taking into consideration other numerous uncertainties, such as mutual interferences, assigned resistance coefficients, VL effect, propeller characteristics, brake-horsepower of the engine, etc., it seems that undue importance is stressed for the slipstream correction. It would seem that the same end, greater accuracy of results, can be achieved in case of standard designs by using proper values of parasite resistance and by assuming such a law of variation of the parasite resistance with change in angle of attack as to compensate for the probable error due to neglected slipstream effect.

Incidentally, this method reduces the difficulties to assigning proper resistance coefficients and a certain law of variation of parasite resistance, while an attempt to correct for slipstream involves further assumptions as to what expression to use for R/Ro and what is the magnitude of the obstruction effect.

It may be added that in climb the slipstream effect is further offset by the presence of the upward component of thrust, which at times, for airplanes capable of steep climbing angles, is somewhat appreciable. In view of the foregoing, this is also disregarded in the present method of performance calculations.

Characteristic Curves, Airplane Polar

Evaluation of airplane characteristics constitutes the most important part of the performance estimate, requiring not only knowledge but judgment as well. At this place it may be stated that the method described in this paper is fundamentally a wind-tunnel method. Because of the author's wind-tunnel experience, combined with performance calculations based on atmospheric wind-tunnel airplane characteristics, it was thought best to attempt to obtain a close agreement between calculated and tested polars. In addition to being a convenient result of author's experience, this method of approach was considered desirable also because it led to a unified method of performance calculation, whether based on theoretical calculations or wind-tunnel tests, and also the accuracy of the preliminary performance of a new design could be judged by how well the calculated polar checked the one obtained from a wind-tunnel model in later stages of the design.

The calculation of characteristics of an airplane consists in the following:

(1) Cell or wing characteristics from wind-tunnel data on isolated airfoil of standard aspect ratio.

(2) Estimate of parasite resistance.

(3) Variation of parasite resistance with change in angle of attack.

(4) Resistance due to horizontal tail area—may be included in (3).

(5) Lift, drag, and L/D on full-size model at 1 m.p.h.

Wing or Cell Characteristics

For the best results, it seems desirable to use characteristics of an isolated airfoil tested at or reduced to a $VL = 25$ to 30 (where V is expressed in feet per second and L in feet). This is equivalent to the standard size of airfoils (5 in. by 30 in. or 6 in. by 36 in.) tested at 40 m.p.h. For 7-ft. or larger wind tunnels the wall effect can be disregarded. Should the model be tested at a different VL, the experimental data must be corrected, and for this purpose one may use the following formulas obtained by Diehl:

Drag Coefficient Correction:

$$C_{D_2} = C_{D_1} - C_{D_m}\left[1 - \left(\frac{V_2L_2}{V_1L_1}\right)^{-0.18}\right]$$

where C_{D_1} = the drag coefficient at a given angle of attack and V_1L_1

C_{D_m} = the minimum drag coefficient at V_1L_1

C_{D_2} = the drag coefficient at the same angle of attack and V_2L_2

Lift Coefficient Correction:

$$C_{L_2} = C_{L_1} + 0.114 \log_{10}\left(\frac{V_2L_2}{V_1L_1}\right)$$

where C_{L_1} = the lift coefficient at V_1L_1 for the particular angle of attack under consideration.

The foregoing formula refers to absolute coefficients, and in engineering units it becomes

$$K_{y_2} = K_{y_1} + 0.000292 \log_{10}\left(\frac{V_2L_2}{V_1L_1}\right)$$

The use of these formulas is limited to a comparatively small range of VL.

Having reduced the characteristics of isolated airfoils to the same VL and which VL lies within the range of 25 to 30 suggested, one may correct the wing characteristics for aspect ratio, interferences, and arrangement. Corrections for interferences, while of the utmost importance, can be estimated only approximately on the basis of tests on similar arrangements, while those due to the aspect ratio and biplane arrangement can be made with considerable accuracy by any of the known methods.

Aspect Ratio Correction. Monoplane correction is made for change in induced drag and induced angle of attack for a given lift coefficient.

Aspect ratio $= S/b^2$, where S is the area and b the span

$C_{L_1} = C_{L_2}$

$$C_{D2} = C_{D1} + \frac{C_L^2}{\pi}\left[\frac{S_2}{b_2^2} - \frac{S_1}{b_1^2}\right]$$

$$\alpha_2 = \alpha_1 + \frac{57.3C_L}{\pi}\left[\frac{S_2}{b_2^2} - \frac{S_1}{b_1^2}\right]$$

where subscripts (1) and (2) denote the two aspect ratios.

Biplane (Diehl). In case of a biplane, the aspect ratio can be expressed as

$$\frac{S}{(Kb_1)^2}$$

where K is a certain coefficient variable with gap-to-span ratio, the ratio of spans, and distribution of wing areas.

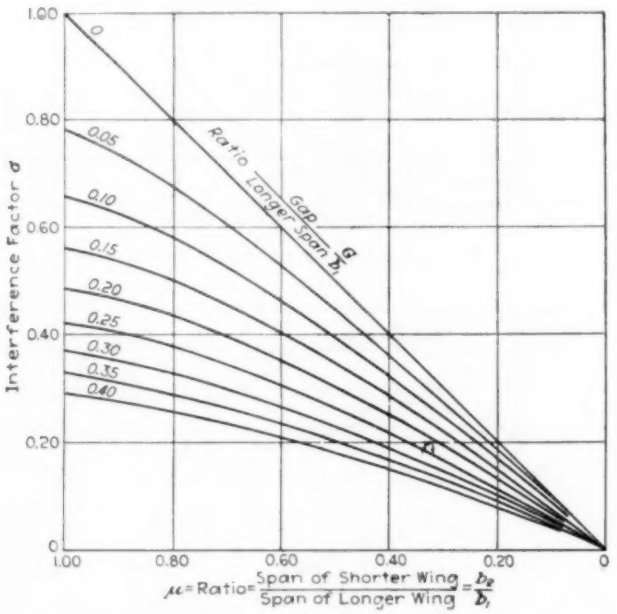

FIG. 1 PRANDTL'S DRAG INTERFERENCE FACTOR FOR BIPLANES IN TERMS OF MAXIMUM SPAN

Denoting:

b_1 = span of longer wing
b_2 = span of shorter wing
μ = b_2/b_1 = ratio of shorter span to longer
$L_1 \cong S_1$ = lift or area of longer wing
$L_2 \cong S_2$ = lift or area of shorter wing
L = $L_1 + L_2 = S_1 + S_2$ = total lift or area
G = interference factor

Then K may be expressed as

$$K = \left[\frac{\mu^2}{r^2(\mu^2 - 2\mu\sigma + 1) + 2r(\mu\sigma - 1) + 1}\right]^{\frac{1}{2}}$$

where $r = S_1/(S_1 + S_2)$ and σ can be obtained from Fig. 1. A more detailed explanation of the induced drag of multiplanes and calculations of equivalent monoplane aspect ratio can be found in Diehl's book, "Engineering Aerodynamics." Appendix 1 gives Diehl's curves, which facilitate finding of K.

Biplane Correction. In case of a biplane cell it is necessary to take into account the mutual interference of airfoils, and there are several excellent methods available. For a detailed discussion the reference is made to the National Advisory Committee Technical Report No. 151, "General Biplane Theory," by Max M. Munk, and "Engineering Aerodynamics," by Walter S. Diehl.

Munk's Method. Dr. Munk's method consists in evaluating the characteristics of a biplane cell by correcting the drag of an isolated wing because of additional induced drag and changing

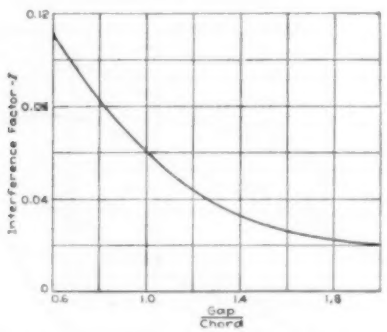

FIG. 2 MUNK'S INTERFERENCE FACTOR FOR INDUCED ANGLE OF ATTACK

the angle of attack by the amount of the induced angle of attack and the additional interference angle of attack.

$$C_{LB} = C_{Lm}$$

$$C_{DB} = C_{Dm} + \frac{C_L^2}{\pi}\left[\frac{S_B}{(Kb)^2} - \frac{S_m}{b^2_m}\right]$$

$$\alpha_B = \alpha_m + \frac{57.3C_L}{\pi}\left[\left(\frac{S_B}{K^2b^2} + I\right) - \frac{S_m}{b^2_m}\right]$$

where I is the interference factor (see Fig. 8).

In the foregoing formulas S/K^2b^2 is the equivalent monoplane aspect ratio for a given biplane. The coefficient K is obtained as explained.

BIPLANE AND TRIPLANE CORRECTION

The literature on triplane and multiplane correction is scarce, and although there does not appear to be any particular need for it, it seems advisable to present briefly a method of biplane and triplane correction evolved by H. Blasius and H. Hamburger which appeared in *Technische Berichte*, Vol. 2, part 2, 1918.

In the author's experience, the Blasius and Hamburger method proved quite helpful for cases of cells with decalage, and on two occasions when this method was used the calculated characteristics of the airplane were confirmed with surprising accuracy by wind-tunnel tests.

The fact that the numerical coefficients are based on profiles tested back in 1917–1918, which are somewhat different from the profiles used today, does not detract from the value of the method, because quantitative discrepancy is not great.

Biplane Formulas:

C_{LU}, C_{LL}, C_{DU}, C_{DL} = lift and drag coefficients, the second subscript indicating upper or lower wing
ΔC_{LU}, ΔC_{LL}, ΔC_{DU}, ΔC_{DL} = the change in coefficients resulting from the mutual interference

C_L, C_D = lift and drag coefficients of the cell
S_U, S_L = wing areas
b_U, b_L = spans
t_U, t_L = chords
G = gap
α_U, α_L = angles of attack (referred to undisturbed air)
β = stagger in degrees

Formulas:

$$\Delta C_{LU} = \frac{C_{LL} l_L}{b_U} \frac{(b_U + b_L)}{2G} \varphi_{LU}$$

$$C_{LL} = \frac{C_{LU} l_U}{b_L} \frac{(b_U + b_L)}{2G} \varphi_{LL}$$

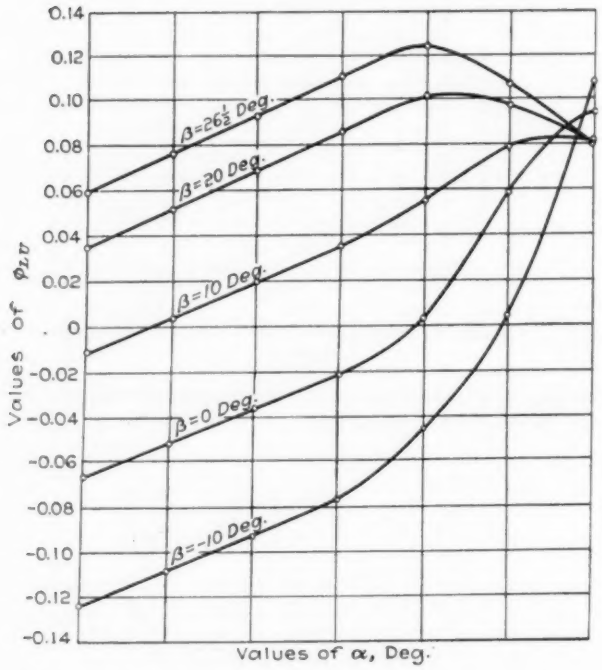

FIG. 3 VALUES OF φ_L FOR BIPLANES

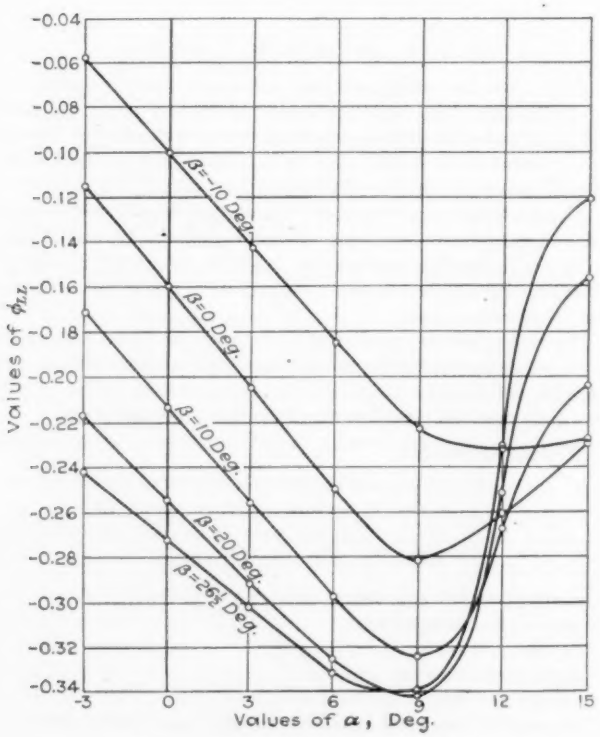

FIG. 4 VALUES OF φ_L FOR BIPLANES

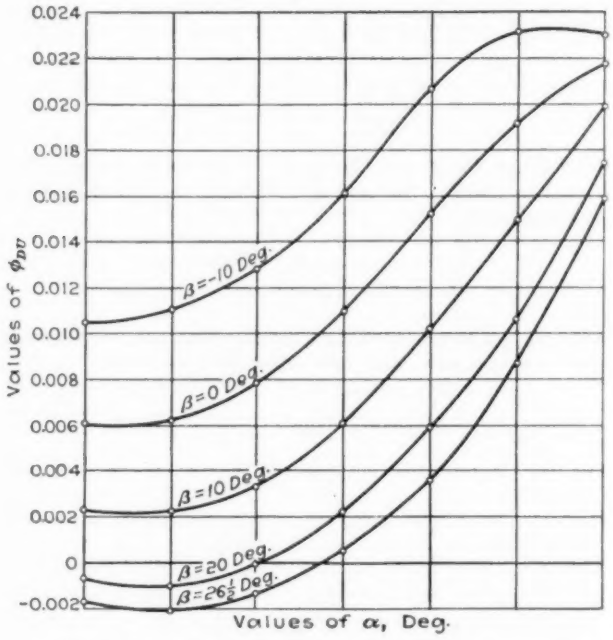

FIG. 5 VALUES OF φ_D FOR BIPLANES

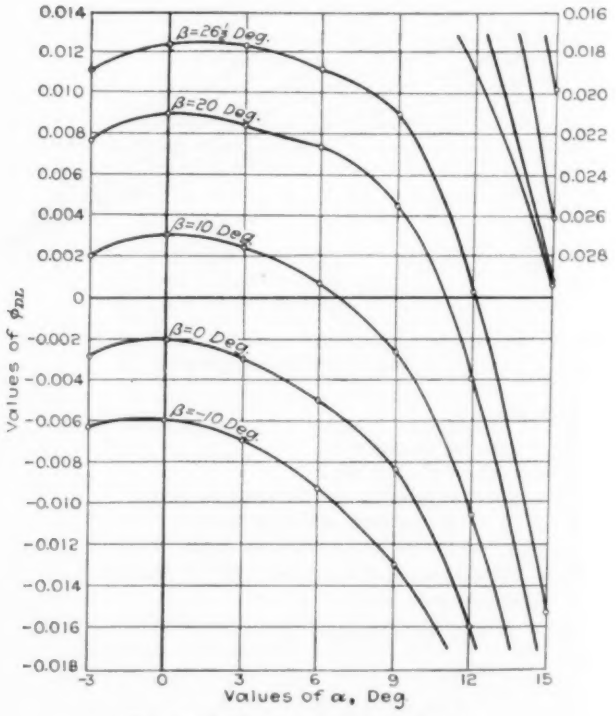

FIG. 6 VALUES OF φ_D FOR BIPLANES

$$\Delta C_{DU} = \frac{C_{LL} l_L}{b_U} \frac{(b_U + b_L)}{2G} \varphi_{DU}$$

$$\Delta C_{DL} = \frac{C_{LU} l_U}{b_L} \frac{(b_U + b_L)}{2G} \varphi_{DL}$$

The coefficients φ are functions of the cell arrangement and the angle of attack of the wing under consideration (see Figs. 3, 4, 5, and 6).

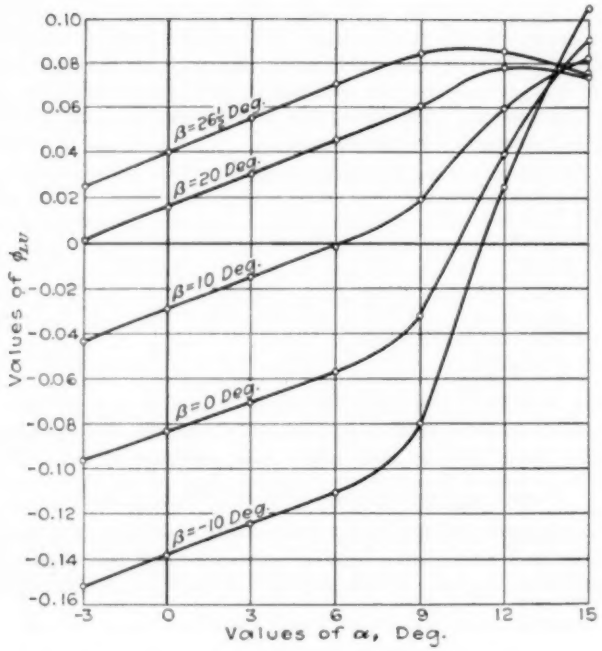

FIG. 7 VALUES OF φ_L FOR OUTER WINGS OF A TRIPLANE

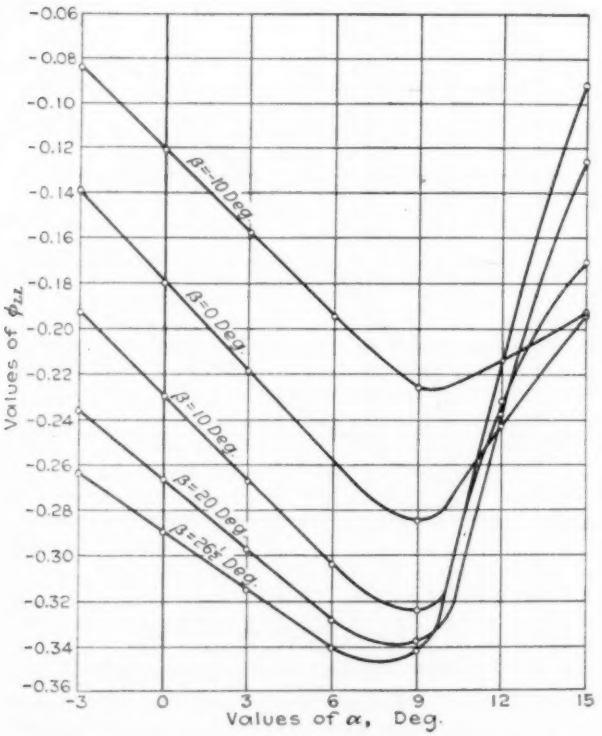

FIG. 8 VALUES OF φ_L FOR OUTER WINGS OF A TRIPLANE

$$C_L = \frac{S_U(C_{LU} + \Delta C_{LU}) + S_L(C_{LL} + \Delta C_{LL})}{S_U + S_L}$$

$$C_D = \frac{S_U(C_{DU} + \Delta C_{DU}) + S_L(C_{DL} + \Delta C_{DL})}{S_U + S_L}$$

Triplane. In case of a triplane the subscripts U, M, L refer to upper, middle, and lower wings, respectively. The interference of the upper and middle wing and middle and lower wing can be accounted for as in the case of biplane, but in addition one must take into account the interference due to the presence of the third wing. For example, in order to calculate the change in the characteristics of the middle wing, one must use the diagrams for the biplane and take into account the change due to the presence of the upper and lower wings, while in order to calculate the change in characteristics of the lower wing, one finds the change due to the middle wing from the biplane charts and the change due to the presence of the upper wing from the chart for the "outer wings of a triplane." Re-

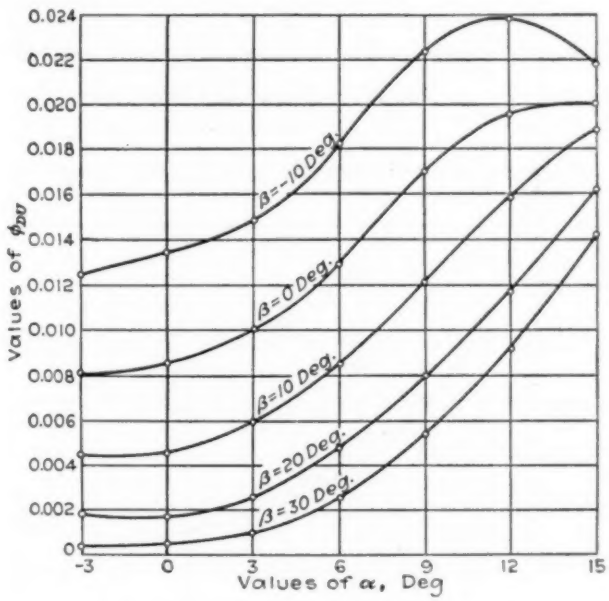

FIG. 9 VALUES OF φ_D FOR OUTER WINGS OF A TRIPLANE

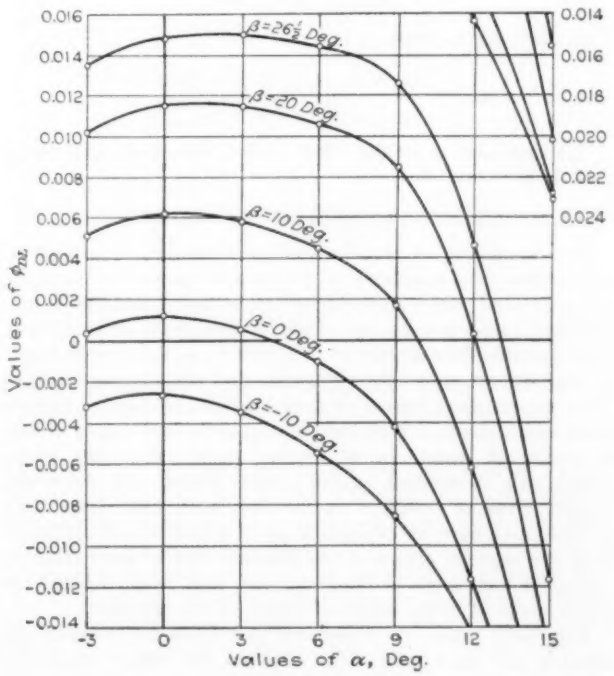

FIG. 10 VALUES OF φ_D FOR OUTER WINGS OF A TRIPLANE

taining the notations, as given, and using the subscripts to indicate the wing, one would have in this case

$$\Delta C_{LM} = \frac{C_{LU} t_U (b_U + b_M)}{b_M \quad 2G_{UM}} \varphi_{LL} \text{ (for } \alpha_M \text{ and } \beta_{UM})$$

$$+ \frac{C_{LL} t_L (b_M + b_L)}{b_M \quad 2G_{ML}} \varphi_{LU} \text{ (for } \alpha_M \text{ and } \beta_{ML})$$

$$\Delta C_{DL} = \frac{C_{LU} t_U (b_U + b_L)}{b_L \quad 2G_{UL}} \varphi_{DL} \text{ (for } \beta_L \text{ and } \beta_{UL})$$

$$+ \frac{C_{LM} t_M (b_M + b_L)}{b_L \quad 2G_{ML}} \varphi_{DL} \text{ (for } \alpha_L \text{ and } \beta_{ML})$$

The total change in the lift coefficient of a triplane would be

$$\Delta C_L = \frac{S_U \Delta C_{LU} + S_M \Delta C_{LM} + S_L \Delta C_{LL}}{S_U + S_M + S_L}$$

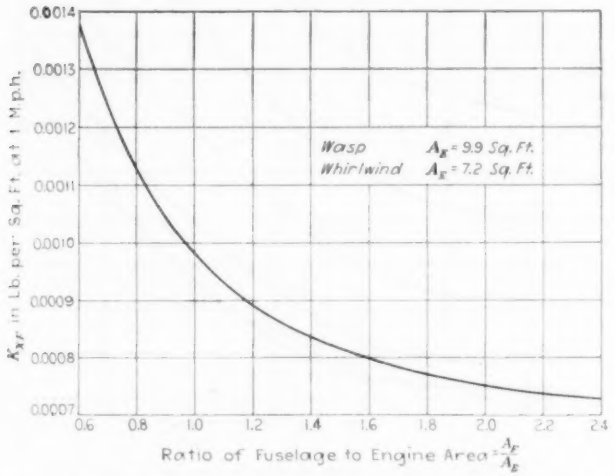

FIG. 11 DRAG COEFFICIENT OF FUSELAGE AND NACELLES OF AIR-COOLED ENGINES

Similarly for the drag

$$\Delta C_D = \frac{S_U \Delta C_{DU} + S_M \Delta_{DM} + S_L \Delta C_{DL}}{S_U + S_M + S_L}$$

The coefficient φ for the effect of the outer wings is given in Figs. 7, 8, 9, and 10.

CALCULATION OF PARASITE RESISTANCE

The calculation of parasite resistance consists in evaluating and adding the resistance of component parts. It must be borne in mind that a mere mechanical addition would be hardly sufficient, and a due account of interference and mutual shielding must be taken into account. It is hard to give any precise rule in that respect, and only experience and wind-tunnel observations may suggest means of taking it into account. Another point which should not be lost sight of is the importance of flow deviation on resistance of certain parts. Radiators under bodies, axle streamlines, engine nacelles placed near the wings, certain types of fuselages in the downwash from large wing surfaces may have an effective angle of attack entirely different from the angle of attack of the airplane, and in some cases no change in their angle to the actual flow may result through the whole range of flying angles of attack of the airplane.

This point must be considered in calculating parasite resistance, and since no rules can be given, the designer must rely on his judgment.

A word of caution is necessary also in regard to so-called streamline struts: some struts, but very few, conform to the best type of streamline strut known, and one must bear in mind the type actually used in assigning the resistance coefficients.

The following list contains parts usually included by the author in calculating the parasite resistance:

Fuselage and engine (when a unit)
Engine nacelles
Radiators
Floats
Hulls
Struts
Wires
Wheels
Tail skid or tail wheel
Armament
Tail surfaces
Interference and miscellaneous

At times other parts must be included such as landing lights wing flares, flotation gear, bomb racks, and bombs, etc.

FUSELAGE; OPEN COCKPIT; WATER-COOLED ENGINES

Fuselages with well-cowled water-cooled engines, well streamlined, and no radiator have a resistance coefficient of about, 0.00045 lb. per sq. ft., but ordinary types would be closer to

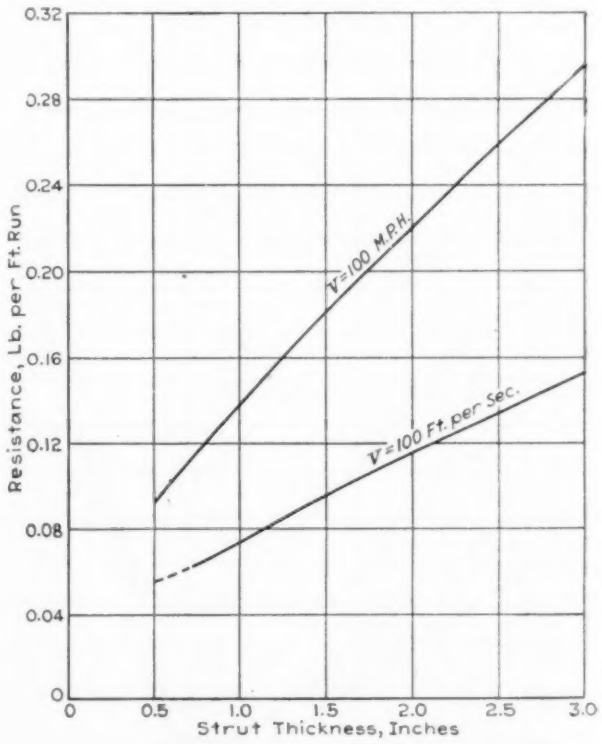

FIG. 12 DRAG PER FOOT AT 100 MILES PER HOUR

0.00060 to 0.0007. Military two-seater types with comparatively clean lines would have a coefficient of about 0.00055 to 0.00060. If no spinner is present, the lines of necessity are not as clean, and about 5 per cent must be added for the loss of proper streamlining. In case of a nose radiator the resistance of the body must be increased about 30 to 35 per cent.

CABIN; WATER-COOLED ENGINES

The resistance of comparatively well-streamlined cabin airplanes without radiator can be taken as 0.0004 for the lower limit and as an average figure of 0.0005 lb. per sq. ft.

Engine Nacelles; Water-Cooled Engines

In general the drag coefficient of an engine nacelle is very close to that of a fuselage, and the increase due to the presence of a nose radiator is from 30 to 40 per cent. When, however, the engine nacelle is located above the wing, the drag coefficient must be increased about 50 per cent to account for the interference. In case of the engine being located under the wing, this correction is less and may be taken as about 20 per cent.

It must be understood that the foregoing figures are only approximate and are not based on any definite test and that in individual cases the discrepancy may be considerable. On an average, however, they will be found sufficiently accurate.

Fuselages and Nacelles; Air-Cooled Engines

In order to obtain the data on resistance of fuselages and nacelles with air-cooled engines, the author analyzed several airplanes the performance and design characteristics of which were known to him, and using the present method of performance calculations obtained the resistance due to the engine-body and engine-nacelle units. The resistance coefficient is plotted against the ratio of maximum cross-sectional area of the body to the total area of the engine and may be used for nacelles, open cockpit fuselages, and cabins. If no spinner is present, a 5 per cent correction may be applied.

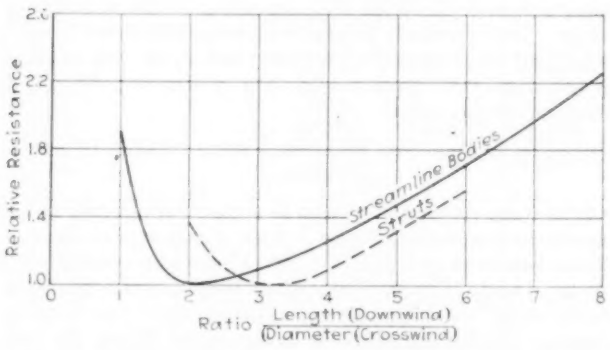

Fig. 13 Variation of Drag Coefficient With Fineness Ratio for Struts and Streamline Bodies

These data apply to the comparatively well-streamlined bodies, and in case of irregular shapes the coefficient would have to be revised, taking into account the fact that the resistance of an air-cooled engine can be considered as resistance proper plus interference. For poor-streamlined shapes the interference resistance would be decreased, but the drag of the body proper would be increased.

Floats. The average resistance of a well-streamlined but not a special racing float would be in the neighborhood of 0.00045 to 0.0005, while an average float and a deep hollow V-bottom float would have a resistance of 0.00055 to 0.0006 lb. per sq. ft. Wing-tip floats well-streamlined would be 0.00035. Wing-tip floats average 0.00055 and as high as 0.0007.

Hulls. The hull resistance coefficient varies from 0.0004 to 0.00065, but for an average hull one may use 0.00055 lb. per sq. ft.

Radiators. Free air radiator would be 0.0018 to 0.0022. A good average figure is 0.0020. In estimating the resistance of a free-air radiator one must give consideration to the possible flow deviation, interference between the radiator and the member of the chassis, etc.

Struts (Diehl). The lowest recorded drag coefficient was obtained on Navy strut No. 1, the offsets for which are given in Table 1 and the resistance in Figs. 18 and 19. For commercial shapes the resistance must be increased about 20 per cent.

Tail Skid or Tail Wheel. The average resistance is 0.0004 to 0.0005. In general the resistance can be approximately calculated when the design is known.

Armament. No definite data are available with exception of a flexible machine gun with a scarf mount, lined fore and aft. Diehl gives the resistance as 0.002 V^2; broadside the coefficient is increased about 50 per cent.

Tail Surfaces. In order to obtain the resistance of tail surfaces one may calculate separately the resistance of vertical tail surfaces, and having calculated the effective angle of attack of the horizontal tail to calculate its resistance. This refinement is, however, unnecessary because of the average error involved in assumed variation of parasite drag with change in angle of attack. It is best to include the resistance of the total tail area in the parasite drag calculation and assume a variation in parasite which would take care of this inclusion. The following, however, are various downwash formulas which seem to give a good agreement with downwash actually observed in the wind tunnel:

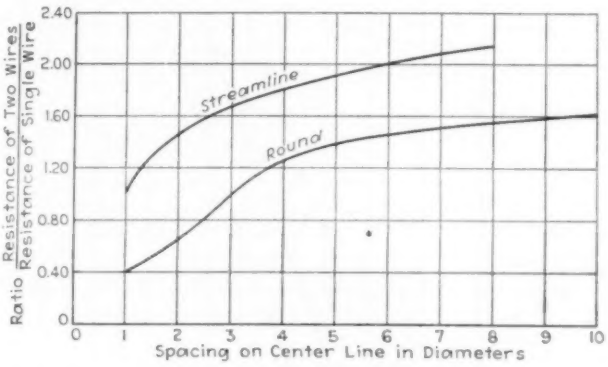

Fig. 14 Effect of Fore-and-Aft Spacing on the Drag of a Pair of Wires

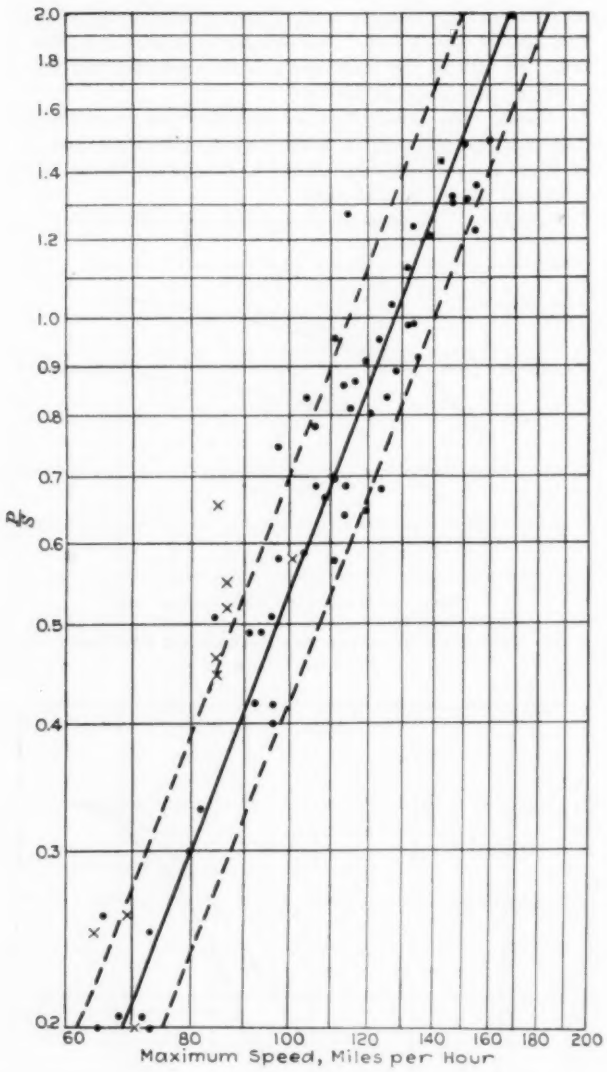

FIG. 16 DERIVATION AND TRIAL OF MAXIMUM-SPEED FORMULA

AVERAGE TAIL CHARACTERISTICS FOR AN ASPECT RATIO OF 3.

$\alpha°$	K_y	K_x
0	0	0.0000400
2	0.00032	0.0000412
4	0.00064	0.0000447
6	0.00096	0.0000505
8	0.00126	0.0000595
10	0.00160	0.0000722
12	0.00185	0.0000895
14	0.00210	0.0001120

Downwash (Diehl).

$$\epsilon = \frac{85C_L}{(K^2b^2/S)}\,(X+1)^{-0.38}(y+1)^{-0.23}$$

where x is the distance behind the trailing edge, y the distance above or below the chord measured in chord length.

Downwash (Warner). For the average tail location on the basis of the foregoing formula Warner suggests the following average expression:

$$\epsilon = \frac{36\,C_L}{(K^2b^2/S)}$$

Downwash (Föppl). The formula which from the author's experience seems to give a very good result is the one given by Föppl with slightly modified coefficients:

$$\epsilon° = \frac{C_{LU}}{2\pi}\,57.3\,\frac{t_U}{b_U}\left[1+\sqrt{1+\left(\frac{b_U}{2x_U}\right)^2}\right] + \frac{C_{LL}}{2\pi}\,57.3\,\frac{t_L}{b_L}\left[1+\sqrt{1+\left(\frac{b_L}{2x_L}\right)^2}\right]$$

where x is the horizontal distance between the trailing edge of the respective wing and the leading edge of the tail.

Downwash (Vedroff). The formula recommended by Vedroff and based on an analysis of wind tunnel experiments is:

$$\epsilon° = \frac{2.9C_L}{\pi(k^2b^2/S)}\,57.3\left[1+\left(\frac{b}{4x}\right)^2\right]$$

where x is the distance from $^1/_3$ of the chord to the point in question.

Interference and Miscellaneous

Inasmuch as it is practically impossible to account for the drag of minor parts and interference between different parts, their effect can be taken into account by increasing the total parasite from 10 to 15 per cent, depending on the cleanness of design. For a carefully streamlined design the effect of small projections and irregularities is larger, and 15 per cent increase always gave very good results. For a standard design 10 per cent would suffice.

Variation of Parasite Resistance With Change in Angle of Attack

It has been customary at times to neglect the variation of the parasite resistance with change in angle of attack or to separate this resistance in two groups of which, one was variable with change of angle of attack while the second one, usually including struts, wires, air-cooled engines, radiators, etc., was taken as constant through the range of flying angles. While the first assumption is unquestionably erroneous, the second will be found somewhat complicated, since the increase in drag may not be due directly to increase of resistance of individual parts, but rather to an increase in mutual interaction and interferences.

The author believes that it is best to assume the whole parasite resistance as variable with angle of attack, this increase being

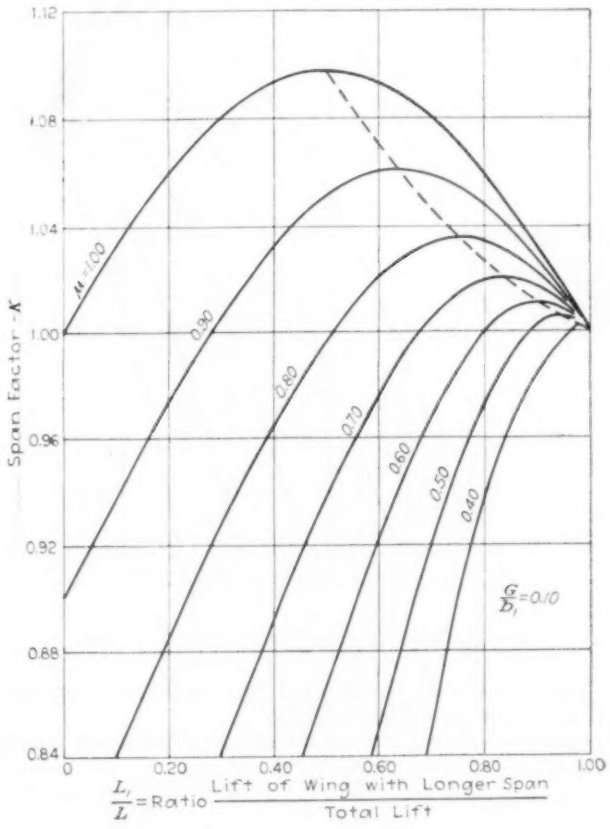

FIG. 19 MUNK'S SPAN FACTOR k FOR $\frac{G}{b_1} = 0.10$

a function of the angle of attack rather than a function of speed range. This increase is individual for different types of airplanes.

The angle of attack in this case is referred to the thrust line of the airplane and not to the wing chord. In view of a somewhat different behavior of floats and hulls, it seems that it is best to assume a different law of variation of parasite resistance of the latter, and consequently two curves of variation are given.

Parasite resistance versus angle of attack (excluding floats and hulls):

$\alpha°$	D/D min.
− 8	1.28
− 6	1.12
− 4	1.04
− 2	1.01
0	1.00
2	1.03

16	1.82
18	2.25
20	3.04

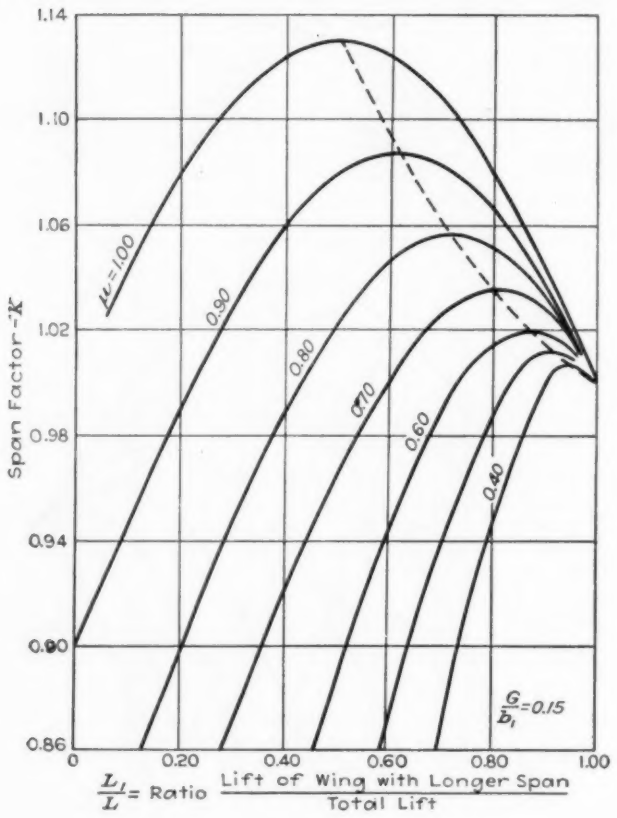

FIG. 20 MUNK'S SPAN FACTOR k FOR $\frac{G}{b_1} = 0.15$

This is an average variation and may vary about 15 per cent on either side for different designs.

Resistance of floats and hulls versus angle of attack (Diehl, N.A.C.A., T.R., No. 236):

$a°$	D/D min.
− 8	1.30
− 6	1.10
− 4	0.95
− 2	0.97
0	1.00
2	1.15
4	1.30
6	1.55
8	1.85
10	2.30
12	2.80
14	3.40
16	4.10
18	4.75
20	5.50

CHARACTERISTIC CURVES; LIFT, DRAG, AND L/D

Having the corrected characteristics of the wing or the cell and parasite resistance against angle of attack, it is possible now to obtain the lift drag and L/D of the full size machine at 1 mile per hour. The summation or resistance is done taking into account the fixed incidence of the wing, since the angle of attack of the parasite resistance is referred to the thrust line and not to the wing chord.

PERFORMANCE CALCULATION

Knowing the characteristic curves of the airplane, it is possible now to proceed with the calculation of the theoretical flight characteristics and general performance of the craft. It is necessary, first, to obtain the horsepower available and horsepower required, the knowledge of which will permit of calculating the maximum and minimum speeds, best speeds to climb, surplus horsepower, rates of climb and times to climb to any altitude, service and absolute ceilings. Furthermore, one can obtain conditions of throttled flight, range, and endurance and solve problems in connection with phases of operation such as take-off and landing runs, etc.

It is assumed that all are acquainted with the methods of calculation in use, but for convenience in Appendix 2 the author has collected such information as may be of benefit in routine performance calculation.

In calculating the horsepower available and the variation of horsepower with altitude, the author in the past has made use of the data collected by him, but since the discrepancies found with Mr. Diehl's curves are well within the experimental limits, it was thought best to adopt the latter information as the first step in an attempt of standardization of performance calculations. Appendix 2 also gives a brief explanation of a new use of the logarithmic polar diagram originated by the author. Although it has already appeared in the print, it is included here for the benefit of those who prefer grapho-analytical solutions and for the sake of completeness of references.

APPROXIMATE ESTIMATE OF HIGH SPEED AND CEILING

In his book, "Aerodynamics," Mr. Warner gives two diagrams which check very well the average characteristics met in practice.

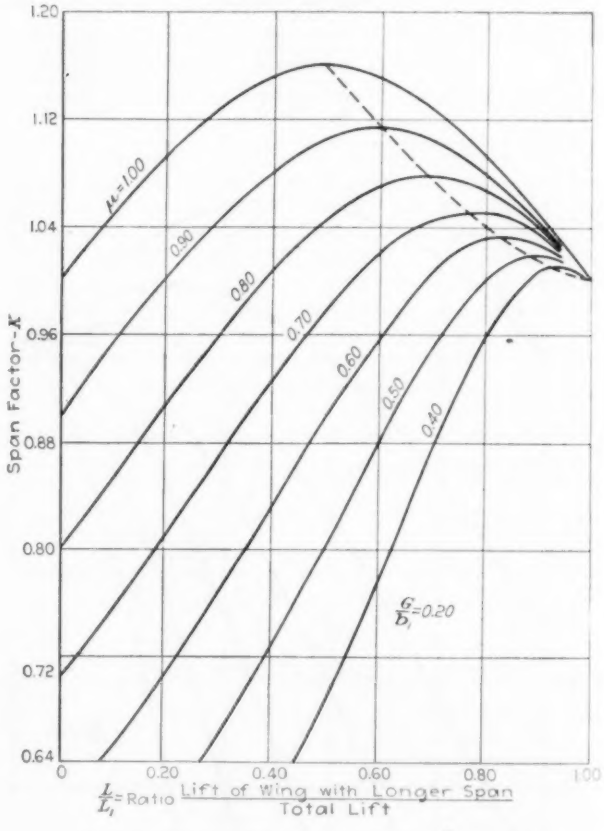

FIG. 21 MUNK'S SPAN FACTOR k FOR $\frac{G}{b_1} = 0.20$

These two diagrams present a further advantage, since one can plot lines for designs of different fineness and thus have a ready reference for an approximate estimate. (See Figs. 16 and 17.)

The average distribution of resistance at high speed and the percentage of total resistance are as follows:

	Well streamlined		
Type of plane	Monoplane	Sesquiplane	Biplane
Type of cooling	Prestone	Prestone	Air-cooled
Engine body	14.5	15.0	23.5
Radiator	6.2	6.0	0
Landing gear	10.5	10.5	8.5
Wing struts, wires, and interference	7.0	11.0	15.0
Tail surfaces	9.2	8.3	7.0
Wing drag	37.0	33.2	30.5
Propeller loss	15.6	16.0	18.5

The foregoing is an example of a typical distribution of parasite resistance in a two-seater military-type airplane. It is based on a very small number of estimates and cannot be generalized.

Conclusions

This paper was written with the intention of giving an engineer a ready reference to the methods and data necessary for practical performance calculations. Most engineers prefer their own methods and trust their own data, but a certain amount of standardization is desirable, and therefore an attempt was made to utilize what was thought the most reliable of available information.

It was impossible to give any proofs or more detailed explanations of the methods given, but it is believed that all are well

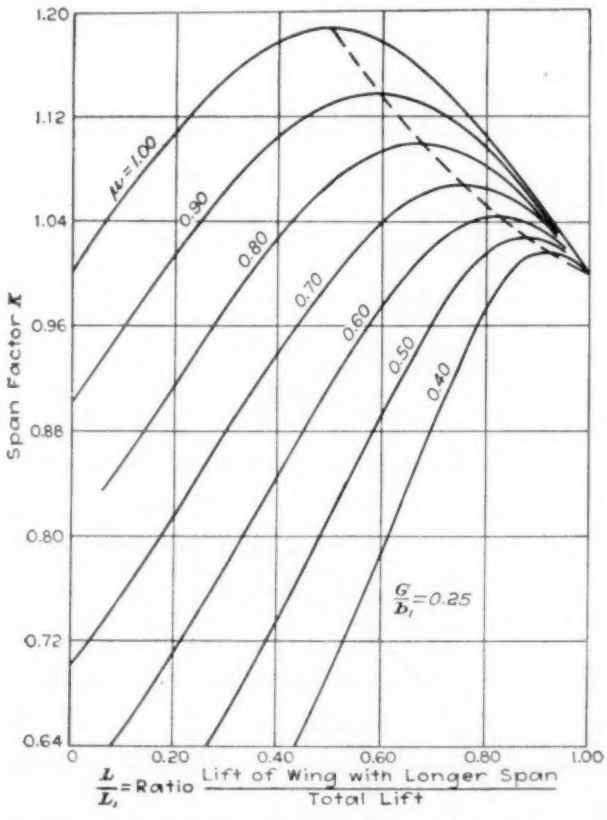

Fig. 22 Munk's Span Factor k for $\frac{G}{b_1} = 0.25$

acquainted with the subject of aerodynamics and will have no difficulty in applying the data.

It is hoped that this paper, in full or in part, will be found helpful by engineers in their everyday experience.

The accuracy of a performance calculation hinges greatly on the experience and judgment of the engineer because of the empirical nature of most of the coefficients used, and it is not surprising that in order to obtain good results, in addition to

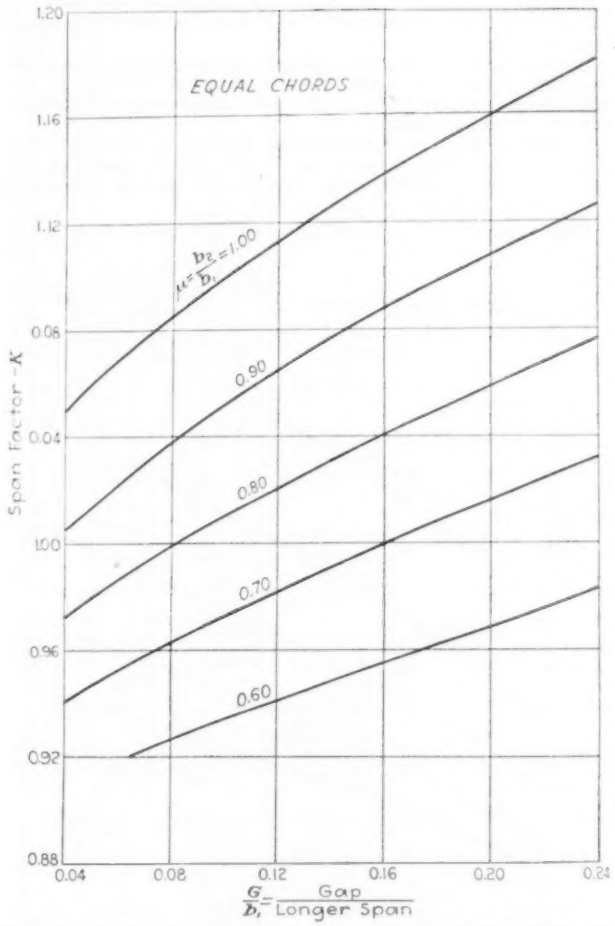

Fig. 23 Munk's Span Factor k for Biplanes With Wings of Equal Chords

experience one must possess what one may call the aerodynamic sense.

Knowledge of the theory and fundamentals is a necessary but not a sufficient condition to be an able performance calculator.

Appendix No. 1

Coefficient K. The magnitude of K may be found or interpolated from Figs. 18 to 24.

Appendix No. 2

Thrust Horsepower Available. Propeller-Engine Unit (Diehl). Propeller diameter: $D = K\sqrt[4]{\rho_0/\rho}\sqrt{\text{b.hp.}/(\text{r.p.m.}^2 . V)}$ in feet and miles per hour. The coefficient K is:

Wooden Propeller

Number of blades		2	3	4
K	Speed	285	255	240
	Climb	320	290	270
	Service	305	275	260

Metal Propeller

Number of blades		2	3
K	Speed	280	260
	Climb	315	300
	Service	300	290

General Efficiency Curve. Propeller efficiency for any value of V/ND ratio can be found knowing the maximum propeller efficiency and design $(V/ND)_0$. Fig. 25 gives values of η/η_0 plotted versus $\frac{(V/ND)}{(V/ND)_0}$.

Maximum Propeller Efficiency. The maximum efficiency for conventional two-bladed wooden and metal propeller is given in Fig. 26 (Diehl).

In order to take into account the mutual interaction of propeller body unit, a correction must be applied as given in Fig. 27. The body diameter should be taken at a point about one propeller diameter aft of the propeller.

In order to obtain the net maximum efficiency of a geared two- or four-bladed propeller, calculate the V/ND ratio for maximum efficiency of a two-bladed propeller and in Fig. 28 find the relative

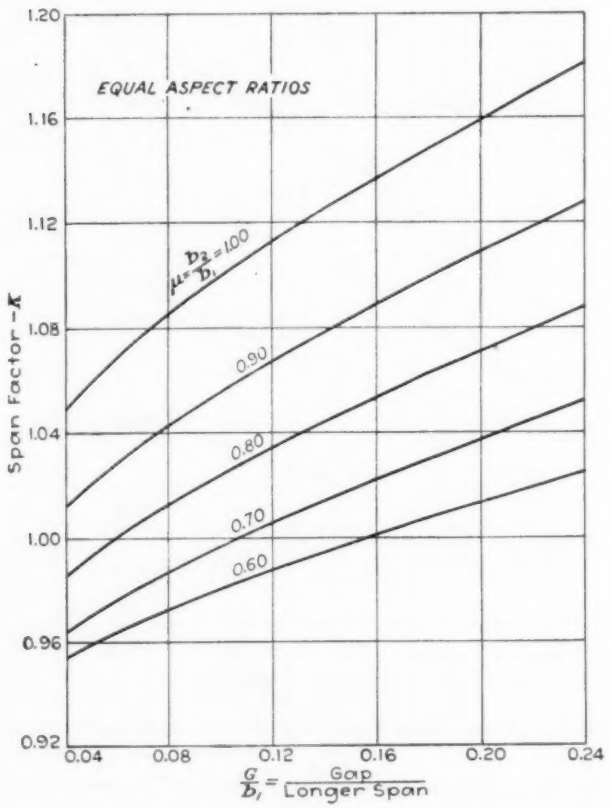

FIG. 24 MUNK'S SPAN FACTOR k FOR BIPLANES WITH WINGS OF EQUAL ASPECT RATIO

efficiency. The net efficiency is obtained by multiflying the maximum efficiency of a two-bladed direct-drive propeller times the relative efficiency (Diehl, N.A.C.A., T.R., No. 178).

AVAILABLE THRUST HORSEPOWER AT SEA LEVEL

In order to know the available thrust horsepower at sea level, it is necessary to know the variation of r.p.m. versus ratio of $V/V_{max.}$, variation of propeller efficiency versus V/ND, and also the variation of the brake horsepower of the engine versus r.p.m. Diehl in his book, "Engineering Aerodynamics," gives the derivation of average curves, and in view of uncertainties in propeller and engine behavior and other factors involved in performance calculation, it will be found sufficiently accurate for all practical purposes to use these average curves. (See Figs. 25, 29, 30, and 31.)

The variation as shown in Table 7 is given for a constant air speed which will be found very convenient in its application.

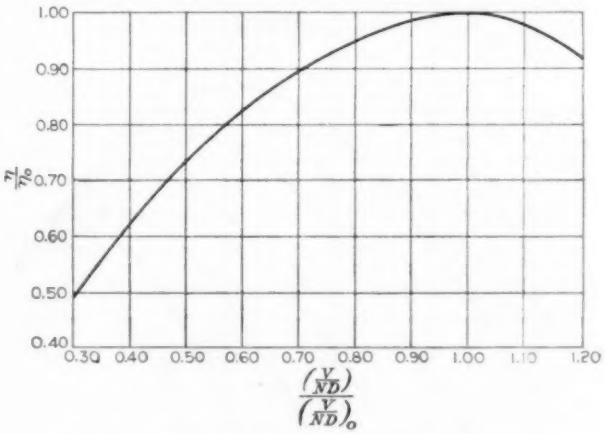

FIG. 25 GENERAL EFFICIENCY CURVE FOR PROPELLERS

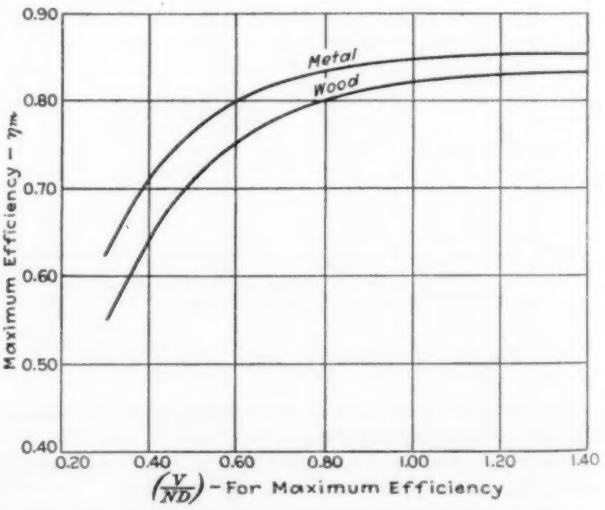

FIG. 26 VARIATION OF MAXIMUM PROPELLER EFFICENCY WITH $\frac{V}{nD}$

A New Application of the Logarithmic Polar Diagram

Knowledge of the characteristic curves of the plane and behavior of the engine-propeller unit permits of calculation of the theoretical performance of the airplane in question. The standard method of obtaining horsepower required and available and series of curves for sea level and altitude is assumed to be known to the reader. This method of calculation is somewhat laborious and requires a number of diagrams which are based on analytical calculations. In his practice the author prefers to use a grapho-analytical method based on an amplification of the logarithmic polar diagram. The method

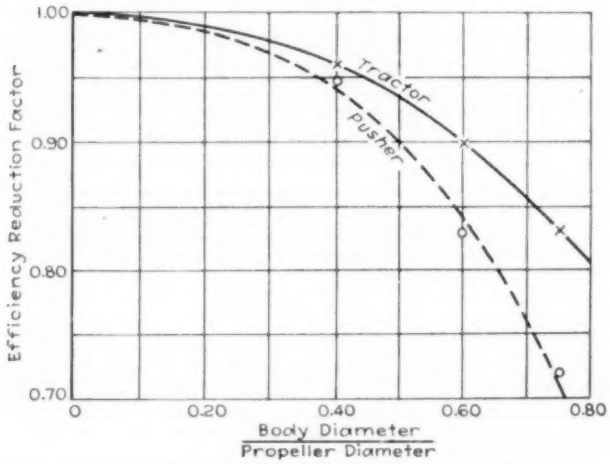

Fig. 27 Effect of Body Interference on Propeller Efficiency

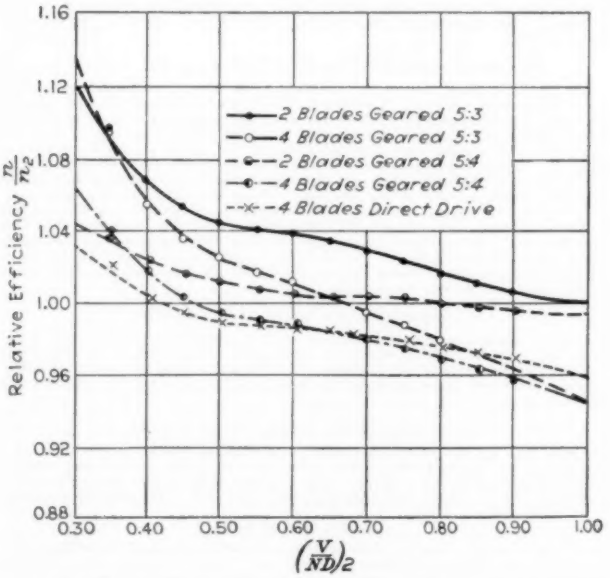

Fig. 28 $\frac{V}{nD}$ for Two-Bladed Propeller at Maximum Efficiency

was first described in the July, 1929, issue of *The Aero Digest*, in part as follows:

Lack of space prevents a detailed explanation of the theory of the logarithmic polar diagram and proofs of the new method, but the logarithmic polar principle is so simple that it will be best for the engineer to prove it for himself. The author suggests that the complicated analytical proofs be avoided since it is best to resort to simple graphical constructions and superpositions. After they are understood, numerous problems not mentioned in this article will suggest themselves and may be easily solved.

The original adaptation of the logarithmic polar diagram is credited to Mr. Rith of the Eiffel Laboratory and may be found in Eiffel's works "La Resistance de l'air et l'aviation" and "Nouvelles Recherches sur la Resistance de l'air et l'aviation." Disadvantages of the original Rith and later methods based on the use of the logarithmic polar diagram are in the approximate nature of the estimated performance obtained and the consequent inaccuracies and discrepancies as compared with other available methods.

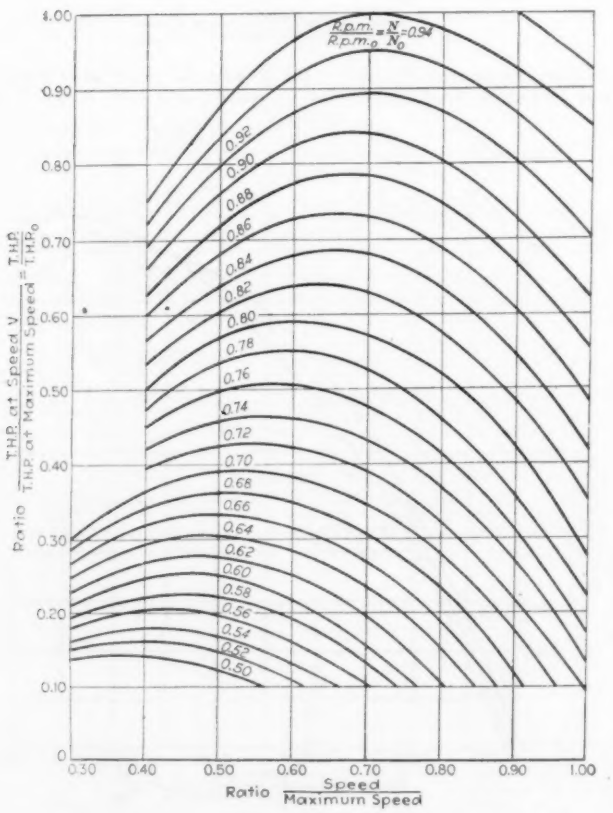

FIG. 33 GENERAL CURVES FOR T.HP., R.P.M., AND V

THEORY OF THE LOGARITHMIC POLAR DIAGRAM

Rith points out that if the characteristic curves of the airplane are plotted as a polar in logarithmic coordinates, the plot represents a functional dependence of all the main factors entering into the two principal equations of the flight characteristics of an airplane:

$$W = LV^2 \text{ and}$$
$$HP = DV^3$$

or expressed logarithmically:

$$\log W = \log L + 2 \log V \text{ and}$$
$$\log HP = \log D + 3 \log V$$

therefore:

$$\log L = \log W - 2 \log V \text{ and}$$
$$\log D = \log HP - 3 \log V$$

From the last two equations it is apparent that we can consider $\log L$ as the sum of $\log W$ and $-2 \log V$, while $\log D$ can be considered as the sum of $\log HP$ and $-3 \log V$. The values of $\log W$ and $\log HP$ can be plotted on the direction of the ordinate and abscissas directly, while $\log V$ can be plotted on a line inclined in such a way that the values projected on the direction of the ordinate will give $-2 \log V$ and the same point projected on the axis of abscissas will give a magnitude of $-3 \log V$. This new axis, called the speed axis, has the slope of 2/3 and the graduations have a modulus of $\sqrt{3^2 + 2^2} = 3.605$ times that of the modulus used on the other axes.

The diagram (Fig. 34) thus constructed gives the necessary functional dependence of the factors entering into the two equations.

In order to take into account the effect of the density of the air and so to obtain the characteristics of flight at altitude, we observe that in the two equations mentioned above we must incorporate the value of relative density. The new equations are written then as:

$$W = \sigma LV^2 \text{ and}$$
$$HP = \sigma DV^3 \text{ where}$$

σ is the ratio of the density at altitude to that at sea level. The necessary transformation can be obtained by assuming the origin of coordinates moved along a 45-degree line so that the magnitudes of L and D assume a new value equal to σL and σD. Consequently, in order to obtain the relationship of the factors involved at altitude, it is sufficient to incorporate a new reference axis (the altitude axis) which has a slope of 1/1, and to plot the logarithmic values of relative density with a modulus equal to $\sqrt{1 + 1} = 1.414$ of the modulus used for L and D axes.

Knowing the theory of the logarithmic polar chart, we can turn our attention to the practical application of it to performance estimate.

It is assumed that the characteristics of the airplane (that is, the lift and drag at one MPH on a full size machine) are determined either through calculations or from a wind tunnel test. Knowing the values of L and D and having a sheet of coordinates available, we plot the logarithmic polar curve.

DETERMINATION OF MAXIMUM SPEED AT SEA LEVEL

On the right-hand side of the diagram (Fig. 35), a vertical logarithmic scale is marked scale μ. This scale facilitates the determination of the available thrust horsepower when the propeller efficiency is known. Draw a horizontal line through the known propeller efficiency (line 1) until it intersects a 45-degree line passing through the point of BHP maximum (line 2). Draw a vertical line (3) through the point thus obtained until it intersects a horizontal line (4) passing through the ordinate indicating the gross flying weight of the airplane. Point A is the thrust horsepower available at the maximum speed. Drawing through point B line (5) parallel to the speed axis, the segment BC obtained between the intersection of this line with the polar (point C) and point B gives the magnitude of the maximum speed of the airplane. To find its value lay out from the origin of coordinates an equal segment on the speed axis and the reading at the point D will give the desired magnitude.

DETERMINATION OF STALLING SPEED

Draw a horizontal line (1) tangent to the uppermost point of the polar (Fig. 36). Draw line (2) through given gross flying weight. Line (2) is parallel to the speed axis. Segment AW (where A is the point of intersection of the two lines) gives the stalling speed of the airplane, which must be measured on the speed axis.

SPEED FOR FLIGHT AT MINIMUM POWER

Draw line (1) tangent to the polar and parallel to the V axis (Fig. 37). Draw line (2) through W corresponding to the given gross flying weight. The intersection of the two lines defines point A in such a way that AB is the speed corresponding to minimum power and AW is the minimum power.

MAXIMUM L/D

It can be easily proved that a vertical scale graduated logarithmically with the same modulus as used for the L and D axes, and located arbitrarily on the drawing will give us the ratio of L/D at the point of intersection of this scale with a line passing through the chosen point and inclined at an angle of 45 degrees. In graduating this scale, we must determine at least one reference point and graduate the scale in the same sense as the L axis. To obtain the value of maximum L/D, simply draw a line inclined at 45 degrees and tangent to the polar (Fig. 38). Point A gives the maximum L/D of the design.

The brief explanation of the theory and a few illustrations of the possible uses of the logarithmic polar diagram given above will suffice to explain the practical use of the new grapho-analytical method which consists of incorporating the curves of horsepower available and required drawn in logarithmic coordinates. This involves an incorporation of a few more reference curves as explained and illustrated in the following paragraphs.

HORSEPOWER REQUIRED AT SEA LEVEL

Knowing $V_{max.}$ calculate values of 0.9, 0.8, 0.7, 0.6, 0.5, 0.4, and 0.3 of $V_{max.}$ and mark them on the speed axis. This is not absolutely necessary for the purpose of obtaining the horsepower required, but later we will see that it will aid us in obtaining the horsepower available. The drawing of the curve of horsepower required will be illustrated by following the procedure for one point; for instance, point $V = 0.5V_{max.}$ (Fig. 39).

Draw line (1) through W and parallel to the speed axis. Project point

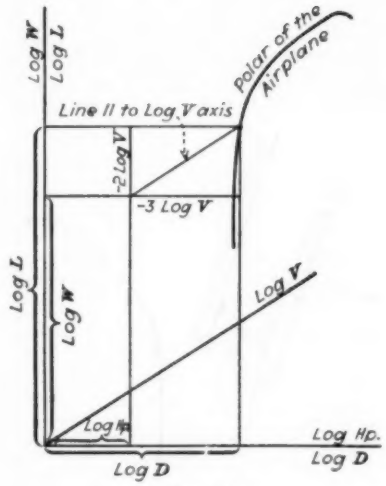

FIG. 34

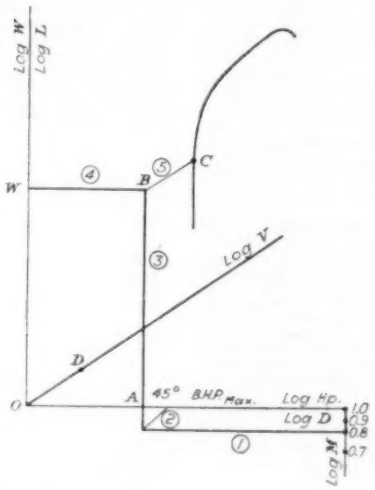

FIG. 35 DETERMINATION OF MAXIMUM SPEED AT SEA LEVEL

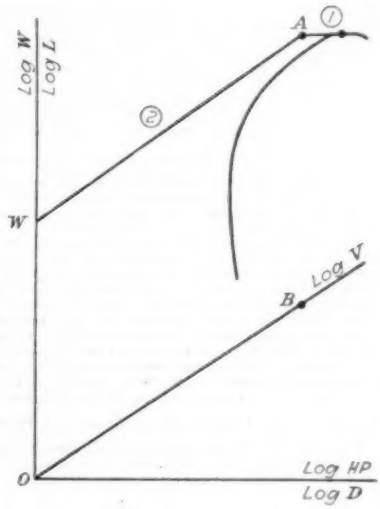

FIG. 36 DETERMINATION OF STALLING SPEED AT SEA LEVEL

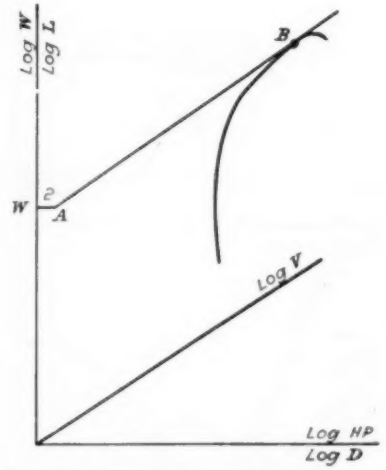

FIG. 37 DETERMINATION OF SPEED FOR FLIGHT AT MINIMUM POWER

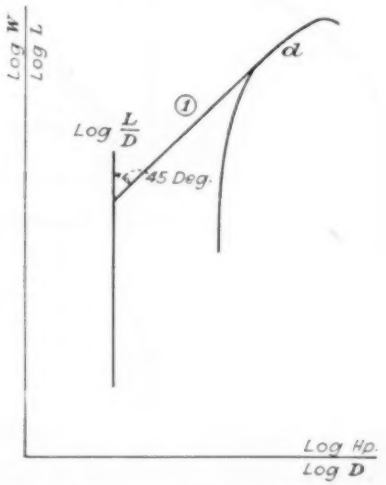

FIG. 38 DETERMINATION OF THE L/D RATIO

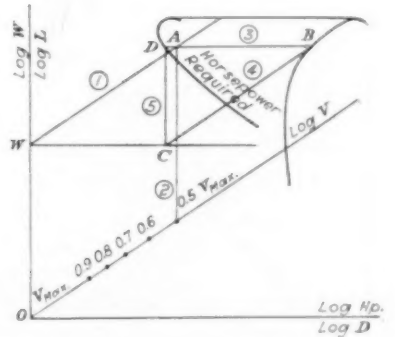

FIG. 39 DETERMINATION OF HORSEPOWER REQUIRED AT SEA LEVEL

$0.5V_{max.}$ on it. This gives point A. Draw a horizontal line through this point. Through the point B draw a line parallel to speed axis until it intersects the horizontal line passing through W. Through the point C thus obtained draw a vertical line until it intersects line AB. Since WC is the horsepower required to fly at a speed equal to $0.5V_{max.}$, point D represents a plot of it drawn at the proper point of the polar curve. Repeating this construction for several points and joining all these points by a smooth line we obtain the horsepower required plotted against the corresponding lift and, by virtue of construction, also the known speed.

HORSEPOWER REQUIRED AT ALTITUDE

In order to obtain the curve of horsepower required at any altitude, it is sufficient to shift the sea level curve to the right by the amount equal to the distance (1) which is measured between the speed axis and the ordinate axis at the height corresponding to the chosen altitude. Fig. 40 shows this construction for an altitude of 20,000 ft.

HORSEPOWER AVAILABLE AT SEA LEVEL

In order to construct the curves for horsepower available at sea level, we introduce three new constructional curves giving the variation of thrust horsepower against the ratio of $V/V_{max.}$

In Table 6 are found the three general curves giving the necessary relationship. In the lower left part of the diagram we incorporate these three curves.

The scale of propeller efficiencies is used now as the scale of THP/THP_0, while the scale of $V/V_{max.}$, is assumed to be plotted on the axis of altitudes (Fig. 41). In this construction we make use of the line (2) from Fig. 34. The power plant used determines which of the three curves shall be used.

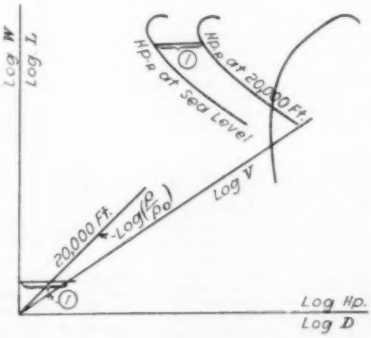

FIG. 40 DETERMINATION OF HORSEPOWER REQUIRED AT ALTITUDE

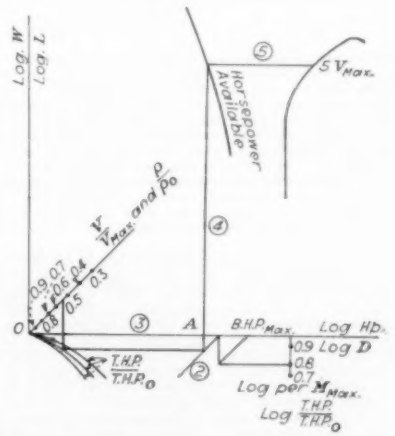

FIG. 41 DETERMINATION OF HORSEPOWER AVAILABLE AT SEA LEVEL

The construction will be illustrated for one point and must be similarly repeated for the rest of the points corresponding to fractions of $V/V_{max.}$ Fig. 38 shows the construction for point of V equal to $0.5V_{max.}$

Having chosen one of the THP/THP_0 curves we project the corresponding

point on the line (2). The point at intersection projected on the HP scale gives the horsepower available at this particular speed. Drawing line (4) until it intersects the horizontal through the point on the polar corresponding to the speed chosen, we obtain point B of the horsepower available curve at sea level. Repeating this construction for several more points and joining them with a smooth curve, we obtain the curve of horsepower available. The curves of horsepower available and horsepower required will intersect at point B of Fig. 2, corresponding to the maximum speed when the horsepower available is equal to the horsepower required.

Horsepower Available at Altitude, Unsupercharged

To obtain the horsepower at altitude, we will incorporate a curve giving the variation of the horsepower with altitude. Since our construction will be made assuming that the speed of the airplane remains constant, we can make use of the data given in Table 7.

Fig. 42 illustrates the construction of the point corresponding to an altitude of 10,000 ft. Inasmuch as the transformation of the polar for any altitude is made by an imaginary shift of the origin of the coordinates along a 45-degree line it is sufficient to locate the point B on the horizontal passing through the 10,000-ft. point on the axis of altitude so that a line drawn through it and inclined 45 deg. will cross the axis of horsepower giving the magnitude CO equal to 0.667 CA; that is, if the point A corresponds to 1000 HP, the value read at C must be 667 HP. Having the curve of variation of horsepower with altitude it is sufficient to slide the curve of horsepower available at sea level parallel to itself by the amount and along the direction (1) corresponding to the desired altitude as shown on Fig. 42.

Horsepower Available at Altitude With Supercharged Engine

Most of the present supercharged power plant installations are made so that the original sea level power is retained up to a certain fixed altitude,

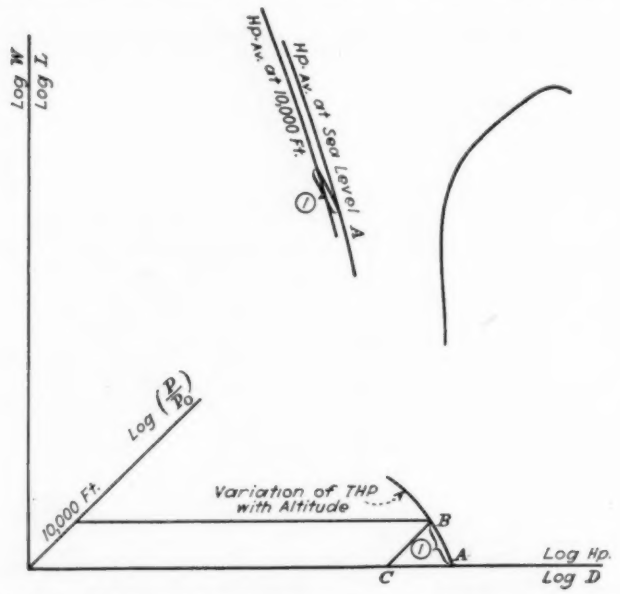

Fig. 42 Determination of Horsepower Available at Altitude, Unsupercharged

above which the power decreases at the normal rate. On our diagram this can be expressed by drawing instead of the previously drawn horsepower variation curve a new curve consisting of two branches: a vertical straight line from point A up to the horizontal, passing through the altitude up to which the sea level power is preserved and a curve from point C which is obtained by shifting horizontally the old curve until points B and C coincide. In the diagram the power was assumed to be retained up to an altitude of 10,000 ft. As the altitude performance on the polar diagram is obtained by an imaginary shift of the origin of coordinates along a 45-deg. line, to obtain the horsepower available at 10,000 ft., we must shift the curve of horsepower available at sea level to the right along a 45-deg. line by the amount equal to the segment (1).

Performance at Altitude

In order to obtain the speed and corresponding horsepower required and available at altitude, we must bear in mind that by virtue of construction that instead of a horizontal line passing through W (as it was done in Fig. 39) it is necessary to use another horizontal line such that if WB is parallel to the altitude axis, the segment WB must be equal to the segment OA where A is the desired altitude. Fig. 11 illustrates this for an angle of attack corresponding to the maximum speed at 10,000 ft. Since the point of intersection of horsepower required and available curves corresponds to the maximum speed, project point E on line BC and OF. Segment OF gives the magnitudes of horsepower required and available, since in this case they are equal. Drawing line CD parallel to speed axis, we obtain the magnitude of the maximum speed given by the segment CD, and point D permits us to interpolate the angle of attack corresponding to the maximum speed at 10,000 ft.

Complete Performance Prediction With the Aid of Logarithmic Polar Diagram

From the foregoing we are now able to obtain the complete data on theoretical performance of a new design. We can ascertain the maximum and stalling speeds for any altitude at which the plane is capable of flying. By joining the points of maximum speeds plotted on the corresponding horizontal lines and noting the intersection of this new curve with the line tangent to the polar and parallel to the speed axis (line used to obtain the minimum power required for flight), we can determine the absolute ceiling.

In order to obtain the best speeds for climbing and to determine the excess horsepower, we can make use of the following observation: From the analyses of a number of airplanes it can be found that the best speed at which to climb at sea level is usually equal to 0.58 $V_{max.}$ At the ceiling,

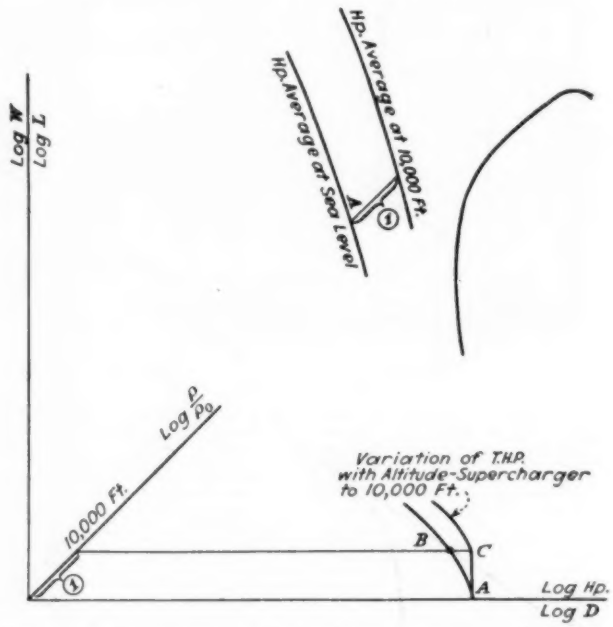

Fig. 43 Determination of Horsepower Available at Altitude, Supercharged

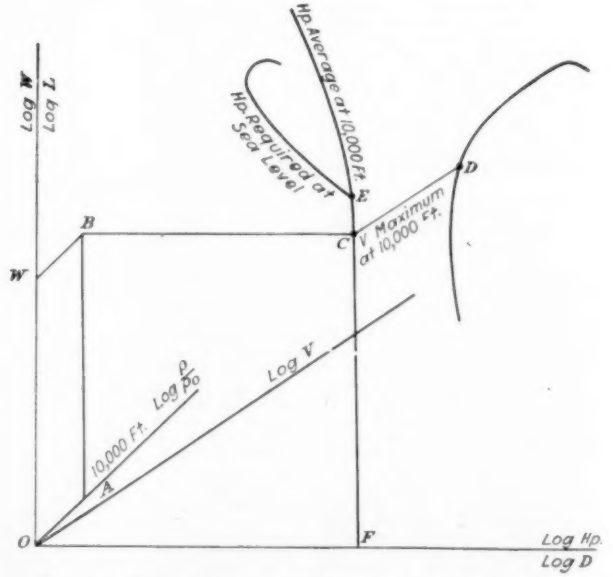

Fig. 44 Determination of Performance at Altitude

the planes would fly at a speed corresponding to the minimum power necessary to maintain flight. If we join by a straight line the point corresponding to the speed equal to 0.58 $V_{max.}$ on the horsepower-required curve at sea level with the point of minimum power necessary to fly at the ceiling, the points of intersection of this line with horsepower-required curves will define, within the accuracy of practical requirements, the best speeds for climbing. Knowing these speeds, we can obtain the excess horsepower available for climb.

We can resort now to standard analytical methods and obtain the curve of rate of climb and time to climb to different altitudes. Fig. 43 shows an example of the use of logarithmic polar as it is employed in routine practice.

The particular advantages afforded by the method described in the article, in addition to those already mentioned, consist of compactness of the record

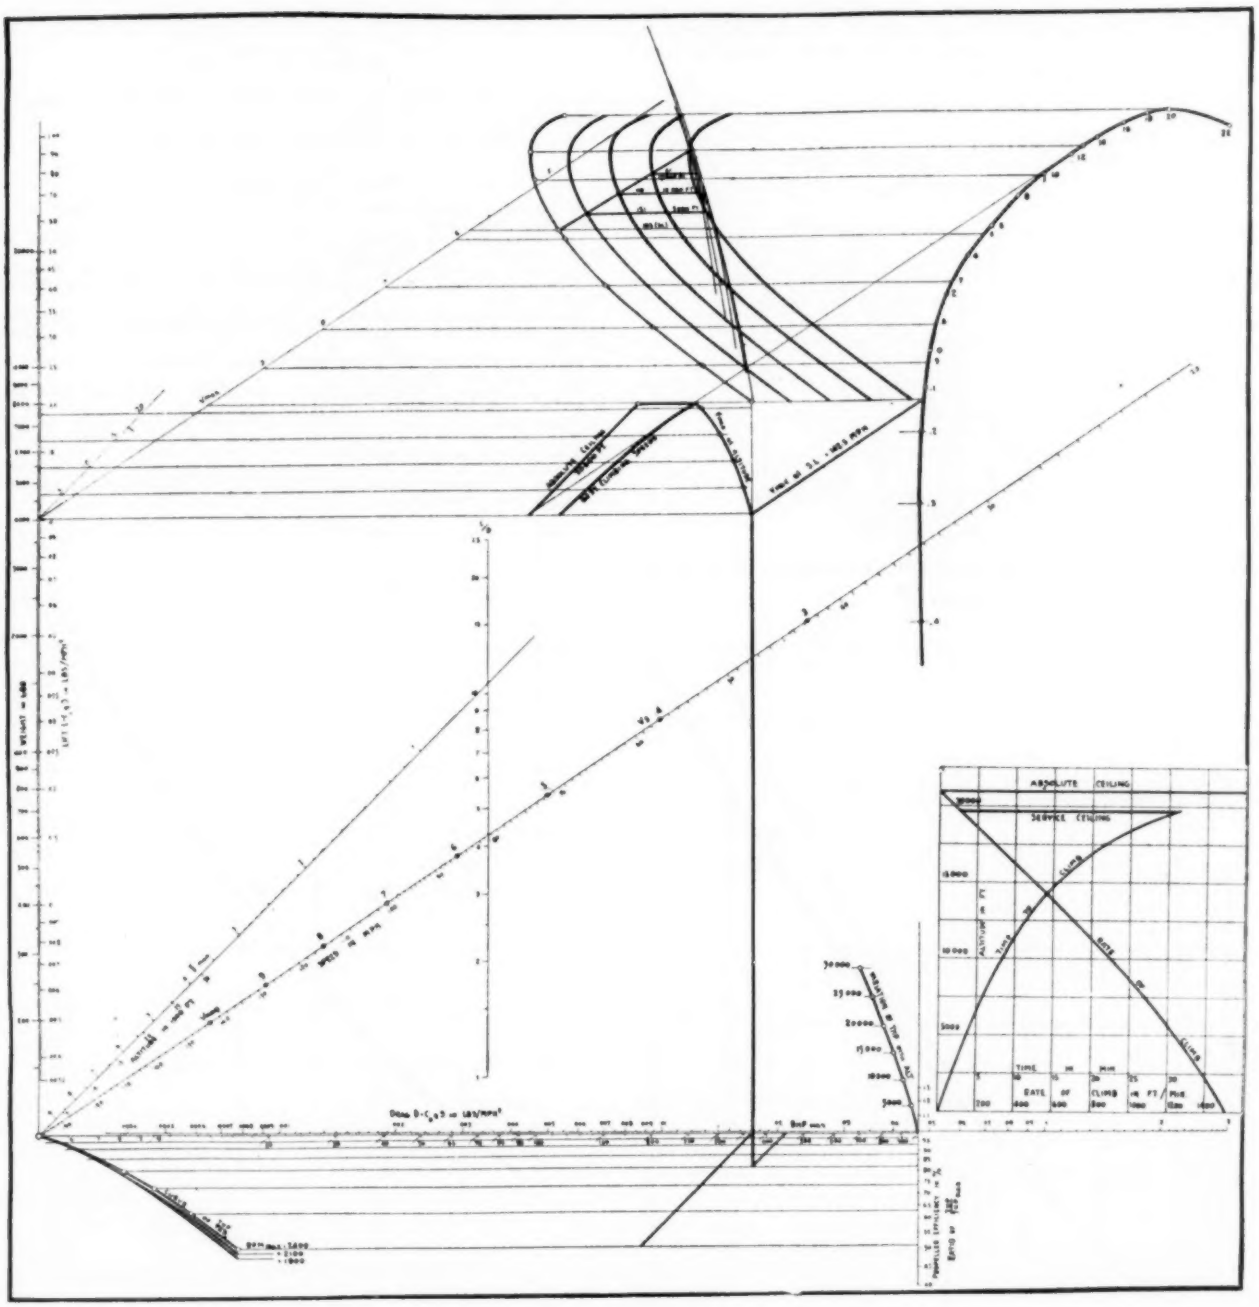

FIG. 45 AN EXAMPLE OF THE USE OF THE LOGARITHMIC POLAR AS EMPLOYED IN ROUTINE PRACTICE

and a ready means of estimating slight changes of design. In many instances lack of time does not allow an elaborate revision of a performance estimate and in such a case the logarithmic polar diagram furnishes an easy and rapid estimate of the effect of changes in weight, parasite resistance, etc. To the trained eye the graphical picture of the polar gives other valuable information such as the general efficiency of the design, the approach to inefficient gross flying weight condition, and such.

RANGE AND ENDURANCE

Breguet:

$$\text{Range} = 863.5(L/D)(\eta/C)\ \log_{10}\ (W_0/W_1)$$

$$\text{Endurance} = 750(V_{C_0}/\sqrt{W_0})(L/D)(\eta/C)\left[\frac{1}{\sqrt{W_1}} - \frac{1}{\sqrt{W_0}}\right]$$

where η is the average propeller efficiency, C the average specific fuel consumption, W_0 the initial gross weight, W_1 the final gross weight, and V_{44} the cruising speed at the gross weight W_2.

Diehl brought the Breguet formula into a simplified form and also obtained his own expressions for range and endurance where instead of average values of specific fuel consumption the initial specific fuel consumption is used.

$R = B_R(L/D)(\eta/C)$
$T = B_E(L/D)(\eta/C)(1/V_{C_0})$
$R = K_R(L/D)(\eta/C_1)$ (no mixture control)
$T = K_E(L/D)(\eta/C_1)(1/V_{C_0})$ (no mixture control)
$R = K'_R(L/D)(\eta/C_1)$ (with mixture control)
$T = K'_E(L/D)(\eta/C_1)(1/V_{C_0})$ (with mixture control)

Figs. 46, 47, and 48 give the factors appearing in the foregoing formulas.

It must be noted that in the case of the Breguet formula one must use the average specific fuel consumption C, which is obtained by calculating the average ratio of maximum to minimum speed and using Fig. 44.

In applying Diehl's formula for range and endurance, it is necessary to use the *initial* specific fuel consumption. In this case ratio of C/C_0 from Fig. 44 must be obtained for the initial value of the ratio of maximum to stalling speed.

Take-Off and Landing Run

Take Off Run (Diehl):
Neglecting the influence of the propeller

$$S_o = KV^2_s(W/\text{b.hp.})$$

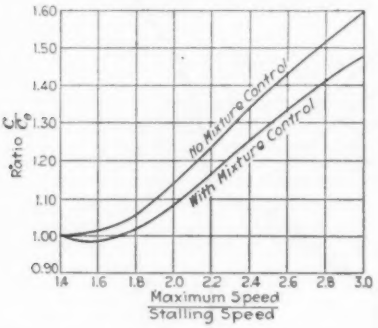

Fig. 46 Variation of Specific Fuel Consumption With Speed Ratio $\frac{V_M}{V_S}$

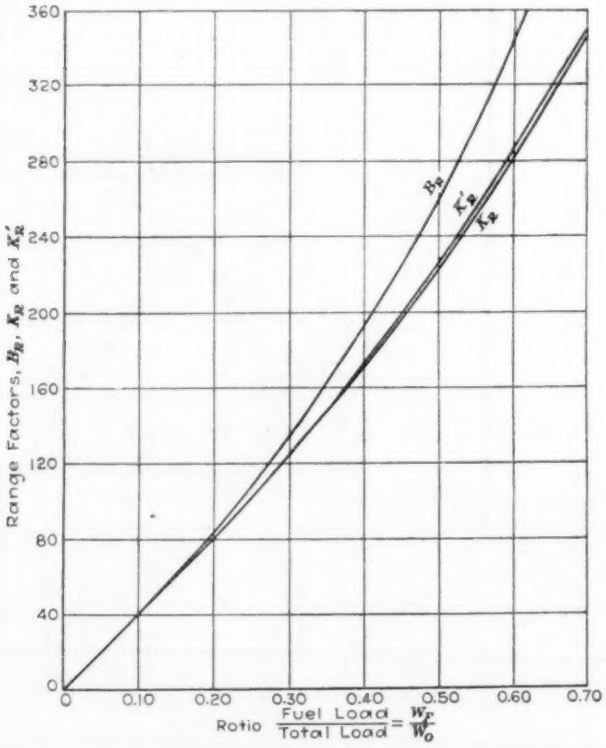

Fig. 47 Factors for Simplified Range Formulas

where S_0 is the take off run, V_s the stalling speed, W/b.hp. the power loading.

The average value of K is 0.012. More precisely, the foregoing equation can be written as follows:

$S_0 = 0.0215\ V_s^{2.25}W/T_0$, where the static thrust $T_0 = 6000[18.7 - 9.5(p/D)]$b.hp./(r.p.m.$D$).

Landing Run:

$$S_L = \frac{V_L^2}{2g(D/L - \mu)} \log_e \left(\frac{D}{L\mu}\right)$$

where S_L is the landing run, V_L the landing speed (feet per second), and μ the coefficient of friction.

The average value of μ is between 0.06 and 0.10.

Reduction of Airplane Production Costs

By J. DON ALEXANDER,[1] COLORADO SPRINGS, COLO.

AS RAPID and uniform reproduction is the essence of efficient manufacturing, production economies will necessarily be limited in the airplane building industry until the yearly output reaches the five- and six-figure class. Few large commercial airplane factories today are operating at the capacity of which they are capable. The demand does not justify it. Thus many of the benefits of heavy production are lost with their attendant blessings of lower cost per unit, lower retail prices, and broader markets.

However, large economies may be effected in airplane production through the utilization of efficient factory planning, modern machinery, and all manner of labor-saving devices. As in the manufacture of any product, a short cut to efficient production lies in exact duplication of every part so that it is interchangeable with every similar part in every unit.

The public does not realize the amount of the engineering, high-grade material, and skilled labor which go into an airplane. Whereas the modern automobile's lines are designed chiefly for beauty, an airplane takes shape in accordance with aerodynamic principles, and the design of an airplane plays a much greater part in determining its performance than does the design of the chassis, engine hood, and top in the characteristics of an automobile. Fortunately for the airplane industry, the better structures and lines from an aerodynamic standpoint are usually the most beautiful.

The airplane engineer, in order to avoid compromising to a large extent on either strength or lightness, has developed scientific structural design to an extreme degree. As a result the factory craftsman is put to a great deal of painstaking detail in order to insure that the parts will not be overweight and yet will bear the designed stresses. Nevertheless, machine methods can be used in many operations with an immense resultant saving in production costs combined with the benefits of a more perfect and more interchangeable product.

In factories operating on a fairly heavy schedule, labor- and time-saving machinery will prove a quick turnover investment. A few instances of machine-made savings are given from those used in the factory with which the author is connected.

Before a molder was installed in the wood shop, the routing of spars required 16 hr. a day on the shaper. It was necessary to run the front spar through the shaper five times and the rear spar three times, while the rib cap strips required five such operations. With the installation of the power-driven molder the front and rear spars were shaped with a single operation each. The spars were molded into exact size, whereas under the hand-feeding process the spars were approximate in shape. The machine-molded spars thus could be quickly and easily placed into position in the jigged wing skeleton.

Instead of producing one cap strip in five operations as under the hand method, now five cap strips are turned out in one operation. The net result is a reduction to 4 hr. of work formerly entailing 16 man-hours of expensive labor.

In other departments as well as in the wood shop large factories will find machine methods a paying proposition from the twin standpoints of economy and quality of product. In the Eagle-rock plant an electric cutting machine in a single operation cuts sufficient cloth to cover $10^1/_2$ biplane wings. Cloth is sewed into shape with an electric sewing machine which double-stitches the fabric in one motion and is capable of 3300 stitches per minute. Women employees handle the sewing neatly and efficiently.

Every factory in time develops small time- and labor-saving innovations which are an important factor in the profit margin on a year's production. A device is used to facilitate the work of waxing thread with which the fabric is sewed and laced to the wing structure. This is accomplished by the simple procedure of reeling the raw thread from one spool to another by means of an electric motor. Between spools the thread passes through a pan of molten wax, and then a wiper regulates the proper amount of coating.

For wing covering, 100 layers of fabric are placed on the table and cut into proper lengths for sewing with a minimum of waste. Cutting is done with an electric cutter of the vibrating-blade type. The number of covers for fuselage and control surfaces which may be cut in one operation is far greater than is necessary to stock at one time.

Wing covers are sewed in an envelope, with the aileron recess and butt of the wing left open. Likewise covers for all other parts are sewed to be slipped over the framework as a one-piece case. Sewing the envelope in advance not only permits a better job of covering, but effects a tremendous man-hour saving. One machine operator consistently can turn out 32 wing covers and fold and put them away in the racks every 8-hr. day. This one process again illustrates the labor economies effected by use of modern machinery and proper arrangement. With a crew of 16 a properly equipped covering department can turn out fully covered parts for eight three-place open biplanes every 8-hr. day.

In the entire process there is no scrap which cannot be utilized. Practically all fabric for wings, ailerons, tail surfaces, center section, and fuselage can be cut from an efficiently designed pattern with an actual waste of not more than 5 yd. per 100 planes.

A standard covering job should be good for the life of the airplane although rough usage and long exposure to severe weather in time may necessitate replacements.

As true line production methods are adhered to as closely as possible, very good results are obtained with an overhead-track system connecting all departments in the factory, and enabling parts to be conveyed rapidly from the main plant to the lionoil and dope rooms which are located some distance away as a fire precaution.

In the old Denver plant two men used to carry a wing from one building to another and back. Now one man can pull 12 wings over the trolley system in less time, resulting in a man-hour saving of 23/24 of the time required under the former procedure. Because of the trolley system one man can handle wings in the dope room without help, cutting labor costs on the operation in two. The overhead transportation system also expedites installation of power plants previously tested as a unit in the fuselage while the ship is going through the assembly line. The 6000-ft. overhead-trolley system has paid material dividends.

A large saving was effected by the introduction of a lionoil wing-dipping vat. Formerly painters spent three hours hand painting a single wing skeleton and it was found that 85 per cent of the paint went into the air as waste. Now the wing is dipped in a deep vat filled with lionoil. Two men can process a dozen

Presented at the Fourth National Aeronautic Meeting, Dayton, Ohio, May 19 to 22, 1930, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

wings in 1/2 hr. at the rate of five "man-minutes" per wing, whereas the former rate was three man-hours per wing.

A new company may determine its future profits or losses before it produces its first plane. No amount of selling can overcome the handicaps of a poorly designed and inefficiently operated factory.

Before the Alexander company began construction of its present factory in Colorado Springs, company heads, factory supervisors, and expert architects studied the planning over a five-months period. The factory was designed and redesigned 25 times before the present layout was decided on. Factory department heads stated concisely their needs and advised as to the most efficient location in relation to other departments.

Jigs are now common in large airplane factories, and result not only in economical production, but in exact duplication of each unit. The Alexander company was one of the first factories to use fuselage jigs so that the steel tubing could be welded and the fuselage turned out exactly interchangeable with its forerunners. Fuselage jigging is most efficient with a perfect interchangeability of duplicate structural members. The welder must be able to pick out the right member quickly and weld it into shape without necessity of filing and fitting it into the fuselage. Various tube members are cut to correct lengths with a power saw and then the ends are shaped so that a large quantity is available at all times, and so that the welder will lose none of his highly paid time finding and fitting the parts. He has only to pick out his part from the numbered racks in a rolling bin and snap it into place in the jigged fuselage. From 25 to 100 duplicate parts are in stock at all times, properly milled at the ends so as to fit smoothly into place. The bin is on castors so that it may be transported quickly between the machine shop and the adjacent welding department.

A jig should be more than a mere framework for the fitting of structures in proper shape. It should embody refinements known to every experienced aircraftsman which enable him to complete his job more quickly and efficiently. Fuselage jigs should permit easy accessibility to each welded joint. The tube should hold in place with minimum attention from the welder and the finished fuselage should be easily removable from the jig.

Where the design permits the use of a sufficient number of identical parts, it is economical to make dies for use on the punch press. Two or three die makers are employed and it is found practical to invest thousands of dollars in dies. Two thousand jigs, dies, and fixtures is a low estimate of the number required in manufacturing airplanes on a large-scale basis.

Until the factory is assured of selling the models in fair quantity, it is impractical to design a special motor mount for every new motor or freak motor which a prospective customer would like to install. If the new motor proves out in service and comes into wide demand, the factory can then afford and turn out the new installation. It is estimated that a new motor installation, and the tests and engineering necessary to win the complete model an approved type certificate, cost approximately $1000.

Factory workers should be encouraged to work out more efficient methods of performing their jobs and perfecting helpful devices. This activity can be stimulated by offering valuable cash prizes each month for practical ideas. A recent innovation which resulted from such a contest was a low couch on castors which enables members of the rigging crew to work more efficiently on the underside of ships.

To develop the now scarcely touched but potentially enormous general market, faster planes must be produced, inexpensive to buy and economical to operate. The initial cost to the buyer can be cut down only by a steady reduction in production costs, brought about by careful study of each operation.

AER-52-26

Airplane Design, Manufacture, and Sales, Commercial vs. Military

By REX B. BEISEL,[1] TULSA, OKLA.

The commercial industry differs materially from the military, and the paper discusses these differences from the general standpoint of design, manufacture, and sale. It would be a great deal more difficult for the commercial builder to enter the military field than for the maker of military airplanes to successfully enter the general commercial field.

NOT MANY years ago the military airplane dominated the field. When the airplane was mentioned, it was discussed purely in the military sense. Its commercial possibilities were realized only after a very slow process of development, handicapped to a great extent by the rapid progress made in the development of the military type. The early commercial airplanes were either adaptations of surplus war machines or were designed on lines closely approaching the familiar military models. However, due to a growing need for strictly commercial types, coupled with the foresight of a number of men, who now head some of the largest commercial companies in this country, the commercial airplane gradually came into its own and at the present time holds the field of importance both as to quantity produced and importance to the country as a whole. In a period of a very few years the commercial airplane has reached a stage of development comparable to the military machine. In a number of ways its development has been even more rapid. There are numerous reasons for this condition, but one which is important is the control of design and approval of types by the Aeronautics Branch of the Department of Commerce. This control has resulted in the commercial airplane being equally as safe to fly and possessing as good flying characteristics as the military plane. As far as comfort is concerned it is greatly superior.

There are, however, a number of points connected with the commercial industry which differ materially from the military and it is the purpose of this paper to discuss these points from the general standpoint of design, manufacture, and sale.

Design

In a strictly comparative sense the military plane is designed primarily to carry armament, whereas in the same broad sense the commercial airplane is designed primarily to carry freight or passengers. As a result, the requirements of each are very different. In a general way the paper will enumerate the requirements affecting the design of the military type.

High performance is the most essential requirement. Unless a pursuit plane, for example, has performance equal or better than its adversary, its value is lost. By performance is meant high speed, rate of climb, ceiling, and maneuverability. It must be easy to control, have excellent maneuverability, and yet be sufficiently stable to permit accuracy of gunfire, especially while diving. The best possible vision from the design basis could always be improved upon from the standpoint of the ideal requirements. The armament must be installed to function properly at all times and be readily accessible for loading or maintenance on the ground. In addition, provision must be made for the installation of bomb gear operated from the cockpit and for the installation of a small radio as additional equipment. It is necessary to install this equipment in a very limited space and still insure the proper function of all parts. The airplane structure must have factors of safety that will insure against its failure even though stressed to a point where the acceleration is as high as the pilot can physically endure and yet be designed with the lowest possible weight. The designer is confronted with the problem of whether to add more horsepower, resulting in more weight and a larger airplane with possible loss of maneuverability and poorer vision, or be satisfied with a smaller plane of less power. Fortunately he is not too greatly handicapped by cost, unless he happens to design an airplane wherein the cost is out of proportion to the improvement in other desirable qualities. The design of a modern fighting airplane requires more courage, ingenuity, and experience than does any other type of military craft. This is borne out by the fact that there are only two contractors in the United States who have successfully produced airplanes of this type.

The military-airplane designer must have, in addition to a thorough knowledge of general airplane design, an equal knowledge of armament and equipment installations, including fixed guns, either in the fuselage or wings, flexible guns, bomb gear, ranging from 25-lb. bombs up to bombs of 4000 lb., torpedo, radio, and camera. If he designs planes for naval use, he must be familiar with float or hull design, arresting gear, and flotation gear installation. If he is good, the application of an amphibian gear to an existing type is considered only a part of the day's work.

In order to properly understand and efficiently handle the design of military types with their numerous and varied installations, the designer should be reasonably familiar with military tactics and conditions encountered in actual wartime service. He should know that it is quite impossible to stand up and efficiently handle the flexible guns in the rear cockpit of a two-seater at a speed greater than 125 miles per hour. Knowing this, he should be able to devise ways and means of shielding the gunner against the terrific air blast or be able to design a special gun mount to overcome this difficulty. He should know when installing the fixed guns on a fighter that the airplane in diving vertically will assume a certain angular attitude with reference to the thrust line, and that unless the guns are set at this attitude they cannot be pointed at the target, and the pilot will report that the plane creeps and destroys his aim. He should know something of formation flying, especially in the case of multi-engined planes with the pilot located in the forward end of the fuselage, or he may turn out a job where the leader's vision is limited and he is unable to properly see the rest of the formation.

It is true that the services provide handbooks and drawing

---

[1] Vice-President and Chief Engineer, Spartan Aircraft Company. Mr. Beisel was born in San Jose, Calif., October 24, 1893; graduated B.S. in M.E., University of Washington, 1916; aeronautical engineer, Design Branch, Bureau of Aeronautics, Navy Department, January, 1917, to February, 1923; chief designer, Curtiss Aeroplane and Motor Company, Garden City, N. Y., February, 1923, to June, 1929; in his present office since then.

Presented at the Fourth National Aeronautic Meeting, Dayton, Ohio, May 19 to 22, 1930, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

containing a great deal of useful information and instruction covering installation of military equipment, but after all the use of any handbook must be accompained by familiarity gained only by experience with the actual work itself.

From the foregoing it can be seen that the design of the military airplane differs inherently from that of the commercial airplane in the following respects:

(*a*) High cost of construction is justified if it results in speed climb or maneuverability higher than existing types.

(*b*) A thorough knowledge of armament installation as well as an intimate familiarity with military requirements is essential to a successful design.

(*c*) The horsepower is as high as can effectively be used.

In contrast to the military plane, where it is considered permissible to sacrifice everything except the proper installation and functioning of the military equipment in order to obtain high performance, the commercial airplane has several requirements, each of equal importance. The designer must give equal consideration to cost, performance, comfort, and load-carrying ability. It is true that certain special types permit of attaching greater importance to any one of these requirements, but in general they are equally important in laying out a new design. These requirements are very definitely related and affect each other so closely that they must be studied collectively rather than separately. Whereas the military designer designs around the highest horsepower and latest type engine adaptable to a particular type, the commercial designer must choose his power plant with greater care. High power means high performance, but also higher initial and upkeep costs. Higher power with increased fuel and oil load in a given airplane also means lower pay-load-carrying capacity unless the landing speed is permitted to exceed practical safe limits. Only recently has comfort received the attention it deserves. True, an increase in comfort means added weight and perhaps a decrease in performance due to a roomier compartment. Fortunately the flying public has reached the stage where a passenger is no longer paying for the thrill of having a gale of wind blown down his neck, but rather is interested in getting to a particular destination in a hurry, and he naturally and rightly demands that it be in comfort. The successful designer will in the future pay more and more attention to the comfort and appearance of the airplane. In this connection one can take a leaf from the book of the automobile designer. Automobiles at the present time are sold as much on comfort and appearance as on any other quality. It might be mentioned that the lack of appreciation of comfort on the part of the designer is directly traceable to the old military influence. The designer who gained his experience on military aircraft was so instilled with the requirements of light weight and high performance that he was very slow to accept the necessity for providing comfortable spring-cushion seats, cockpit heaters, non-breakable glass windows, adequate baggage compartments, and similar comforts and necessities because of the resultant additional weight or lower performance.

It is extremely essential, therefore, that the commercial designer not only appreciate the relative costs of different types of design, but must also be capable of designing a given type of construction such that it can be built in the cheapest manner possible. Essentially the commercial airplane must be of cheaper construction than the military airplane. Here again he must balance low cost against light weight and aerodynamic cleanness of design. In determining cost he is handicapped in not knowing accurately on what quantity production he can safely figure. He cannot count on ever being paid for the engineering and shop costs of the first experimental article as is so often true in the case of the military designer who can anticipate reasonable production if his design is a success.

The tendency at the present time as a result of market conditions, is to build cheaply almost regardless of quality. The argument which comes from the sales department is that the way to sell airplanes is to sell them cheaply. The easiest and simplest way is to sacrifice quality. This is a condition which presents a new problem to the designer. He should face it squarely and continue to insist on quality of design. If any structure or vehicle of transportation requires quality of design, none requires it to so great an extent as the airplane. Rather than sacrifice quality he should concentrate on evolving a simpler design and if necessary reduce cost through the use of lower horsepower. The problem, as the author sees it, is not to unload airplanes on the public, but rather to educate the public to the necessity, convenience, and safety of the airplane. This certainly cannot be accomplished at the present time by inferior quality.

The military designer must be a specialist on armament installation. The commercial designer also must be familiar with details other than the design of the structure of the airplane and its component parts. He not only has to contend with such problems as stability, controllability, especially at low speed, fire hazards, and easy-riding qualities while taxying, but must also be thoroughly versed on coach design, interior finish, heating and ventilating, and other similar requirements affecting the comfort of the passengers and crew. It is extremely necessary that a great deal of attention be given to these latter items. It is interesting to realize that the extensive use of brakes and even tail wheels on military airplanes was adopted only after being successfully developed and used on the commercial airplane.

A problem which has not yet received sufficient attention on the part of the commercial designer is the prevention of noise and vibration. Passing out cotton to be stuffed in the passengers' ears shows thoughtfulness on the part of the transportation officials, but is certainly unsatisfactory and only a half-hearted solution of the problem. Slower propeller-tip speeds, exhaust mufflers, and insulation of cockpits against noise and vibration must be studied and adopted by the designer if air transportation is to be a success.

Manufacture

At the present time the manufacturer of military airplanes on the whole requires and uses more extensive equipment and employs a higher grade of experienced personnel than is true of the commercial manufacturer. Basically, the military airplane is the last word in refinement of design and light weight and is the chief reason for the foregoing condition. Equipment such as heat-treat furnaces for both steel and dural, sand-blasting equipment, swaging machines, numerous lathes, milling machines, grinding equipment, several sizes of punch presses, hydraulic presses, shapers, tube-bending equipment, special woodworking equipment, and special equipment for fabricating parts from dural and sheet-metal parts are essential in the manufacture of military aircraft. The foregoing equipment is used in the manufacture of commercial airplanes, but for the most part only by manufacturers who are contractors to the U. S. Government. The tendency in commercial construction to build economically limits the use of special equipment to as small an extent as possible, especially in the case of equipment used primarily as a means of weight reduction in the airplane with a resulting increase in cost.

The following are a few examples of design and construction which, although permissible on military aircraft, are prohibitive on commercial aircraft if they are to be built at a figure low enough to insure sales:

(*a*) Beams fabricated of dural sheet employing either box or latticed construction assembled and often constructed almost entirely by hand.

(*b*) Comparable with this construction is the tubular steel beam with latticed tubular webs which is heat-treated after assembly.

(*c*) Fuselage of monocoque metal construction requiring a great amount of hand forming and hand riveting.

(*d*) Fittings and parts requiring extensive machining operations and heat treatment as a means of weight reduction.

A number of planes especially in the larger types or high-performance class embody a number of expensive manufacturing processes in their construction. Such planes, however, are being sold to operating companies, and the number that have been sold or that will be sold is limited. It should be recalled that, with the exception of airmail carriers, none of these companies is making money, due in part to the high cost of flying equipment. The class of people to whom airplanes must be sold in order to insure quantity production are the individual or small-firm owners. This class will not buy unless the price is low, which naturally means inexpensive construction. It is quite true, of course, that the present expensive construction could be very appreciably reduced in cost if produced in sufficient quantity. However, there are numerous arguments against large-quantity production. In the first place it is problematical whether there would be a sufficient market for the quantity production necessary to permit of an appreciable price reduction. The building up of a market must be a gradual process of education, familiarity, and understanding of the possibilities of the airplane on the part of the public, accompanied, as the market grows, by a similar increase in production and by improved methods of manufacture. There is ample precedent in other branches of industry for the truth of this statement. Another reason against extensive tooling and jigging in the manufacture of a certain model is that production over a relatively short period of time will inevitably fall off due to the airplane becoming obsolete as a result of the constant changes in the art.

Even though the production of both military and commercial aircraft is relatively small, the commercial manufacturer has one distinct advantage over the military manufacturer in production control. This is the matter of changes. The Army and Navy are realizing more and more the condition which results from introducing changes during the course of production. However, the military manufacturer still has this problem to contend with, and it still causes him many a sleepless night. In the majority of cases, the cost of changes in military airplanes is paid for, but the actual final cost to the manufacturer can hardly be calculated. Production is a process comparable to the workings of a machine where the assembly of each part of the airplane can be likened to a cog in a train of gears. To disturb the workings of this machinery it is only necessary to throw one of these cogs out of mesh and it will have its effect on nearly every other cog in the train. The author has seen a whole production line held up because of a slight change in mounting the fixed gun. Until this change was completed the entire fuselage installation, as well as the assembly of landing gears, wings, and tail was held up. Not only were production schedules disrupted, but other work had to be found for the idle units affected, resulting in still additional changes in the program. Inasmuch as a military airplane demands the utmost in perfection, changes in design and construction are often excusable, but it is always possible to keep these changes down to a minimum by careful testing of the experimental or previous production articles. It often happens that a change made without service testing proves less desirable than the original part or assembly. Changes invariably introduce weight because of the fact that they are not an inherent part of the original structure but rather something additional. Enough such changes may so influence the final weight of the airplane as to make it much less satisfactory than in the original state.

In the case of the commercial airplane the company may thoroughly test the experimental article to its own satisfaction. It is possible then to run a predetermined number of airplanes through production with no changes whatever. At least the company itself is master of the situation, deciding whether a change is absolutely necessary from the possible effects on sales and is not influenced by a definite decision from the customer. Previous to the release of a new production schedule all necessary changes can be incorporated as a part of that production at the very beginning of the schedule, thus preventing any holdups later.

Another factor which makes the cost of military airplanes higher than commercial airplanes is government inspection. On the whole, government inspection is desirable and often very necessary. However, it does affect the cost of the finished airplane in that it introduces another cog in the train of gears. It is impossible to prevent production holdups due to delay in either government or company inspection. With no control over the government inspection system the contractor cannot affectively speed it up by pressure or overtime work. It often happens that the subject of rejection is of such a nature that even after a protracted discussion it is difficult for the resident government inspector to make a final decision, and it is then necessary to hold up production awaiting a final decision from headquarters, which naturally takes time. If the part in question were for a commercial airplane it could be rejected at once. Even though slightly defective or not in accordance with the drawings, the company could use it if it did not too seriously affect the final quality of the product. Or the company could balance the cost of rejection against the final effect on present or future sales of the airplane. In comparison, if the government is paying for a certain specified article, it naturally expects to receive that for which it has contracted.

Materials used in airplane construction also affect the final cost. All military airplanes are built from materials meeting rigid government specifications. This material being of the highest quality, naturally commands a higher price. The commercial manufacturer can here again carefully compare the use of certain materials with any possible effect on sales and many find it desirable to use less expensive material without feeling that it reduces in any way the quality or value of the finished article. As often happens each of two articles, accessories for example, may be equally good from the standpoint of the manufacturer, but only the one approved by the government can be used on military airplanes. The A. & N. standards have been a great help in simplifying the procurement of material for government contracts. It is believed highly desirable for commercial manufacturers to adopt these standards wherever possible—first, because the material used on commercial airplanes should be, so far as strength and safety requirements are concerned, the best obtainable, and, secondly, standardization in material and parts simplifies procurement and reduces costs.

Sales

Perhaps the chief difference between military and commercial sales is that in the former the sales department deals with a large organization while in the latter it deals with an individual. Commercial airplanes are bought by organized transport companies, but even in this case only a few individuals connected with the company are concerned with the actual purchase of the airplane. Designing and selling airplanes to separate individuals, each with a different idea as to what he wishes to purchase, is quite different from selling to a large organization which desires a particular type for which there are definite specifications as to load carried, performance desired, and even the motor required.

In commercial sales it is necessary for the sales department to

determine upon one or more types of airplanes to be manufactured, without, in the great majority of cases, even consulting the customer as to his wishes or desires. It is necessary for the sales department to anticipate them and gage, as carefully as possible, the price at which a particular model will be salable as a production article. It is then necessary for the engineering department to design accordingly. Even though the airplane when built is not entirely up to expectations or is inferior to the product of a competitor, the sales department still has a reasonably good chance of making individual sales either through expert salesmanship or through the inability of the purchaser to pass expert judgment on the article he is buying. The purchaser of a commercial airplane must rely, to a very great extent, on the integrity of the salesman, except possibly with respect to flying qualities which, more often than not, are determined with a light load. It is impractical to put the airplane through a long series of tests to obtain performance and detail flying qualities since the time required in a demonstration test is usually a matter of minutes rather than days and possibly weeks. The average commercial customer is much more apt to be impressed by a good line from a clever salesman than by anything he can learn in a fifteen-minute flight, especially if the airplane is being demonstrated by the salesman who through experience can make a so-called "crate" handle like a pursuit ship.

The sales procedure which will bring the largest number of ultimate sales must be predicated on a high-quality airplane, having the best possible characteristics. This can be done by very careful design, testing, and changes. It will first of all sell the salesman, who will naturally be enthusiastic. If in addition he is armed with honest data as to performance, a reputation can be built up which cannot fail to insure ultimate sales volume.

Military sales on the other hand are conducted quite differently. As a general rule airplanes are purchased on a basis which permits the service to carefully consider one or more articles of a particular type. Unless the airplane to be constructed is built entirely on "his own" by the contractor, which happens only in the minority of cases, the design is carefully considered either by a board of officers or by various officials who are considered experts in their particular line. Specifications embodying, in considerable detail, exactly what the service demands or requires are drawn up for the contractor to follow. The contractor's engineers carefully discuss the preliminary plans submitted to the service with the board or corps of experts and a very definite understanding of the airplane to be constructed is obtained. The contractor and purchaser are then in a very close agreement as to the exact requirements and just what product is contemplated. Such selling is basically through the engineering rather than the sales department. Aggressive sales ability in the usual sense is of little avail unless the engineer himself can sell his job to the engineers of the service purely on the merits of his design and on his ability to produce. A language is spoken which is clearly understood on both sides and facts are the only arguments that count. A somewhat unsatisfactory condition exists in the calling of a board made up of a group of officers experienced with respect to the particular type being considered for approval, either in the preliminary design stage or as the first experimental article. Although the members of such boards invariably constitute the pick of the service in so far as judgment and ability are concerned, they are seldom permanent members. For example, a board may be called to approve the "mock-up" and preliminary designs of a newly proposed type. Later, when the first experimental article is tested, which may be after a period of a year or more, a new board is called which unfortunately often consists of an entirely different group of officers. They are very apt to be a bit prejudiced with reference to the findings and recommendations of the previous board, especially so if the findings and arguments of the latter are not carefully discussed or considered. Changes are recommended which could not meet the approval of the original board. This results in an unfavorable condition in so far as the contractor is concerned, especially if considerable design modification is necessary. If it were possible to pick at least 60 per cent of the members of each new board from members of the old board there might be a decided improvement in the foregoing condition.

Even though the contractor decides to build an airplane entirely on "his own," he invariably obtains unofficial approval of the design by determining either through contact with various competent individuals in the service or by actually submitting preliminary layouts and specifications for general approval and criticism.

The procedure of building on "his own" is very desirable from several viewpoints. In the first place, the contractor is able through his engineering organization, if the latter possesses the necessary experienced personnel, to obtain a very good picture of the service requirements. This can be done without being unduly handicapped, in his desire to turn out an acceptable article, by the individual opinions of a few official experts whose duty it is to make decisions. This statement is not meant to be derogatory in any way. It is quite evident that the acceptance of a particular type, in so far as quantity production is concerned, is dependent on the opinions of a greater number of persons who will use the airplanes under actual service conditions. It should be easier, therefore, for a competent engineer, entirely unprejudiced, to intelligently arrive at definite conclusions with reference to airplane requirements rather than to depend upon the judgment of a relatively few individuals. It may also be the case that the contractor has a particular "hot" idea, the worth of which can only be proved by actual construction of the airplane. He may consider it well worth while to gamble a certain amount of money on the strength of his belief.

Further, when building on "his own," the contractor is not affected by government inspection. The article will later be approved from this standpoint, especially in so far as it affects later production. But if he is experienced, neither the contractor nor the service itself need be unduly concerned with this point. Also, the contractor is freed from the necessity of meeting certain delivery dates. However carefully these dates may have been estimated, any error is naturally on the low side, and either a great deal of embarrassment results or the job is rushed through too quickly, with the usual result of overweight, poor design, and poor workmanship and finish.

Another advantage of building on "his own" is that the contractor retains all design rights at least until after the completion of a production contract. Inasmuch as he is then all tooled-up for production he should be able to put in a low bid on new production and still make money. An extremely unfortunate condition exists in the official laws controlling the letting of government contracts. They require under certain conditions that the contractor sell his design rights, with the first experimental article, which may contain a number of features actually classified as or bordering on inventions. In case his bid was low on the latter, as a result of keen competition and in order to be sure to obtain the contract, his production bid may have to be somewhat high in order to make up for experimental losses. In the event that a competitor bids lower on the production contract he gets the bid without having to stand the original engineering costs and can be reasonably sure of making money on the contract. Many offer the argument that the contractor uses poor business judgment in making his original experimental bid low simply to get government business, even at a loss. A recently published opinion by an official of one of the large aircraft corporations refers to this practice as "cut-throat competition." No doubt there is

some basis for such a remark, but on the other hand it is equally true that a contractor may find that his bid was in error due to his not being able to estimate accurately on certain new design features or types of construction. Rather than turn out an inferior article he accepts the loss and turns out a creditable but expensive airplane only to find out later that he has lost a much hoped-for production contract. In any case the situation, as it exists, is not conducive to developing the very best in military aircraft unless we agree that this can be accomplished by the contractor building on "his own." Even this procedure is apt to be a gamble.

In conclusion it is believed that it would be a great deal more difficult for a commercial manufacturer to successfully enter into the military field, assuming no previous military experience on the part of the personnel, than for the military manufacturer to enter into the commercial field even though inexperienced in this branch of the industry. This would be especially true in the latter case if production were limited to the higher-priced, higher-performance class of airplanes.

AER-52-27

The Construction and Operation of Gliders

By GILBERT G. BUDWIG,[1] WASHINGTON, D. C.

The construction, operation, and maintenance of gliders present problems for which there is little precedent. From the regulatory standpoint, the rules of the Department of Commerce will permit licensing of those built prior to October 1, 1930, by passing a satisfactory visual inspection and test. After that time, the construction of gliders will come under more severe rules for licensing.

THE glider situation is a rather comprehensive subject for discussion, and it is difficult to determine what phases of this rapidly growing activity should be reviewed here in order to serve the most constructive purpose. The construction, maintenance, and operation of gliders present problems for solution for which there is little, if any, precedent. However, in light of experience, certain conclusions suggest themselves and it is upon these points that this paper will be based. Early this year the general interest in gliders indicated the necessity for constructive regulation. The Department of Commerce undertook the problem, and as a result, certain amendments to the Air Commerce Regulations, including the Airworthiness Requirements, have been made. As all are probably aware, the policies that the Department has adopted are a direct result of innumerable recommendations and suggestions which were received from those interested. In addition, a number of conferences, both formal and informal, were held with a view of determining how the glider situation could be best handled from a regulatory standpoint. It was finally decided that an amendment to the Airworthiness Requirements, so far as gliders and light aircraft were concerned, was advisable. Therefore, suggested amendments were circulated upon which comment was invited, although a provision was made that the suggested amendments could be used in the interim as a basis for obtaining Approved Type Certificates for such types.

However, due to the substantial number of gliders which have already been built and are in operation, and the inability in most cases of the manufacturer or builder to furnish drawings and stress analyses to the Department for approval, gliders built prior to October 1, 1930, will be licensed on passing a satisfactory visual inspection and test. Gliders built after October 1, 1930, must, however, come under the following three general classes to be considered eligible for license:

1 Gliders manufactured under Approved Type Certificates. This corresponds to the present procedure involving the licensing of airplanes which are built under Approved Type Certificates.

2 Gliders constructed by any one provided they are built in accordance with specifications and designs previously approved by the Department of Commerce. This permits the construction of gliders by any one whosoever, provided they are built in accordance with an Approved Type Certificate and specifications.

3 Gliders not manufactured under Approved Type Certificates, but which meet the requirements for such a certificate. This covers gliders which meet the requirements, but for which an Approved Type Certificate is not desired, perhaps due to production being discontinued or the construction of a single glider only.

In view of the great interest shown by the general public in the use of gliders, the type of operation to which the glider will be subjected and the more favorable weather conditions under which a glider will be flown, the Department felt the qualifications and restrictions of glider-pilot licenses should be more lenient than those of any class of airplane pilot. The following are the requirements set forth in the Air Commerce Regulations to cover such glider pilots:

An applicant for a commercial glider-pilot's license must pass the present physical requirements for a private-airplane-pilot's license, and in addition, must satisfactorily pass a flight test consisting of normal take-offs and landings, a series of gentle and moderate banks, precision landing, and 360 deg. turns both to the left and to the right. The holder of this grade of license is entitled to fly commercially and to instruct students for hire in licensed gliders.

A non-commercial glider-pilot's license has been established for which there is no physical examination, and such licenses will be issued to those who are able to demonstrate their ability to pass the flight tests involved. This license will entitle the holder to fly licensed gliders for pleasure or sport, but not for any commercial purpose. They cannot, of course, instruct for hire. The flight test required for this grade of license will be the same as that for a glider-pilot's license with the exception that the 360 deg. turns will not be required.

The glider-student-pilot's permit issued by the Department will enable any person to take instruction in licensed gliders from a licensed glider pilot. These permits are issued by supervising inspectors or field inspectors of the Department to any person upon application.

There is no physical requirement for this permit nor for the non-commercial pilot's license other than having the applicant sign a statement to the effect that he or she has good vision in both eyes either with or without glasses, complete use of both legs, both arms, and does not suffer from any constitutional disease or has ever had convulsions or fits.

Design and Construction

As stated previously, in light of increasing experience, a revision of the Airworthiness Requirements was advisable. The design load factor specified in the proposed amendment—6 for the

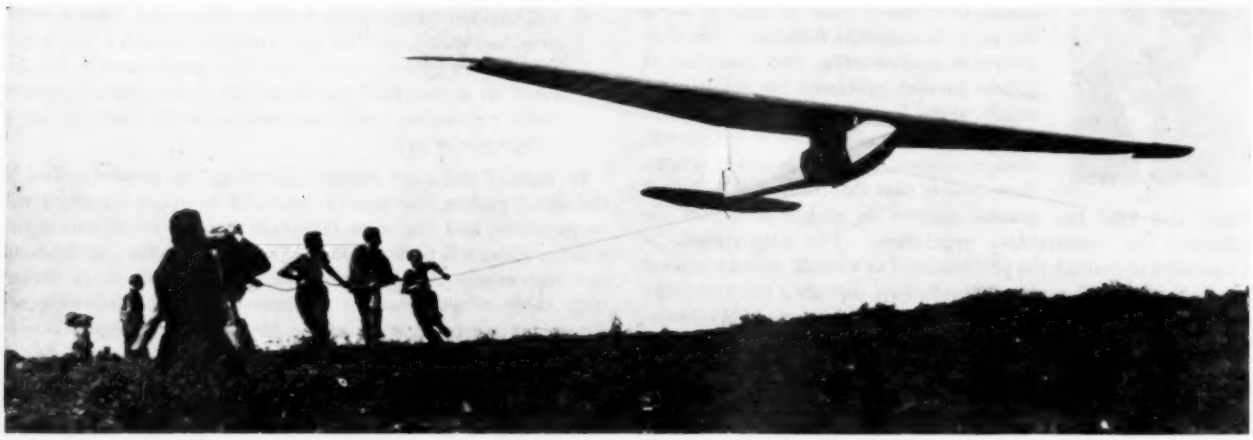
---

[1] Director of Air Regulation, Department of Commerce. Mr. Budwig was born in 1895 at Cleveland, Ohio. He has been connected with commercial aviation since 1916 and was employed during the World War as civilian instructor stationed at Chanute Field, Rantoul, Ill.; Kelly Field, San Antonio, Tex.; Rockwell Field, San Diego, Calif.; and March Field, Riverside, Calif. He flew the air mail immediately after the war, and then did two years of "barnstorming," and later an amount of free-lance test piloting. Mr. Budwig became affiliated with the Aeronautics Branch of the Department of Commerce in June, 1927, as aeronautical inspector, was appointed Chief of the Inspection Service in May, 1928, and was made Director of Air Regulation on October 4, 1929. He is a member of the Professional Pilots Association and the Early Birds.

Presented at a meeting of the Aeronautic Division with the Chicago Section, Chicago, Ill., August 25, 1930, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

high angle of attack condition, 4.25 for the low angle of attack condition, 2.5 for inverted flight, and 5 for landing conditions—was based upon aerodynamic data and a study of existing types. As a result of this study, it is believed that these factors are equally applicable to all types of gliders. As will be pointed out later, however, it is not always possible to design the structure and detail parts exactly to these factors. To accommodate handling on the ground and to provide for unusual landing conditions, it is generally necessary to make the fittings and their component parts considerably larger than would be necessary to meet the minimum requirements. It is felt, therefore, that these strength requirements should be considered as an absolute minimum, particularly for training types.



As far as structure and aerodynamics are concerned, the problems encountered in glider design are fully commensurate with those of the smaller airplanes. Aside from the stalling speeds involved, there is little or no difference between a glider flight and a "dead stick" landing with powered aircraft. It is essential, therefore, that the same degree of structural strength and aerodynamic control be provided for the former as for the latter. Although the structure of the glider is possibly somewhat simpler than that of the airplane, the problem of control, particularly lateral, is more difficult of solution.

In the case of the soaring glider, moreover, one may venture to state that its design is an art comparable with the best efforts in airplane design where weight, control performance, and aerodynamic finesse play such an important part.

Wings

In the case of primary and secondary training types, the conventional two-spar rectangular plan form of construction predominates. Due to the fact that these gliders are flown and as a general rule handled by beginners, it is essential that the wing structures have ample strength and rigidity. This is accomplished by incorporating in the design a double system of drag-wire bracing, liberal use of plywood at wing tip and wing butt, a substantial aileron false spar, adequate wing-tip skids, a well-reinforced leading edge, and a taut, securely attached covering. Wing panels incorporating all of the above-mentioned features have been constructed with a weight of less than 0.60 lb. per sq. ft. The wing covering should be provided with inspection doors or transparent panels at critical points so that damage occasioned by a hard landing or by dragging a wing tip will be discovered before the glider is flown again. The wing-tip skids should be deep enough to protect the aileron and should be so designed that they will fail before any damage is done to the spars. The wing-attachment fittings must be designed with an ample margin of strength to resist the drag loads imposed by wing-tip landings. In the case of the primary training type, these drag loads will materially exceed any load that would be imposed upon the fitting in flight. It is advisable to have the cabane fitting in the landing-wire system so designed that it will fail before the attachment fitting at the outer strut point pulls out. The reason for this is that it is a much simpler proposition to repair the fitting at the cabane than it is to remove the fabric and replace the fitting at the strut point. Although it is not a requirement of the Department, it is strongly recommended that when hard wire is used for the external bracing of the wings, double wires be used throughout.

The more advanced types, i.e., the soaring gliders, use single-spar construction or closely interbraced two-spar design. Due to the high aspect ratios and large spans involved, torsional rigidity becomes a very important matter. This is ordinarily obtained through the use of a reinforced leading edge in combination with the spar or spars which are usually of the box type

Launching a Glider

Fuselages

Most glider fuselages are constructed either of spruce and plywood, or of steel tubing in either a single central truss or along the lines of conventional airplane fuselages. Here again the requirements of rigidity and provision for handling will determine the design of a large portion of the structure of primary- and secondary-training type. In the case of soaring gliders, due to the greater proportion of tail-surface area to size and weight of glider, the design of the structure after the wing will ordinarily be determined by the required tail-surface loads. The proposed amendments to the requirements specify a loading of 12 lb. per sq. ft. for horizontal tail surfaces and 9 lb. per sq. ft. for vertical tail surfaces. It has been found that these loadings result in a fuselage structure that possesses sufficient rigidity and stands up well under service conditions. In the construction of the rear portion of elementary training-type gliders, the design should be stronger than is necessary to support the tail-surface loads. In the design of the forward portion of a glider fuselage, the most important element to be considered is the protection of the pilot. He must be protected from hard landings, side-slip landings, striking obstructions, and nosing over. In order to accomplish this, the structure around the pilot should have an ample margin of strength. The vertical members just behind the pilot must bear the brunt of hard landings. If a wooden support is used, it

should be well taped and doped to prevent splintering. The structure underneath the pilot, including the landing gear, should be capable of withstanding severe side loads. In order to protect the pilot's legs, the skid proper should be extended well forward. Experience to date has shown that a slight additional weight in the structure at this point is of considerable value from the standpoint of safety.

Control Surfaces

As gliders are operated at speeds considerably lower than those encountered in powered flight, it is obvious that, in order to provide adequate control, the ratio of control-surface areas to wing areas must be considerably greater. This is particularly true in the case of rudder and ailerons. This increase in size introduces the problem of rigidity. In the case of training types, the horizontal and vertical tail surfaces are usually externally braced, and it is essential that this bracing as well as the attachment to the fuselage structure be carefully designed. Because of the use of automobiles for towing, it is necessary that the tail surfaces be investigated for flutter. As towing speeds in the neighborhood of forty to fifty miles per hour are often reached, speeds in excess of these values should be used in testing for tendency to flutter.

When wing-tip ailerons are used, care should be taken to investigate the torsional rigidity of the actuating tube and particular care must be taken to protect the aileron from damage in handling or in striking the ground.

Control System

There should be no hesitancy on the part of a designer to provide ample margins of strength of cable, fittings, and horns in the construction of a glider-control system. The handling and disassembly that a glider undergoes out in the field would prevent a theoretically designed system from being reliable very long under service conditions. The same care to eliminate friction and wear that is observed in airplane practice should be applied to glider controls. The use of standard turnbuckles, shackles, pins, and bolts, is advisable. Although the control system may be greatly overstrength at different points, it will be found that the confidence it inspires in the pilot will amply repay the extra expense and material involved.

Equipment and Furnishings

The strength of the safety belt and of its attachment to the primary structure is one of the most important safety features. The Department's requirement of the strength of 850 lb. for the belt and its attachments is considered a minimum. It is desirable also that the seats provide some lateral support for the pilot in order not to throw eccentric loads on the safety-belt attachment.

Considerable care should be exercised in the design of the towing hook and its release mechanism. The release lever should be conveniently located, easily operated, and positive in its action.

Maintenance

The maintenance of gliders, with the exception of freedom from power-plant troubles, is similar to that encountered in the operation of airplanes. However, due to rougher handling and the operation of gliders over less favorable terrain by less experienced personnel, it is obvious that gliders are subject to a greater amount of minor damage. They should, therefore, be more frequently and adequately inspected. The Department has taken recognition of the repair problems involved to the extent of permitting minor repairs to be made under the supervision of a licensed airplane mechanic without the necessity for the usual departmental inspection; that is, provided a notation to this effect has been made in the log book over the signature of the licensed mechanic responsible.

If, however, the damage to any component, such as the fuselage or the wing, exceeds 50 per cent in the opinion of the inspector, the repairs must be approved by a Department inspector before the glider again may be operated. As in the case of minor damage, proper notation shall be made by the responsible mechanic, and in addition there must be an endorsement by the approving Department inspector.

This liberal policy with reference to the repair of gliders was purposely established so as to facilitate the repair of gliders by their operators. Among other things, the policy eliminates the submission of technical data for the approval of repairs as is now the case in the repair of aircraft. It is believed that more frequent and adequate repairs will result from this facilitation of approval.

Glider in the Air

Operation and Student Training

Too much importance cannot be placed on the necessity for intelligent glider operation and there is definite need for improvement throughout the country in the methods used. There is also a somewhat general disregard for fundamental safety requirements. Specifically, there are innumerable cases of unqualified pilots who are violently catapulted or towed by auto-

mobiles to hazardous altitudes. This practice results not only in bodily injury and occasionally with fatal results, but in considerable damage to gliders as well, all of which has a decidedly detrimental effect on the glider movement.

Experience dictates that a student, before being allowed to leave the ground in a glider, should be given a thorough course in "ground flying." This generally consists of placing the student in a primary-type glider faced into the wind, on level ground, thus permitting him to practice the use of aileron control. This can be done in an average primary glider with a wind of from ten to fifteen miles an hour. By this method, a student is able to learn the feel of the aileron control by moving the stick from side to side and observing the action obtained. Following considerable practice at this, he may then be shown the use of the rudder and the ailerons at the same time, the coordination of these controls under conditions analogous to that during actual flights. When it is assured that the student has a reasonable knowledge of the effect of these controls, together with a fundamental knowledge of the use of the ailerons, his training may proceed.

The method which has apparently been the most satisfactory in this country for training from this stage seems to be conservative, well-directed automobile towing. However, at this stage of instruction, great care should be exercised and too much importance cannot be placed on the skill of the person handling the automobile. The student should be given innumerable trips along the ground at speeds insufficient to permit him to rise, for the purpose of teaching him the coordination of the controls involved. It is only after a thorough training in the use of the controls that the car should be run at speeds sufficient to enable the glider to leave the ground for even a short distance. When, however, it is decided that the student has sufficient knowledge to permit short jumps, the automobile or a catapult may be used for the purpose. Very short flights should be made and at very low altitudes, probably not exceeding five or ten feet, until the student has learned to some degree the hazards involved in the incorrect operation of any of the controls. Catapult launchings should be skilfully handled and the altitudes to which the glider can reach should be gradually increased. Unusually forceful catapulting should be restricted to experienced pilots.

When the student has reached the stage where he can be towed or catapulted to altitudes of twenty-five feet or more, he may then be permitted to practice gentle turns. This will enable him to familiarize himself with the peculiarities of the controls and the difference in control at various speeds. Great care should be taken by the instructor in charge of these flights to impress on the student that speed is essential to flight and that where there is no speed there is no control. By this time, the student should begin to understand the principles of flight and the advisability of smooth flying. In view of the fact that practically all gliders built in this country have relatively fast elevator action and relatively slow rudder and aileron action, the judicious use of the elevator control should be stressed. A student's advance in his instruction from this point is largely a matter of experience during which time strict supervision should be maintained.

It has been our experience that glider clubs actually function but an average of a few days a month, the balance of the time being devoted to repairing the glider. This condition, for the most part, is due to inadequate instruction and to poor structural details of the gliders involved. It also should be borne in mind that the present necessity for constant maintenance is having a very decided detrimental effect on the glider movement. The responsibility in most cases lies directly with the manufacturer for not making necessary corrections in design or construction as may be dictated from operation experience. Defective material has played an important part in a number of disastrous crashes. In some cases the material used is of such poor quality that it seems unbelievable that any one familiar with aircraft construction could have permitted its use.

It seems likely that this condition will, to a great extent, be eliminated when the use of approved gliders is more general. A majority of the states require that aircraft operated in interstate commerce be federally licensed, which of course includes gliders. It appears likely that state enforcement, when applied to gliders, will eliminate unairworthy equipment.

It is apparent that consideration is being given to the manufacture and the distribution of small "kicker" engines for use with gliders, thus converting them to power equipment. There is considerable development already under way to manufacture a light engine of low horsepower for this purpose. It should be borne in mind that when this is done the glider becomes a low-powered airplane and is subject to the requirements for such craft, which are set forth in the proposed revisions to the Airworthiness Requirements.

The interest in glider flying has increased tremendously, but unless the situation is adequately and intelligently regulated, it seems likely that there will be a decrease in interest due to causes which are for the most part avoidable. It would be well and to the interest of all concerned if more attention were paid to flying characteristics and structural details of gliders and adequate instruction in their use. Also, many disastrous accidents would be avoided if the use of unairworthy gliders were discouraged.

In conclusion, it might be well to mention that the present excellent cooperation which is enjoyed between the Department of Commerce, the glider manufacturers, and various clubs and associations will go a long way toward finding a satisfactory solution for the adequate construction, operation, and maintenance of gliders.

Discussion

DONALD F. WALKER.[2] The splendid work of the Aeronautics Branch of the Department of Commerce has resulted in the establishment of sane regulations and will permit, at considerable sacrifice to the personnel of the department, of proper inspections and adequate supervision of the design, construction, and flying of motorless aircraft. The National Glider Association is pleased to avail itself of this opportunity to again thank Colonel Young and his staff for their cooperation and to ask that no opportunity be allowed to pass for urging on the representatives in the Congress of the United States the vital importance of providing the Aeronautics Branch with ever more adequate appropriations for their essential work.

In no other line of manufacturing can a slight defect in materials, a small error in design, or poor craftmanship result in so serious, indeed often fatal, accidents as in the manufacture of aircraft, including gliders. In no line of operation has the man at the controls so little latitude as regards human error as in flying. Therefore strict control must be exercised, while at the same time good judgment must be used, to see that the exercise of authority is not carried so far as to cripple or stop operations, inventive genius, and experimental research. In only one instance do the rules laid down by the department pass over the line, in the writer's judgment, and that is in the matter of requiring licensed airplane mechanics for certain repair work, and even here the department is showing such tact in administration as to remove the greatest part of the handicap.

It is true that there are few actual flying days per month for the average club. However, it must be remembered that only Saturday afternoons and Sundays and holidays are available

[2] Manager, The National Glider Association.

for flying unless the club members have flying facilities much nearer their homes than has the average group. On the other hand, minor repairs can be made at night in small workshops in the neighborhood. Yet there are too many repairs necessary.

So far, the emphasis in America has been laid on providing gliders at the least possible expense to the clubs and others interested. It is possible that the desire to lower the initial cost has actually increased the long-term cost. It is argued strongly by several clubs that the primary training gliders are too cheap; that they do not stand up well under any training methods; that they are dangerous for any but the simplest auto-towing, generally conceded as the most efficient method of training; and that they can be neither easily soared nor safely airplane-towed. While it is admitted that they are relatively easy to repair, they point out that continuous repairs afflict the owners and kill interest. It is generally conceded that a serious "crack-up" in a primary is very likely to mean the hospital or even death for the pilot. True, it can be argued that the primary is often abused and should be used for limited purposes, but when that is said it is admitted that a ship that can be used for all purposes including training and that gives higher performance and greater safety to the pilot is superior for initial purchase.

The result has been the development of the utility glider in America. The utility glider is one that can be bought as cheaply as possible consistent with qualities permitting every use by the owners.

These utility gliders have not yet reached perfection. They can always be further refined, but they are undoubtedly the best purchase today for the average club if it can raise the initial price, which is some $200 in excess of the average primary. These ships usually are on the technical border line between a primary and a secondary glider. In fact, as the utility glider increases in popularity and decreases in price, the very terms "primary" and "secondary," always arbitrary, will pass from use, and there will be stock utility gliders for everyday use and custom-built soarers for the wealthy and those of scientific mentality. Nor will the soarers in the ordinary "breaks" of weather, piloting, and luck win all the contests, although theoretically they should.

The utility gliders are now in production with wing areas not larger than that of a primary, some being tapered for higher performance and some being square-tipped for easier repair. Nearly all the manufacturers offer a choice of wings, some being larger and of higher performance than others. One can buy a small set for training. While training, they can save their money, and when they have completed their training, they can buy a bigger set for advanced work.

It is in the fuselage that the utility glider comes into its own. They are of steel tubing, enclosed, and equipped with one center wheel and sometimes with a skid. The wheel is equipped with a brake for spot-landing purposes. These fuselages are just as light as wood, and while theoretically no stronger, when they reach the point of failure, they bend and do not splinter and break. Serious accidents where such ships have spun and dived into the ground have resulted in no harm to the pilot. Only one death out of 16 accidents has occurred in this type of ship, and in that case a good pilot in satisfactory flight was seen to fall forward, hands outside the cockpit, and dive out, it obviously being a case of heart failure, fainting, or something of that kind. These ships are stressed for airplane towing and cloud and storm soaring, as strenuous a form of flying as many outside the services will ever engage in. They have been used in all these forms of flight and have held up. Captain Frank Hawks' "Eaglet" is one of them, and no glider ever put up with the punishment nor gave better performance than did that ship.

However, disregarding the "Eaglet" and its older sister, "Franklin 9491," as both were larger and more expensive ships than what is usually called a utility glider, let consideration be given only to what the little utility jobs have done. They have been used for months in auto-towing training, shock-cord training, and shock-cord licensing flights, where they secured licenses for pilots taking off from the same hills where they had tried for months to get licenses in primaries; they have been flown to the very limits of auto-towing advanced work; they have been airplane-towed successfully with the consent of the Department of Commerce; and, finally, Jack O'Meara, of the Baker-McMillen Company, hopped off at Elmira, N. Y., and made three flights of over one hour each, full soaring. What else can be done with a glider? If one has a great soarer built for certain conditions, he dare not risk it under different conditions. If one has a primary and is wise, he will train cautiously and nothing else. But one can go the whole route in the utility at less total cost because of fewer accidents, and if the insurance man is wise he will give ample coverage on life and limb and will gather in many premiums and pass out few benefits.

And, finally, if a glider can be towed by airplane, it is an airplane. The glider fraternity await only the appearance of the right motor to show how to shift quickly and easily from a glider to a light airplane.

AER-52-28

Some Improvements in Wind-Tunnel Balances Made Possible by Use of Vacuum Tubes

By FRED S. EASTMAN,[1] SEATTLE, WASH.

The paper presents some novel ideas on wind-tunnel balance design. It describes a new electromagnetic balance, which determines the current required to produce a balancing force. The claims are made, as against the motor-driven balance, that it is less costly, that it has no moving parts in the beam, is practically instantaneous in its response to sudden changes in force, can be quickly adjusted to almost any desired degree of sensitivity, and is readily adapted to recording devices to do away with the point-by-point method of obtaining curves.

THIS PAPER is divided into three parts. Part 1 deals with the difficulties encountered in the ordinary motor-driven balance; part 2 describes a means of improving such a device by using vacuum-tube control; and part 3 introduces a newly developed electromagnetic balance.

1 The Motor-Driven Balance

The automatic electric balance which is now in common use for measuring forces on wind-tunnel models may seem to be almost superhuman to any one who has had no experience with them. This is because the unsuspecting bystander sees a man press a single button, and immediately afterward several small weights begin to move to and fro on the delicate wind-tunnel balances. There may be as many as four or five of these balances operating at the same time, and each one moves its own little weight until its beam remains quite steady, with the little movable weight on one side of the fulcrum exactly balancing the aerodynamic force which is transmitted from the wind-tunnel model through a small wire to the other side of the fulcrum. As soon as all the balances become steady, the operator pushes another button, which stops any further movement of the little weights. He then proceeds in a leisurely manner to determine the forces which were acting on the balances, by noting the position of each of the several small weights.

This all seems so simple and yet so remarkable to the stranger that he fails to notice how long and patiently the operator has to wait before the moving weights become steady, and of course it would hardly occur to the bystander that the elaborate equipment before him may require frequent and careful attention to keep it in such perfect running order. Nevertheless, this is all perfectly true, and a brief explanation of the way in which these automatic balances operate is enough to suggest that a good supply of patience and persistence is required of any one who wishes to get satisfactory results from them.

A diagram of a common method of connecting these balances to a source of electrical energy is shown in Fig. 1. Since the real aim is to make the small electric motor, which is attached to the balance beam, drive the movable weight to the left when the beam tips clockwise and to the right when the beam tips counterclockwise, it is necessary to provide a means of automatically reversing the motor whenever the beam moves slightly one way or another. The control contacts at the right-hand end of the beam serve this purpose, since the current in the armature flows in one direction when the beam touches the upper contact and in the opposite direction when the beam touches the lower contact. The result is that, as long as the beam is balanced in the mid-position between the two control contacts, no current flows in the armature of the small motor, but the instant the beam becomes unbalanced in either direction, one of the control contacts closes the circuit through the armature, and since the magnetic field is present at all times, the motor starts to rotate and moves the traveling weight in the proper direction to balance the beam once more.

This much of the action of this weighing device is exactly as is desired, but unfortunately the traveling weight does not stop the very instant that it reaches the new position for balance, because its inertia carries it a little too far, so that the beam has

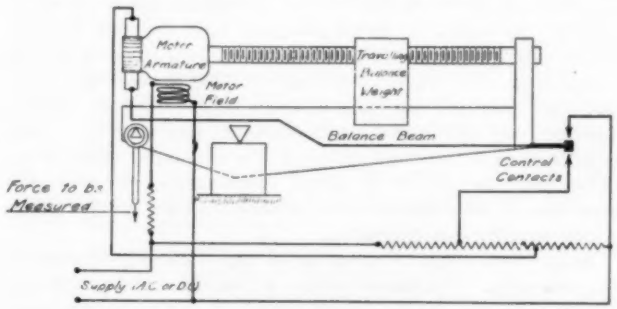


Fig. 1 Motor-Driven Balance

to swing slowly over to the other contact to reverse the motor and bring the weight back toward the proper position. If the traveling weight would always stop at the precise spot for perfect equilibrium, after the second or even the third reversal of the motor, the situation probably would not be particularly objectionable, but it must be remembered that the air forces on the wind-tunnel models are never absolutely constant, so that the position for equilibrium is continually changing very slightly, with the distressing result that if the traveling weight ever does reach a really steady condition, the chance of its remaining still for any appreciable time is extremely remote. To make matters worse, most of the testing work which is done with wind tunnels requires the use of three or more of these balances, and to be sure of accurate results all of them must be steady at the same instant,

[1] Instructor, Department of Aeronautical Engineering, University of Washington.

Presented at the Seattle Aeronautic Meeting, Seattle, Wash., May 28 and 29, 1930, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

so that the person operating the balances must wait patiently, with his finger constantly in readiness to push the button, if he hopes to catch a single instant during which all the traveling weights are motionless.

There is one very simple way of remedying this difficulty, but it seriously impairs the sensitivity of the balance. However, if great accuracy is not necessary, the control contacts may be separated so as to allow an appreciable movement of the beam, with the result that if the beam is slightly stable, small changes of force do not move it far enough to touch the control contacts. This has another great advantage because the contacts touch less frequently, so that there is less tendency for them to become burned and pitted when the connection is broken.

The importance of this last remark will be apparent if the action of the contacts is thoroughly understood. This action is best illustrated by imagining the beam unbalanced and one contact conducting the full armature current to the motor, which is driving the little weight toward the position which would balance the beam. As the weight approaches the proper position, the force between the contacts becomes less and less, until at the instant that the beam begins to swing there is no force pressing the two contacts together. Since the beam has a very large inertia compared with the very small unbalancing force, it moves very slowly and gives ample time for a very short electric arc to do some slight damage to the contact surface, even though the current is very small, probably less than a quarter of an ampere. Although the damage done by this one tiny arc may not be enough to harm the action of the balance, it is apparent that it will be a rapidly accumulating action, because the next time contact is made the sparking may start to occur slightly before the beam begins to drop. This is because the force between the contacts is not sufficient to press out impurities or roughness, and so the damage done this time will be much greater, and each succeeding time still greater, until finally the motor will operate sluggishly or not at all, because only a poor connection is made. It will then be necessary to clean the contacts carefully by hand, and this is not only a nuisance, but the frequent handling of the balance is sure to do some damage to the hardened knife edges which support the beam. It seems odd that these contacts cause so much more trouble than those on spark-ignition systems, but the reason is apparent when it is remembered that the ordinary make-and-break contacts are quite different in that they are pressed together very tightly and are drawn apart very quickly. These conditions tend to reduce sparking to a minimum, while on the other hand the extremely gentle touching and the very slow separating of the contacts on the balance beam are the very things which magnify this difficulty.

So far there seems to be no simple way of entirely eliminating this sparking. Condensers placed across the contacts will help the situation, but cannot entirely remedy it. Of course it is possible to reduce the current handled by the contacts, if the motor is reversed by controlling the field current instead of the armature current, but since the field has a higher inductance, sparking may be just as serious as in the case of higher current and less inductance. Moreover, it is very desirable to maintain at all times a very strong magnetic field to start the motor quickly and to aid in stopping it by means of the resulting magnetic losses.

Apparently no motor-driven balance can have all the desired qualities at one time. If extreme sensitivity is desired, the contacts must be close together, and the result is that more attention will have to be given to the contacts and more time will be required for the balance beam to obtain equilibrium. Assuming, for the moment, that the contacts may be kept clean and smooth, a reduction in the time to reach equilibrium without change in sensitivity might be obtained by decreasing the inertia of the moving parts or by increasing the accelerating and decelerating forces on the motor, and obviously neither of these alternatives allows much room for improvement. However, both the sensitivity and the time to reach equilibrium depend largely upon the ease and rapidity with which the circuit through the control contacts can be opened and closed, so that even the slightest sparking at these contacts is a serious disadvantage.

In conclusion, it may be said that aside from faults arising from mechanical design, such as lost motion in moving parts or improper damping devices, practically all the difficulties which occur in the ordinary motor-driven balance may be traced either to the inertia of the moving parts or to sparking at the control contacts, or to both.

2 Vacuum-Tube Control for Motor-Driven Balances

Granting that the two inherent faults of the motor-driven balance are the inertia of the moving parts and the sparking at the control contacts, it is apparent that, once a balance is constructed, the only way to improve its operating qualities without making any radical changes in its mechanical design is to reduce the contact difficulties to an absolute minimum.

As a possible means to this end an attempt was made to operate the motor-driven balance through a system of sensitive magnetic relays, so that the contacts would have to control

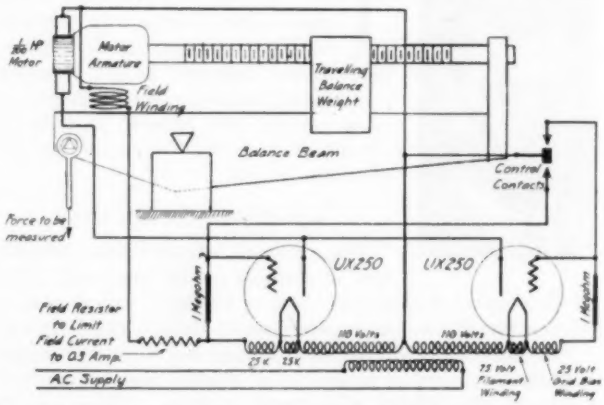

Fig. 2 Vacuum-Tube Control for Motor-Driven Balance, Alternating-Current Operation

only a very small current. However, a little experimenting showed that the brief interval of time lost in closing and opening the relays caused the weights to overrun the balance position before the current in the motor circuit was reversed, and the result was that the motor-driven weights had a very much greater tendency to oscillate back and forth about the position of balance. No attempt was made to remedy this situation by using quicker-acting magnetic relays, because the evident desirability of having absolutely instantaneous control over the current passing through the motor suggested the possibility of using the three-element vacuum-tube relay.

It is well known that the plate current of a given vacuum tube may be varied from zero to the maximum safe value for the tube by merely changing the voltage impressed on the grid, and, moreover, there is no measurable time lag between the change in grid voltage and the change in plate current. In this respect the vacuum tube is admirably suited to the needs of the electric balance, but it might be supposed that it would be impossible to operate the motors by means of the small plate currents obtainable from vacuum tubes using reasonably low plate voltages, preferably between 100 and 200 volts. However, the UX-250 vacuum tube will deliver a current of 0.25 amp. when a potential of about 95 volts is impressed on its grid and plate together, and it was found that this was ample to operate the

small $^1/_{200}$-hp. 110-volt motors used on the balances built at the University of Washington.

A good many different circuits were tried out while attempting to determine the simplest and most satisfactory method of connecting two UX-250 vacuum tubes so that they would control the motor on one of the balances. Figs. 2, 3, and 4 show three of these circuits which have been found to be satisfactory.

Fig. 2 shows what is probably the simplest way of connecting the vacuum tubes to the usual motor-driven balance. Since alternating current is used, any desired voltages may be obtained by means of a single transformer with a tapped secondary winding, as shown, or by the use of several separate transformers. To prolong the life of the vacuum tubes it is best to use the lowest plate voltage that will pass sufficient current to operate the motors, and it was found that 110 volts was sufficient for the particular balance used in the preliminary experiments. Therefore, the transformer shown in Fig. 2 has a 220-volt winding, mid-tapped to give two 110-volt windings, one for the plate of each tube; and at the two ends of this winding are the 7.5-volt filament supply windings which must be able to carry a current of 1.25 amp. The extra 25-volt windings are to furnish the necessary grid bias to cut off the plate current when the beam is balanced, and could readily be replaced with two $22^1/_2$-volt dry batteries, since very little current flows in the grid circuits.

When the balance beam dips down, a connection is made between the grid of the left-hand tube and the motor armature, which is at the same potential as the plate of the same tube. This means that both grid and plate receive the same alternating voltage, and since current will flow only when the plate is positive with respect to the filament, the motor armature receives a pulse of direct current during one-half of each cycle of the

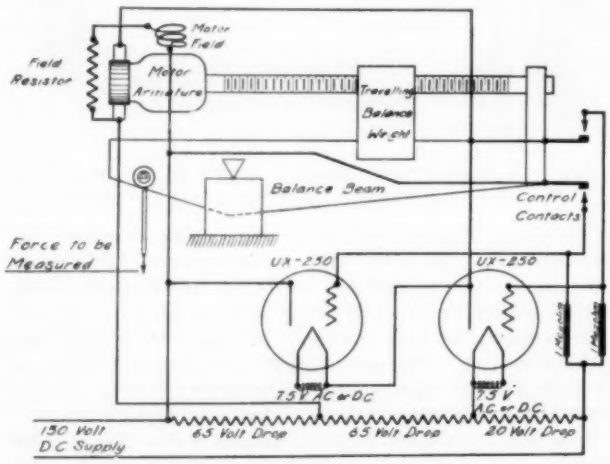

FIG. 3 VACUUM-TUBE CONTROL FOR MOTOR-DRIVEN BALANCE, DIRECT-CURRENT OPERATION

alternating voltage. Moreover, the same thing is true if the beam tips up, but in this case the right-hand tube will supply pulses of direct current which will be in the same direction through the armature, but which will occur in the opposite half-cycles of the alternating voltage. The result is that the motor develops a pulsating torque, the direction of which depends upon the polarity which the alternating field maintains during the particular half-cycles that the armature receives its pulses of direct current.

If this scheme is studied carefully, it will be apparent that the field current must be in phase with the armature current in order that the motor may develop the maximum possible torque. This was verified while trying out this circuit, and it was found that it is quite important to have a resistance of 400 ohms or more in series with the field winding.

No appreciable vibration was noticed which could be attributed to the alternating magnetic field or the pulsating torque of the motor, but since it is quite possible that some parts of the model suspension system in a wind tunnel might resonate with the slight vibrations that must exist in any device using alternating current, the direct current circuits shown in Figs. 3 and 4 were devised.

The operation of these two circuits is easily understood. Briefly stated, the vacuum-tube relays in Fig. 3 perform the

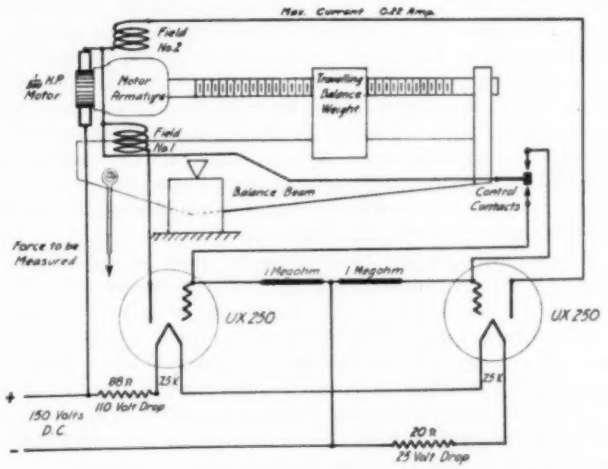

FIG. 4 VACUUM-TUBE CONTROL FOR MOTOR-DRIVEN BALANCE, DIRECT-CURRENT OPERATION

same duties as the control contacts in Fig. 1, so that the armature circuit is opened and closed by relays which operate instantaneously and have no troublesome contacts. The current which must be handled by the contact points on the balance is less than 15 milli-amp., and therefore these points may be made of very fine platinum wire striking against a tiny piece of platinum foil. Fine contacts, slightly pointed, will give better results than large flat contacts, because higher unit pressures may be obtained, thus insuring excellent connection even though the beam swings very gently one way or another. Moreover, positive and instantaneous control over the motors is practically insured by the fact that the sensitivity of the grid circuit of a vacuum tube is so great that contact resistances even in excess of 1000 ohms would not seriously impair the operation of the vacuum tubes as relays.

Turning now to Fig. 4, which is a diagram of the balance now in use at the University of Washington, attention is called to the extreme simplicity of connections. All the equipment which is required consists of the two UX-250 vacuum tubes, two 1-megohm grid-lead resistors, and two resistors capable of carrying 1.25 amp., one of which has a resistance of 88 ohms and the other a resistance of 20 ohms. Light globes may be used for the latter two resistors if desired. Two 75-watt mazdas in parallel will approximate the 88-ohm resistance, and one 50-watt 28-to-32-volt lamp will serve for the 20-ohm resistor.

The only alteration required to convert the ordinary electric balance to this new circuit is to replace the usual motor with one equipped with two field windings. In case it is not possible to obtain such a motor, an extra winding can often be wound on a form and slipped over the top of the original field coils of the motor. This was done for the balance now in operation at the University of Washington.

The reversing of the motor is accomplished by simply allowing

the current to flow through the armature and one or the other field windings, according to which vacuum tube receives a positive grid potential from the control contacts. The direction of the current is always the same through both armature and field windings, but one field is connected to drive the motor in one direction and the other field is connected to drive it in the opposite direction.

One difficulty which might become objectionable is the fact that, because the filament of the two vacuum tubes are connected in series for the purpose of decreasing the current taken from the line, the filament of No. 1 in Fig. 4 will be at a higher potential than that of No. 2. The result is that the potential, and therefore the current, between plate and filament is higher in tube No. 2 than in tube No. 1, so that the motor will tend to run a little faster in one direction than in the other. However, if the characteristics of the two vacuum tubes differ sufficiently, the plate currents can be practically equalized by simply putting the more active tube where it receives the least plate voltage. In any case it is a simple matter to equalize the current flowing through each tube by placing a few hundred ohms resistance between the upper control contact and the grid of tube No. 2.

Any ordinary electric balance can be made almost entirely free from contact troubles by using one of the vacuum-tube control circuits described here. Of course if the motor requires more than 0.25 amp. for satisfactory operation, it will be necessary to use two or more UX-250 vacuum tubes in parallel in place of each one shown in Figs. 2, 3, and 4. Moreover, it may be found necessary to alter the control contacts in some such manner as has been previously suggested, because some of the metals which are commonly used for contact points tend to coat over with a thin layer of a poor conducting oxide, and while this coating may not seem to have any harmful effect when the contacts handle the full armature current of the motor, it may be quite troublesome when the current is too small to cause any appreciable heating or sparking.

The use of the vacuum tubes as described here should cause

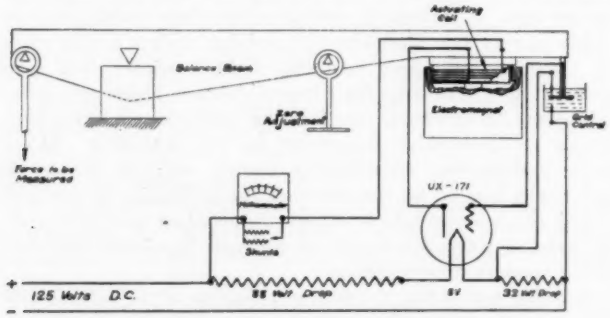

FIG. 5 ELECTROMAGNETIC BALANCE

a decided increase in the sensitivity of any motor-driven electric balance, because the motor will respond instantly to even the most gentle pressure between the contacts. Furthermore, since the contacts can be placed very close together without any danger of an arc forming between them, the very slightest movement of the beam will actuate the motor. Of course this will make the balance more active, and therefore more time may be required for the traveling weight to find a steady position, but it has been found that it is possible to improve this condition by shifting the center of gravity of the beam slightly below the fulcrum, so that the beam will be in stable equilibrium. The sensitivity is impaired very little by this procedure when the contacts are very close together, and it is possible to obtain remarkably quick readings, when great accuracy is not necessary, by simply separating the control contacts any desired amount.

3 THE ELECTROMAGNETIC BALANCE

The new electromagnetic balance is still in the experimental stage, but it should attract a good deal of interest because it is quite different from any weighing device that is known to have been used before. Comparing it with the previously described motor-driven balances, the electromagnetic balance is less costly, has no moving parts on the beam, is practically instantaneous in its response to sudden changes in force, can be quickly adjusted to almost any desired degree of sensitivity, and is readily adapted to recording devices to do away with the point-by-point method of obtaining curves. These are all distinct advantages, and so far no serious disadvantages have been foreseen.

The experimental balance of this type which is now in operation at the University of Washington is shown in Fig. 5. The beam is balanced against the unknown force by a magnetic pull on the "actuating coil" which is attached to the right-hand end

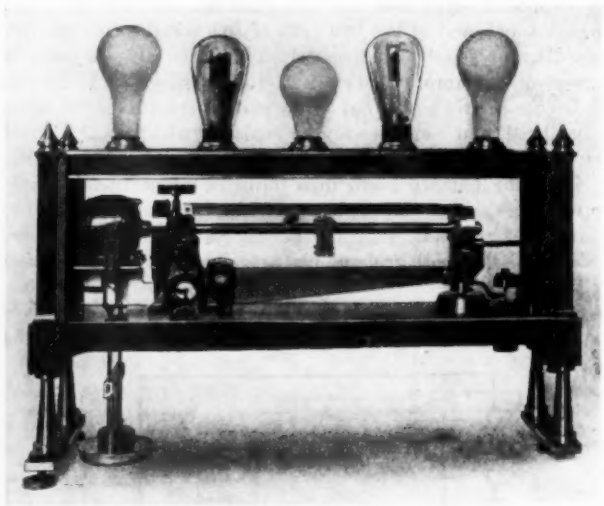

FIG. 6 VACUUM-TUBE-CONTROLLED MOTOR-DRIVEN BALANCE
(This was designed and built at the University of Washington.)

of the beam. This coil consists of a few hundred turns of very fine wire wound on a very thin cylindrical tube. The overall thickness of the wire and tube is 0.06 in., and this whole ring-shaped winding is placed in the circular air gap of a powerful electromagnet, allowing sufficient clearance to prevent any possible rubbing. The electromagnet is so designed that most of the iron will be saturated, and therefore any small fluctuations in its exciting current will scarcely affect the magnetic flux.

This part of the electromagnetic balance is very similar to the electrodynamic loud speaker which is so commonly used in radios and electric phonographs. Moreover, the magnetic pull on the actuating coil of the balance is obtained in exactly the same manner that the motive force is obtained to drive the vibrating cone of the loud speaker. The important thing to remember in this connection is that the force is proportional to the current flowing through the little coil in the air gap, and also to the strength of the magnetic field passing through this little coil. In the case of the electromagnetic balance special care is taken to maintain a practically constant magnetic field, so that the force which is transmitted to the balance beam should be directly proportional to the current in the actuating coil. It follows that the current required to balance the beam is a direct measure of the unknown force, and if this current can be automatically adjusted to keep the beam in perfect balance, we will have an ideal device for measuring forces.

This has been done in the experimental balance shown in Fig. 5 by the use of a UX-171 vacuum tube and a special liquid potentiometer. The moving electrode of the potentiometer is attached to the balance beam, and its purpose is to decrease the bias voltage on the grid of the vacuum tube in case the beam tips up, and to increase this voltage in case the beam tips down. The plate current of the vacuum tube passes through the actuating coil of the balance, thus producing a downward electromagnetic force on the beam, the strength of which depends upon the value of the plate current. The result is that if a sufficient load is applied to the left-hand end of the beam the moving electrode of the liquid potentiometer will rise a little, and in so doing it will reduce the negative bias on the grid of the vacuum tube, and therefore increase the plate current and create a downward electromagnetic force which will balance the applied load. A milliammeter placed in the plate circuit measures the current flowing through the actuating coil, and it is a simple matter to furnish the proper shunts to make this meter read directly in grams or in pounds.

One of the remarkable features of this type of balance is the rapidity with which it responds to sudden changes in force. Even when the load is suddenly increased from zero to full-scale deflection, only a fraction of a second is required for the pointer of the milliammeter to come to rest at its new position. Moreover, the pointer should be absolutely steady as long as there is no change in the applied load, because the beam is in a truly stable condition and any tendency to swing in either direction is instantly opposed by a change in electromagnetic force.

Another notable feature is the ease with which the sensitivity of the device can be varied. If the maximum plate current available from the UX-171 tube is 50 milliamp., a meter having a range of not over 0-5 milliamp. should be used, so that the sensitivity may be adjusted by using different shunts. For example, if the balance could measure a force of 500 grams with 50 milliamp. flowing in the actuating coil, the 0-5 milliammeter would measure this with a suitable shunt across it, and in this case if the meter had 100 divisions on its scale, the finest division would represent 5 grams. If greater accuracy should be desired, the shunt could then be removed, and full-scale deflection would then represent 50 grams instead of 500 grams, and the finest division would represent 0.5 gram instead of 5 grams. Even greater accuracy might be had if a more sensitive meter is used, but this should not be carried too far without proper precautions, because any accidental increase in load might easily burn out the more sensitive instruments. Another alternative is to place a shunt across the actuating coil instead of the meter, and in this way no harm can come to the electrical instrument, because the 0-50 milliammeter would be used, and the current can never rise above the maximum which the vacuum tube will pass. However, it has been found that the balance begins to act sluggishly if the actuating coil is shunted by too low a resistance, so that this method of varying sensitivity is also limited.

It might be supposed that the electromagnetic balance cannot combine great accuracy with large range because the range is fixed by the maximum reading of the milliammeter. The fact is that the range can easily be extended indefinitely by adding weights to a pan hung from the beam on the right-hand side of the fulcrum, as in Fig. 5. If the distance from this pan to the fulcrum is made exactly equal to the distance from the fulcrum to the point of suspension of the unknown load, then in case the milliammeter should indicate a load of 500 grams, a standard 500-gram weight may be added to the pan to bring the needle of the meter back to zero. This addition of a known weight to the pan will also afford a quick and convenient check on the calibration of the meter.

In spite of the fact that the experimental electromagnetic balance has been operated successfully for more than a month, there is much room for improvement in the liquid potentiometer for controlling the grid bias of the vacuum tube. So far no liquid has been found that will continually maintain a constant potential gradient of 50 volts across a distance of less than 0.01 in. Glycerin has been used with the greatest success, and several designs for the moving electrode have been experimented with in an attempt to reduce the irregularity in potential gradient which is apparently caused by small gas bubbles. However, there seems to be little hope of obtaining an entirely satisfactory liquid potentiometer for the circuit shown in Fig. 5, because such a large voltage must be impressed across a very thin layer of liquid. Fortunately there is a simple remedy for this difficulty, the success of which is almost certain, due to the fact that the bubbling in any liquid becomes less when the impressed voltage is reduced. It is therefore proposed to decrease the voltage across the potentiometer liquid from 50 volts to 5 volts, or less if necessary, and insert a vacuum-tube amplifier between the moving electrode and the grid of the UX-171. In this way the very small changes in voltage of the electrode attached to the beam can be amplified to the value necessary to control the current in the actuating coil of the balance.

This idea has not been tried out yet because the simpler circuit in Fig. 5 was found to be good enough for the preliminary experiments, but there is very little reason to doubt that absolute satisfaction can be obtained if the potential drop through the liquid can be kept very low. Moreover, if necessary it would probably be possible to do away with the liquid potentiometer entirely by devising a means of controlling the grid voltage of the UX-171 tube by allowing the beam to change the capacity of a small condenser. This would require the use of a more complicated circuit using several vacuum tubes, but in case liquid potentiometers should eventually prove to be troublesome in any way, which is very unlikely, this additional complication would hardly be objectionable.

The experimental electromagnetic balance described in this paper has already proved the practicability of measuring forces by determining the current required to produce a balancing electromagnetic force. In spite of the fact that when the device is used for a considerable period of time it becomes slightly unsteady, due to the formation of gas bubbles in the liquid potentiometer, the force measurements were in all cases perfectly reliable, and if the equipment was allowed to stand idle for a brief period of time, the gas bubbles would pass off and the balance would give perfectly steady readings once more. The methods suggested for overcoming the difficulties due to the gassing of the potentiometer liquid are practically certain to give absolute satisfaction at all times, and therefore it is believed that an electromagnetic balance can be built which will have several very decided advantages over any of the wind-tunnel balances in common use today. A brief summary of some of the more important of these advantages follows:

1 There are no moving parts on the device except the balancing beam, and this part moves only very slightly, in accordance with the applied load.

2 The initial cost of one of these balances should be far less than that of the average motor-driven balance, because there are fewer parts to make, and the size and weight of these parts are relatively unimportant because the balance is finally calibrated by choosing a suitable shunt for the milliammeter.

3 A wide range of sensitivity can be had from a given electromagnetic balance by simply using different shunts across the milliammeter. This is of special importance in measuring the small changes of the drag of a model due to slight modifications of its form.

4 The electromagnetic type of instrument gives an almost instantaneous indication of sudden changes in applied load, so

that quite rapid fluctuations in force can be followed by observing the pointer of the milliammeter.

5 The calibration of the device is practically as permanent as the calibration of the electrical indicating device and can be checked and readjusted in a moment's time.

6 It should be possible to make the electromagnetic balance operate graphical recording electrical instruments, so that the variation of the lift and drag forces on a wind-tunnel model could be automatically recorded as the angle of attack is changed. If a similar device could be used to record the air velocity at the same time, all the necessary engineering data could be obtained from the resulting graphs, so that the human element would be entirely eliminated from the wind-tunnel tests, and all the data could be obtained in a few minutes instead of several hours.

Design and Manufacture of Airplanes From the Point of View of Low Production Costs

BY RUSSELL F. HARDY,[1] TROY, OHIO

EXPERIENCE gained in the automotive industry has saved the aircraft industry many millions of dollars. The most valuable information obtained has been along the lines of production. A large quantity of any product built with up-to-date methods usually results in low manufacturing costs. Consequently, to build airplanes having a low manufacturing cost, one of the first things to consider is: Will they be produced in sufficient quantity so that the cost per unit will be appreciably low?

This question, of course, involves many factors including the facilities for quantity production as well as the capability of the entire sales organization in disposing of the product. On the other hand, the sales department will not be able to sell quantities of a product unless it takes well with the general public.

Assuming that the product will be accepted by the general public, various items of importance in the design and manufacture of an airplane should be considered.

The first thing to be decided is the type of aircraft which is to be built—whether it will be military, cargo carrying, passenger carrying, or for the private individual. Assume that it is desired to produce a great number of a certain type. At the present time it should be the objective to sell the product to the private individual who perhaps has never piloted an airplane and has had only an occasional ride. This will necessitate that the airplane be at least of the two-place type or more. The two-place type will be perfectly satisfactory during the time in which the purchaser is receiving his instructions. At this point opinions will vary. What type of airplane will best suit the purpose of training the purchaser as well as giving satisfactory service after he has obtained his license? Surely he will not object to having room for one passenger, and very likely he would be more desirous of carrying two if the initial cost of the airplane is only slightly more and the performance difference very small.

A few engineering investigations may next be made to ascer-

Presented at the Fourth National Aeronautic Meeting, Dayton, Ohio, May 19 to 22, 1930, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

tain the difference in weight of the airplane structure due to the increased pay load of one additional passenger and baggage and also to determine the difference in performance. If these differences are small, it is very likely that the airplane will be of, at least, the three-place type, providing the engine to be used is capable of carrying the load with satisfactory performance.

Having decided upon the number of persons which the airplane is to carry, one might next consider whether it is to be of the open or closed type. Again there will be many differences of opinion, and very likely most of them may be justified. It would appear that most of the training airplanes in the past have been of the open-cockpit type. However, at the present time there are a few small planes used in training which are of the closed type. Both have their advantages, to

FIG. 2 A FLEET OF WACO AIRPLANES DELIVERED TO THE AVIATION BUREAU OF CANTON, CHINA

be sure. It is almost certain that the open type can be built at a lower cost, a fact which is also true in the automotive industry.

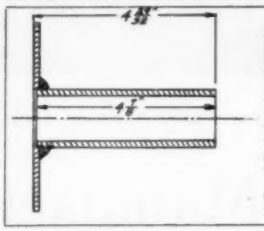
There have been many articles written on the subject of monoplanes versus biplanes, and it will be the duty of the designer to decide which type will most satisfactorily meet the requirements. One can now begin to picture what the airplane is to look like when completed. Perhaps it will be a two-place closed-type monoplane or a three-place open biplane. After the general type has been decided upon, line drawings of the fuselage, wings, and empennage can be started. The type and weight of the engine to be used must be known at this stage so that a balance diagram may be obtained. Since the balance diagram should be constructed before the airplane is built, the various weights and their locations will necessarily be approximated. This would seem to be a rather difficult task, but with a little experience a designer can estimate the weight empty of the airplane very accurately. There are many other items which must be decided upon at this time, some of which are airfoil section, area and type of wings, and location and capacity of fuel and oil tanks.

It is very important at this stage of the design to make certain that the general proportions and arrangement of the wings, landing gear, fuselage, and empennage present a satisfactory appearance. This is best accomplished by constructing a full-size mock-up of the airplane which incorporates the features already decided upon. While a few airplanes are said to be built entirely from drawings, the author has usually found that much time can be saved through the aid of an inexpensive mock-up. A mock-up should at least include that portion of the fuselage in front of and including the space occupied by the rearmost occupant. Stub wings should be placed in the proper location so that visibility and ease of entrance to the airplane can be determined. The arrangement of the seats is of utmost importance so that plenty of leg room and comfort for the occupants will be assured. In some cases the mock-up might include the structure back to and including the empennage. The turtle deck can be covered with thick paper and in this manner the general lines of the airplane may be obtained. The structural parts of the mock-up can be made of wood and these wood members will be in the same location as those which are later to be made of steel tubing.

After the mock-up has proved to be satisfactory with regard to general dimensions and appearances, line diagrams of the fuselage and landing gear may be drawn and from these the preliminary analysis may be made. Stress diagrams can be made with unit load conditions and from these diagrams it may be determined whether any of the members take excessive loads. If it is found that they do, then a different arrangement of the structural members may be necessary.

Before any final analysis is made, however, the maximum horsepower of the engines to be used must be known, in order that the proper load factors may be obtained. Since many manufacturers of aircraft rely on outside sources for their engine supply, it is usually hard to decide what horsepower engines should be used in a particular design. From a standpoint of flexibility it is desirable to be able to equip the airplane with engines having a varying range of power. However, the higher powered engines determine the maximum load factor to be used, and as a consequence the structural weight will be greater than would be necessary for a lesser powered engine. Assuming that the entire structure will be identical for different engines with the exception of the engine mount, the airplane having the lesser power will be penalized by the unnecessary structural weight.

It is usually desirable to build an experimental airplane be-



THE WACO AIRCRAFT CO.

ENGINEERING CHANGE RECORD

Part No. 2001 Date 3/14/30

Dwg. No. Letter D

Part Name Tube, Axle Retainer Models Effected R, W, & F

Due to the change in length of the axle #1878, it will be necessary to change the length of the axle retainer tube from 4 7/8" to 4 29/32". This will permit the flange to be welded flush with the end of the retainer tube.

The flange may then be machined even with the end of the retainer tube which will make a satisfactory backing for the thrust washer.

This change supersedes the change dated 11/21/29.

Submitted By John Doe Checked By George Jones Approved By Richard Roe

Effective At once.

FIG. 3 DESIGN CHANGES ARE RECORDED ON A CARD OF THIS TYPE

fore too much work is done on the analysis, in order that the test pilot can determine whether the balance, performance, and stability are satisfactory. Approximate methods may be used to determine sizes of the primary members such as wing spars, longerons, empennage members, and others. It is understood that the wing section and area have already been decided upon. The experimental model should be constructed so that the dihedral, incidence, and perhaps the stagger may be varied in order that the characteristics previously mentioned may be studied. It is very seldom that the approved airplane, later to be built in quantities, is the same as the one upon which the first tests are run.

After the tests have been run, it is advisable to complete the stress analysis of the various primary and secondary structural units. The primary units comprise the main structural members of the wing cellule, fuselage, and landing gear. The secondary units consist of fittings, lugs, clips, and other small members.

After the sizes of the fuselage and landing gear members have been determined from the stress analysis, complete units should be built up and drop tests conducted in order to determine whether they will later pass the Department of Commerce requirements. The ailerons and empennage surfaces

should also be static-tested so that there will be no delay due to insufficient strength or unsatisfactory action at a later date when these units are tested in the presence of the Department of Commerce inspector.

Even though the fittings, lugs, clips, and other secondary units have been analyzed, it is very advisable when possible to perform tests on them to determine their actual strength. These parts may have shown ample margins in the stress analysis, but much can be learned about them during destruction tests. Aileron control mechanisms may be connected to a slow-speed motor through a series of reduction gears, and operated over long periods of time under an imposed load in order to be assured of the proper functioning of all parts.

After the completion of satisfactory load tests, the stress analysis and the necessary drawings should be submitted to the Department of Commerce for checking and approval. When the approval is obtained, the airplane may be subjected to the various flight tests, and if these are satisfactory an approved-type certificate will be issued to the manufacturer.

Before the airplane can be produced satisfactorily in quantities it is necessary to have detail drawings of the various parts. The experimental drawings are checked very carefully and turned over to the production drafting department where production part numbers are assigned and detail drawings made. The part names and numbers are recorded alphabetically and numerically so that information may be quickly given to various departments requesting it. Specifications in accordance with these names and numbers are compiled by the planning department, and production orders may then be issued to the various departments.

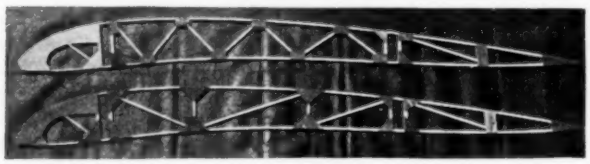


FIG. 4 TWO TYPES OF RIBS HAVING THE SAME WEIGHT
(The upper rib is less costly to build since eight of the web members have the same length. It also has much greater strength due to the smaller span between members.)

FIG. 5 ABOVE, ALUMINUM-ALLOY CASTINGS OF STICK SOCKET AND CONTROL-SHAFT BEARING—BELOW, AILERON HINGE MADE FROM DROP FORGING

Any changes in design or construction must be recorded on an "engineering change card" and approved by one of authority in the engineering department. A permanent record of the changes should be kept in order that service orders may be filled correctly at a later date.

Throughout the entire design, standardization should be kept vividly in mind. If the airplane is of the biplane type, the upper and lower wings should be as nearly identical as is possible and practical. The spar fittings should be made up from blanks and plates which may be used interchangeably throughout the design. Compression ribs should be spaced so that different length internal drag wires may be reduced to a minimum. Ribs should be identically the same as far as possible. It may also be desirable to use metal tubes, preferably duralumin, for compression struts throughout the wing, and in this manner eliminate the special compression ribs. If several experimental wings having different airfoil sections are to be built up, it is cheaper to construct them with a plywood web instead of the truss type, for with this method of construction the airfoil section may be cut out on a bandsaw and the cap strips bent to conform with the contour of the rib. If the truss-type rib is to be employed, a jig is necessary to hold the various members in position during gluing and nailing operations.

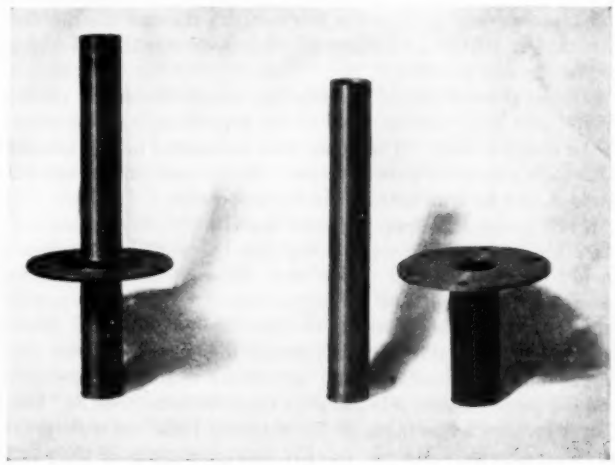

FIG. 6 TWO TYPES OF CONSTRUCTION FOR BRAKE-TORQUE FLANGE AND AXLE
(At left, brake-torque flange welded to the axle. The entire unit is then heat-treated and finished to size. As an improvement an axle which is heat-treated and machined to size, shown in the center, is later pressed into the retainer and flange unit shown at extreme right. There is no welding on this axle, which results in greater strength and cheaper production costs.)

If the truss-type rib is to be adopted as standard, it should be designed so that its production costs will be reduced to a minimum. All web members should have the same length as far as possible so as to reduce costs. Also, a standard gusset should be used in as many places as possible. Various types of ribs should be built up, and a decision as to which should be used can be made after characteristics of strength, weight, and costs have been determined. The internal brace-wire fittings can usually be standardized and this will reduce wing costs materially.

Parts in the nature of aileron hinges, of which there are usually a great number per airplane, can be produced very economically from drop forgings. The die cost is the main item to be considered, but when it is distributed over thousands of parts, an appreciable saving in production costs will be realized.

Many parts, such as stick sockets, can best be produced in the form of an aluminum-alloy casting. The unit is light in weight and its strength can be determined by severe static and fatigue tests imposed upon the part in a manner similar to that which it receives in service on the airplane.

Parts, such as spar bracket, side plates, and clips, can either be stamped out or nibbled. It is always well to have a very accurate estimate of the quantity to be produced so that cost figures may be obtained which will make it possible to determine whether the part should be produced on a press or on a nibbler. The nibbled part has to be finished by filing, while the stamped part may be used as it comes from the press. A change in design is more easily made and is less costly in the case of a nibbled part than in that of a stamping which necessitates the reworking of the die and punch.

Structural members of the fuselage frame should be cut to length, and have their end cut to the proper angle and contour in the machine shop. They may then be stocked in bins labeled with their respective part numbers. Hand work on the various parts should be eliminated as much as possible.

If it is decided to equip the same model with different engines, then the question arises as to whether the complete fuselages should be built up in units with different integral engine mounts or in a single unit up to the engine mount which at this point is equipped with fittings to take different mounts. From a standpoint of production it is desirable to have the demountable engine mount, as fuselages may be built up in advance of orders and the proper mount selected after the order is received. Then, too, there are advantages to be obtained from the standpoint of the purchaser. He can quickly change engines of the same type in the event of a necessary overhaul or can install an entirely different type of engine by purchasing the proper replacement mount.

The merits of removable mounts are opposed by certain undesirable features, one of which is the tendency of the mount to become loosened at the points where it connects the fuselage unless a great amount of care is taken in the design of the fittings. Then, too, the cost of building a fuselage and separate mount is greater than if the two were built in one unit. Parts fabricated by welding should be held in rigid jigs so that variations in the finished product may be reduced to a minimum.

Welding jigs should be designed so that the parts may be easily inserted, welded, and removed. In the welding of large units, such as landing-gear vee struts, it is often advisable to check them, after they have been completed, in a test jig to determine whether they are within the tolerances. It is also advisable to weld up a master fuselage which is exactly correct with regard to tube sizes and dimensional distances. This fuselage is used as a check on the welding jigs which may be found in error after repeated use. If at any time assemblies are made with difficulty, the part in question may be quickly checked against the master fuselage.

The inspection department plays a very important part in keeping production costs down to a minimum. All material should be inspected before it is fabricated into the various parts. If the part happens to be a welded assembly, it must later be inspected from the standpoint of a weld, and in addition must be checked against the blueprint specifications in order that it will fit properly when assembled on the airplane. The inspection department should be under the supervision of the engineering department, for in this manner any questions which may arise may be settled directly and promptly.

No matter how perfectly an airplane may be designed from the standpoint of standardization of parts, the production costs will be high unless proper routing of stock and materials is employed. The raw stock should pass through the receiving department to stockrooms which should be adjacent to the various departments in which it is to be made up. The stock is then requisitioned from the stockroom and put through the various working processes. If the parts are completed in the machine shop they may then pass to the stockroom in which completed parts are kept. If the part is not completed until it passes through welding operations, it may then be returned to the stockroom to be later requisitioned by the welding department. The part may then be welded, sandblasted, inspected, rustproofed, and stored in the stockroom for finished parts. The various departments and stockrooms should be arranged so that the part will travel the least possible distance.

Thus, it is seen that the essential factors which contribute to low production costs in the manufacture of aircraft are: First, an acceptable design which will lead to quantity production; second, correct procedure with regard to designing, standardizing, experimenting, and testing; and third, efficient production methods including capable personnel, satisfactory equipment, rigid inspection, and proper routing of materials.

Discussion

H. Rawdon.[2] The writer can in one or two instances take an opposite stand to the statements contained in the paper on the design and production of airplanes for low cost. Anything economically accomplished must be systematically done. The exact system to be used is not definite, like a mathematical proposition. There are, however, general principles which can be considered.

The design which would be an economical job for a production of 500 units per year would not necessarily be of the same relative production cheapness when the production had reached an annual volume of 10,000 units. Likewise, the manufacturing system will have to be modified in the two cases, though they may fundamentally be similar.

The first step in producing an airplane is the determination of the requirements of the buying public. With this information at hand it is possible to proceed with the details. The writer will elaborate on some points in accordance with his own personal opinions and observations.

It should be the duty of the sales department to analyze the requirements of the buying public, and to intelligently predict the volume of consumption of the article to be manufactured. In the case of the airplane it is very essential to have the foregoing information accurate if the design is to be intelligently developed. It is the writer's opinion and observation that the lack of such analyses has in many cases resulted in very costly experiments, both in design and production.

It has been the policy of most companies to cater to "custom built" trade. This process is evidently not economical in production. The unit cost of construction runs high for such type of work. The greatest profit is to be made with standardized products. There is also another difficulty encountered with these special airplanes, that of the legal aspect. The requirements of the United States Department of Commerce that a machine is built in exact accordance with the approved type means that the special-built airplanes will require additional work and expense in preparation and submission of data necessary to secure the commercial-type license. Requirements and fancies of the general buyer have been varied and fluctuating in the past and have been difficult problems with which to deal.

The extent that standardization of parts can be carried is also a function of the number of individual models built by the manufacturer. The writer cannot agree with the idea of identical upper and lower wings. There seem to me to be other

[2] Travel Air Co., Wichita, Kansas.

problems, aerodynamical, appearance, and even fabrication considerations, that would offset the small advantages from the manufacturing end. Would it not be of more definite advantage to have it said, the same and identical lower wing on two separate types? This presupposes a biplane design. The writer personally is not a monoplane enthusiast, while he takes it that the author favors the biplane type. Both types have their advantages and adherents.

The consideration of the mock-up is essential, and usually it does not pay, in the experimental design, to go too far in making production drawings. The mistake is often made of releasing airplanes for production and sale before they have been thoroughly tested and corrected for minor defects with details. Not only should cheapness of production be considered, but also that of servicing those articles that are in the hands of the customer. It will prove more expensive to the manufacturer who has to replace parts due to faulty design than it will to the manufacturer who has the design faults found and corrected before he has sold his article to the public. In the end it is the article that makes the most profit for a given sale price. This profit is a function of other considerations as well as the cost of manufacturing. In general it pays the manufacturer to proceed with some caution. Demand that exceeds production output is usually conducive to expensive manufacturing policies. This has been the situation the past two years.

Very often it happens that temporary dies can be made and simple fitting blanks can be stamped at a saving in lots as small as 15 airplanes. In the initial design a certain amount of flexibility should be allowed for, so that later on if it is proved that the airplane is in popular demand the details can be redesigned to adapt them to methods of quantity production. In this way it is often possible to save much expense in die construction and various tooling-up processes where the demand proved less than anticipation.

Functionally the inspection department reports to the engineering department, since the drawing is the primary source of information. However, the inspection may report to the chief engineer or the general manager, and in either case can be found examples of successful functioning. Much importance is attached to what is to be inspected and the stage of construction at which the inspection takes place. Material inspected at the proper stage usually saves much expense later on.

The assumption of acceptable design, that is, in regard to the quantity to be consumed, is usually open to much questioning, and is best proved by actual trial and experience.

Author's Closure

The author wishes to take this opportunity to thank Mr. Rawdon for his discussion. While in one or two instances he has seemingly taken an opposite stand, these differences in opinion might be attributed to a lack of clarity or completeness in writing the paper.

Mr. Rawdon states, and justly so, that "It should be the duty of the sales department to analyze the requirements of the buying public." The assumption that this had been done was intended to have been brought out in the third paragraph of the paper, which reads: "Assuming that the product will be accepted by the general public, various items of importance in the design and manufacture of an airplane should be considered."

It is not always easy to estimate, even roughly, the demands of the buying public. Last year and the present year have been excellent examples of this, but we can attribute this exception of the rule to the financial unrest throughout the country. Many production schedules if carried out as originally planned this spring would have left, and in some cases have actually left, the company with large numbers of unsold articles.

In the paper it is stated: "If the airplane is of the biplane type, the upper and lower wings should be as nearly identical as is possible and practical."

Aerodynamically, there may be some slight advantage in having different upper and lower wings, but the author does not believe that this advantage will offset that of being able to keep the majority of parts interchangeable. The appearance is usually taken care of by separating the upper wing panels with a center section of span equal to or greater than the width of the fuselage which separates the two lower wings. Standardization should not in any case be carried out to the extent that the impractical features outclass the advantages.

AER-52-30

High-Performance Gasoline Aircraft Engine

Its Problems of Fuel, Oil, and Materials of Cylinder Construction

By S. D. HERON,[1] DAYTON, OHIO

The paper discusses the available fuels and anti-knock compounds for aircraft use. The question of the anti-knock values of widely different fuels is one concerning which but little is known. The determination of these knock values was the object of the experiments conducted.

THE constant striving for increase of output from aircraft engines of given size and displacement has led to increase of compression ratio, improvement in volumetric efficiency, supercharging, and increase of engine speed. The first three factors, other things being equal, demand improvement in the anti-knock quality of the fuel used. The fourth factor tends to diminish the required quality of the fuel up to the point where the increased rate of heat flux to the cylinder and piston causes overheating. When overheating thus occurs, it is susceptible to fuel changes. Although the reduction or elimination of such overheating by means of fuel can be and has been obtained in high-performance engines, for aircraft and other purposes, by the use of alcohol and alcohol mixtures, the method is hardly practical for service aircraft engines on account of the resulting high specific fuel consumption.

That increase of compression ratio, up to the point where detonation occurs, results in increase of output has long been known, but so far as the author knows, A. H. Gibson[2] was the first to discover that such increase possessed peculiar advantages for aircraft use, inasmuch as it diminished the specific heat flow to the cylinder walls and thus reduced the problem of disposing of the waste heat. In the case of some air-cooled cylinders, Gibson in 1916–17 discovered that not merely was the specific heat flow diminished, but that apparently the total flow also was sharply reduced, as in several air-cooled cylinders the mean and maximum cylinder wall temperatures dropped as the compression ratio increased with otherwise constant conditions. Increase of compression to the point just below that at which detonation starts results in increase of power output, reduction of specific fuel consumption, and reduction of specific heat rejection. Reduction of both engine weight and fuel consumption are of primary importance in aircraft. Reduction of either specific or total heat rejection by the engine is of outstanding importance, as the amount of parasitic resistance involved in transferring to the atmosphere the heat rejected by the cylinder-cooling system is thus reduced. Supercharging, while it allows of greater increase of output with a given fuel improvement than is possible with high compression, does not improve fuel consumption—in general, rather the reverse—and it increases the heat rejection to the cylinder walls in some cases to such an extent that marked increase of fuel consumption is necessary in order to prevent failure from overheating.

The limiting factor in the use of any fuel in an aircraft engine is its tendency to detonate and thus heat the cylinder and piston unit. There is some evidence that, while under a given set of conditions two fuels may have equal tendencies to audible detonation, their effects in heating the cylinder and piston unit may show somewhat decided differences.

Until recently, the most widely used fuel in American aircraft engines has been straight-run Mid-Continent domestic aviation gasoline, meeting the Federal Specification Board requirements for distillation. In the past, when a fuel superior to this has been required, the addition of benzol has been general. Average straight-run Mid-Continent D.A.G., from the anti-knock standpoint, is an exceedingly poor fuel for modern aircraft-engine use. It is inferior to much of the low-test gasoline available for automobile purposes. Large supplies of automobile anti-knock gasoline are available which approximate in anti-knock value a mixture of 70 per cent average Mid-Continent D.A.G. with 30 per cent benzol. With increase of compression ratio, volumetric efficiency, and cylinder-wall temperature, Mid-Continent D.A.G. has ceased to be a satisfactory fuel for a majority of modern engines. A large amount of the modern equipment in use in the Air Corps will not operate on Mid-Continent D.A.G., even when throttled at ground level and not opened out fully below an altitude of 8000 ft.

Pending an investigation of the most suitable fuel for present and future equipment, the Air Corps decided to add 3 cc. of tetraethyl lead per gallon to all gasoline for use in such equipment as would not operate on the fuel procured to its Specification 2-40F, which specification, in general, results in the supply of average Mid-Continent D.A.G. The arbitrary addition of 3 cc. of tetraethyl lead to gasoline meeting Specification 2-40F in no sense represents an anti-knock value, but the resultant fuel is at least 3 cc. of lead better than it otherwise would be.

At the time the invitation to write this paper was accepted, the author hoped to be able to be much more definite on the subject of available fuels and anti-knocks for aircraft use than is now possible. The question of the anti-knock values of widely different fuels in both aircraft and fuel-test engines is one concerning which but little is known, nor is a thorough understanding likely to be gained for the next two or three years. Therefore, it is at present only possible to indulge in generalities on the subject.

SECTION 1 DETERMINATION OF ANTI-KNOCK VALUE

Until recently, it has been generally supposed that the relative anti-knock value of two fuels measured under one set of conditions was approximately similiar under other conditions. In practice, different laboratories, working with varying equipment and technique, were unable to agree on the relative ratings of fuels of widely different character, notably lead blends versus benzol blends. In general, the attitude of each laboratory was to suspect the other of careless or inaccurate test methods.

In the latter part of 1928, the Matériel Division, partly as a

result of its work on the use of liquid cooling media at temperatures in excess of 180 deg. fahr. and partly as a matter of accident, found that cylinder temperature had an extremely market effect upon the relative ratings of fuels. The engine used was an early form of the Series 30 Ethyl Gasoline Corporation Knock Test Engine, with 8 to 1 compression ratio and an operating speed of 600 r.p. m. Detonation was measured with a bouncing pin. The amounts of benzol and lead required in two different gasolines to equal a standard consisting of 80 parts (by volume) of 2–2–4–trimethyl pentane and 20 parts normal heptane were obtained at cooling-liquid temperatures varying between the limits of 150 and 350 deg. fahr. (with circulating evaporative cooling). The tests in question were rather crude and could not be repeated to close limits. However, repeat tests showed that there was no question of the general order of the effect, and investigation by other laboratories has shown similar effects. The results of these tests are shown in Fig. 1. The outstanding feature is the rapid relative loss of anti-knock value of benzol with increase of cylinder temperature. Other aromatic compounds, such as ethyl benzene and a mixture of alkyl benzenes, both produced by organic synthesis by the Carbide and Carbon Chemicals Corporation, showed a similar loss of anti-knock effect with increase of cylinder temperature.

The results shown in Fig. 1 at once indicated that, with the

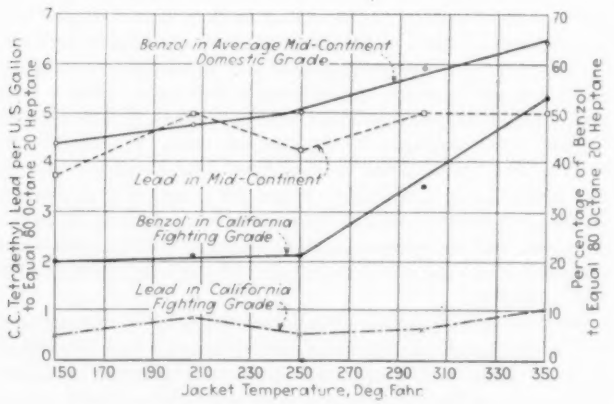

FIG. 1

wide variation of cylinder temperature found in aircraft engines, fuel-test engine conditions would need to be so adjusted as to strike an average of the relative effectiveness of widely varying fuels as determined in multicylinder aircraft engines. It appears obvious that with the wide differences in cylinder temperature, compression ratio, volumetric efficiency, rate of revolution, etc., found in various types of aircraft engines, the relation between lead and benzol will vary widely and that it will not be possible to do more then set test-engine conditions to average the results obtained.

The Matériel Division has started a program to determine the relation between the anti-knock effects of widely different fuels in multicylinder aircraft engines. For the present, the method in use is to determine the minimum amounts of tetraethyl lead and benzol in a base gasoline which, from the anti-knock standpoint, is so poor that the engine under test will not operate on it without substantial anti-knock additions. It is planned to test a variety of types of engines in this manner, if possible, with different base gasolines and then to adjust test-engine conditions so that they reproduce the average anti-knock relation between lead and benzol found in multicylinder engines. As later discussion will show, almost any variation of test-engine conditions seems to affect the relation between lead and benzol. It may therefore prove necessary to attack the problem from the standpoint of obtaining the amounts of a given anti-knock required in a series of widely differing base gasolines to produce maximum output, minimum fuel consumption, etc., in any given engine. The relation between fuels is obtained by determining the minimum amount of anti-knock that will give maximum output, minimum fuel consumption, and minimum cylinder temperature with the carburetor so leaned out as to drop the power 1 per cent (best setting) from the maximum available at any fuel consumption on the fuel under test. Maximum power, minimum fuel consumption, and minimum cylinder temperature are usually obtained simultaneously (at best setting) when sufficient anti-knock compound has been added to the base fuel, and further anti-knock additions do not produce any measurable effect. As an alternative to changing the method of determination of relationship between fuels of different types in multicylinder engines, it may be necessary to entirely change the method of single-cylinder test of fuels.

In all single-cylinder engine tests of fuels, the Matériel Division has adopted the procedure of testing at that air-to-fuel ratio which produces maximum tendency to knock. The necessity for this has been clearly shown by Campbell, Lovell, and Boyd.[3]

In the early work with high cooling-liquid temperatures in fuel-test engines, the Matériel Division installed cylinder-head thermocouples to determine the relation of test-engine cylinder temperatures and those of hot running aircraft engines. In determining maximum knock mixtures strength for a given fuel and comparing fuels of diverse knock characteristics, it was noted that differences in knock intensity were invariably accompanied by differences of cylinder-head temperature. As this offered a possibility for an even more direct method of determining detonation than the bouncing pin, a temperature method was sought which would show much smaller changes of knock intensity than could be detected by the cylinder-head temperature. Furthermore, as the limiting factor in the use of any fuel in an aircraft engine appears to be the tendency to heat the cylinder and piston unit, the method possibly has a sounder basis for evaluating aircraft-engine fuel than one relying upon detection of audible detonation or rate of pressure rise.

In order to magnify temperature differences for small changes of knock intensity, temperature measurement of an indirectly cooled surface within the combustion chamber seemed the best line of attack. The plugs shown in Fig. 2 were therefore constructed and fitted into the bouncing pin hole in the Series 30 Ethyl Gasoline Knock Test Engine. Operating at 900 r.p.m., all three types of plug show a minimum change of 3 deg. fahr. for a change from 3 to 3⅛ cc. of tetraethyl lead in several gasolines. Up to 3 cc. of lead, the sensitivity shown for a change of concentration of ⅛ cc. of lead appears to be independent of lead concentration.

At 350 deg. fahr. jacket, the type 3 plug shows a temperature change of 5 to 7 deg. fahr. for a change from 50 to 51 per cent benzol in California Fighting Grade gasoline.

Occasionally, the fuels were found that, when matched by the bouncing pin, did not match audibly or by cylinder-head temperature. Fuels which match by the cylinder-temperature method will sometimes show a pronounced difference in audible detonation.

A considerable amount of investigation will be necessary before it is possible to determine whether the bouncing-pin method, the temperature method, or, possibly, the method of testing by incipient knock, gives the closest correlation with the tendency of fuels to limit aircraft-engine output.

[3] "Importance of Mixture Ratio in Rating Fuels for Knock," John M. Campbell, Wheeler G. Lovell, and T. A. Boyd, *Industrial and Engineering Chemistry*, vol. 20, no. 10, October, 1928.

Using the temperature plug in a Series 30 Ethyl Gasoline Knock Test engine, running at 900 r.p.m., the Matériel Division obtained the tetraethyl lead equivalent of 50 per cent C.P. Benzol in a California Fighting Grade and a Mid-Continent Domestic Aviation Gasoline at cooling-liquid temperatures varying between 150 and 400 deg. fahr. The results shown in Fig. 3 indicate very large variations with change of cylinder temperature by this method of test. Preliminary tests made by the Ethyl Gasoline Corporation, and shown in Table 1, using a similar engine at 350 deg. fahr. jacket temperature and the same Mid-Continent D.A.G. and benzol, but different California Fighting Grade gasoline, show the effects of engine speed and knock intensity upon lead-benzol ratings by both bouncing-pin and temperature-plug methods of test. The lead equivalents of 50 per cent of benzol in the two gasolines were determined by both methods at two engine speeds and at two knock intensities. The effect of engine speed in changing the relative rating between lead and benzol, shown in Table 1, has been observed in the testing of undoped fuel. A highly naphthenic California gasoline was matched with a benzol Mid-Continent D.A.G. blend at 600 r.p.m. and 350 deg. fahr. jacket temperature. On raising the engine speed to 900 r.p.m. without other change than increase of throttle opening, the amount of benzol in the D.A.G. required to match the California was found to be considerably increased.

Some investigators have obtained a sensitivity of knock determination of considerably less than 1/2 per cent of benzol in a given fuel under fixed engine conditions. While this is a remarkable achievement, its usefulness as applied to aviation fuels would, from the effects shown in Figs. 1 and 3 and Table 1, appear to be open to doubt.

It would seem that a series of tests in a variable compression engine working at full throttle with both varying jacket temperature and engine speed would be of much value. The Air Corps, however, is not in a position to carry out such tests at present.

The foregoing discussion of determination of anti-knock value and the effect of test-engine conditions upon it serves to show that it is not possible to do much more than generalize upon the subject of anti-knock values of fuels for aircraft engines and that a large amount of multicylinder-engine data will be necessary for any-

thing like a complete understanding of the problem. Some sort of knock test, however, for fuel for the modern aircraft engine of high performance is vastly better than no test whatever, as it will provide at least a partial control of anti-knock value. The Air Corps has equipment now in service which will fail in a few minutes if operated on fuel of lower anti-knock value than that on which it has been developed. The Air Corps has therefore issued tentative specifications for anti-knock fuel, using its best present judgment as to the specified test conditions. Revision of these specifications as further experience is obtained will undoubtedly be necessary.

In setting any specification for anti-knock value, it is highly desirable to have a reproducible primary knock standard consisting of a mixture of two pure compounds for reference purposes. The Heptane-Octane (2–2–4–trimethyl pentane) scale, first proposed by Graham Edgar,[4] has for the present been adopted by the Air Corps. This scale is at present considered preferable to the normal Heptane C.P. Benzol scale used by Brown,[5] Stansfield and Thole,[6] and others, as the temperature effect shown in Figs. 1 and 3 does not cause the disturbance with the Heptane-Octane scale that it possibly does with a scale involving the use of aromatics.

SECTION 2 AVAILABLE FUELS AND ANTI-KNOCKS

1 Fuels

The Matériel Division has taken the standpoint that it will adopt the best possible base gasoline having any wide availability and to this add the maximum usable quantity of anti-knock material, of which large supplies can, if necessary, be obtained.

The practice of the Air Corps until recently was to use Mid-Continent D.A.G. and to add benzol to this when fuel of superior anti-knock value was required. For service purposes, benzol in excess of 20 per cent cannot be used owing to freezing in the fuel tanks and lines, and even this amount causes considerable additional trouble with ice formation in the carburetors and induction systems when the water content of the atmosphere is high. For special purposes, such as racing, benzol contents have occasionally been as high as 80 per cent. In service, if trouble with ice formation in the induction system is to be avoided, the freezing point of the fuel should not be much in excess of —60 deg. cent., and this limits the benzol concentration to approximately 20 per cent.

Other aromatic compounds, such as toluene, are free from the freezing disadvantages of benzol. Alkyl benzene has a freezing point of approximately —60 deg. cent., and in concentrations up to about 50 per cent, apparently has a better anti-knock value than benzol. The production of toluene is quite limited and hardly equal to the demand and would likely not be available at all in time of emergency. The supply of alkyl benzene depends upon benzol production, but due to the increase of volume as a result of synthesis and the higher anti-knock value, 100 gal. of benzol synthesized to alkyl benzene produces approximately the same effect as 270 gal. of benzol. Alkyl benzene apparently could be competitive in price with benzol for equal anti-knock effect.

It is not considered that present or possible production of any aromatic anti-knock would warrant relying upon the exclusive use of such compounds, even in the best available gasolines for the anti-knock fuel requirements of the Air Corps. A service-test program of alkyl benzene added to highly anti-knock gasoline in supercharged air-cooled engines is shortly to be undertaken.

When the Air Corps started to investigate fuel problems, the first step was to test as many of the available aviation gasolines as possible with a view to obtaining as good a base fuel as possible. The result of this test program was to show that available California straight-run aviation gasolines were equal to average Mid-Continent D.A.G. plus 25 to 50 per cent benzol. Some cracked gasolines at lower cylinder temperatures were found to be better than the best California gasolines. As the California gasolines with tetraethyl lead added seemed to be subject to relatively less loss of anti-knock value with increase of cylinder temperature in terms of Heptane-Octane than any fuel blend tested, a first-class California Fighting Grade gasoline with 3 cc. of lead added was tentatively chosen as a standard. A variety of cracked gasolines have been rated at 900 r.p.m. and 350 deg. fahr. jacket temperature on the Series 30 Ethyl Gasoline engine. Only one cracked gasoline that will meet Air Corps requirements for gum has been found that will equal the tentative standard with less than 6 cc. of lead per gallon. Present Air Corps requirements for anti-knock gasoline specify the Series 30 Ethyl Gasoline Knock Test Engine with 300 deg. fahr. jacket temperature at 600 r.p.m., and it has been found that this reduction of jacket temperature and engine speed results in several gum-stable, cracked gasolines meeting the specified anti-knock rating of 87 Octane-13 Heptane with less than the allowable maximum lead concentration of 6 cc.

Cracked gasolines have been little used for aviation purposes, as the Federal specifications for aviation gasolines allow only 3 mg. of copper-dish gum. While this requirement is almost impossible to meet with cracked fuels, the Matériel Division has found cracked gasolines that do not increase gum in storage, and while having higher values than the Federal specifications allow, do not cause trouble from gum deposits in service. The Matériel Division operated one 9-cylinder 430-hp. air-cooled radial engine and one 12-cylinder 425-hp. water-cooled vee engine on cracked gasoline, showing a glass-dish gum value of 10 mg. after accelerated aging (test described later) and containing 3 cc. of lead. The air-cooled engine was flown for 66 hours and the water-cooled engine for 128 hours, both exclusively on this fuel, and on stripping the engines, no difference in condition due to the use of cracked gasoline in place of straight-run fuel could be detected.

Low and stable gum values in cracked gasoline appear to be obtainable. Even completely vapor-phase cracked gasolines of exceedingly high anti-knock value can apparently be made gum-stable by the use of gum inhibitors. It would seem that the use of such gasolines for anti-knock aviation fuels is worthy of study and test. So far, the cracked gasolines tested by the Matériel Division at high cylinder temperature have proved inferior to straight-run California gasolines when lead is added to both. Whether the relative inferiority is due to loss of anti-knock value of the cracked base as a result of the temperature effect or whether tetraethyl lead is less effective in raising the anti-knock value of such bases has yet to be determined, at least so far as the Matériel Division is concerned.

While the California gasolines, so far, appear to be the best available base, the problem of supply of such fuel in many of the states away from the seaboard is rather difficult, and cracked gasolines appear to offer a possible alternative. Developments in cracking may result in the production of gasolines that are less liable to loss of anti-knock value at high cylinder temperature, and investigation of this phase would seem desirable.

The depreciation of anti-knock value of cracked gasolines at high charge temperatures appears to be a generally observed

[4] "Measurement of Knock Characteristics of Gasoline in Terms of a Standard Fuel," Graham Edgar, *Industrial and Engineering Chemistry*, January, 1927.

effect. Other laboratories, using test methods quite different from those of the Matériel Division, have found this.

The anti-knock value at fairly high cylinder-temperature conditions of the best base fuel that the Matériel Division feels can have any wide availability is approximately 75 Octane-25 Heptane. This is about equal to that of doped and cracked automobile gasolines now sold in large quantity, although many of these, while giving this anti-knock value and higher at 212 deg. fahr. jacket temperature, will not do so at 300 deg. fahr. While the initial anti-knock value of the base may be roughly 75 Octane-25 Heptane, different fuels of this initial anti-knock value may, and do, require considerably varying additions of anti-knock compound to bring them to the present Air Corps standard of 87 Octane 13 Heptane.

Volatility. The Air Corps has tentatively adopted Federal Fighting Grade volatility requirements (modified as discussed under Vapor Lock, Section 5) for its anti-knock gasoline specification as it has been found that even such volatile fuel as this requires considerable heating of the intake system for maximum fuel economy.

The use of fuel of average automobile volatility (30 per cent over at 100 deg. cent. and 200 deg. cent. plus end point) in military aircraft engines almost always involves a very considerable drop in output. A recent test on a Curtiss D-12 engine with an automobile gasoline of ample anti-knock value showed a drop in power of 10 per cent over that given by D.A.G. In the same engine, the use of very volatile natural gasoline (which cannot be considered for service use with present fuel systems) gives an increase of power and reduction of fuel consumption over that obtainable with D.A.G., the improvement in power no doubt being due to increase of volumetric efficiency as a result of greater evaporation and increase of charge density prior to entrance to the cylinder and the reduction of fuel consumption to improved distribution.

Gum. The recently issued tentative Air Corps Specification for Anti-Knock Fighting Grade Gasoline has eliminated the copper-dish gum requirement and tentatively substituted an accelerated aging test with oxygen. This test consists essentially of treatment with oxygen at 100 lb. pressure for two hours at 212 deg. fahr., followed by evaporation of 100 cc. in a glass dish, the maximum allowable gum being 15 mg. This test is an early form of one now in use by the Standard Oil Company of New Jersey[7] and to whom its use by the Air Corps is due.

The anti-knock requirements of the recently issued specification are such that some refiners will probably supply cracked gasoline. The accelerated oxygen aging test has therefore been adopted in view of the known unreliability of the copper-dish test for other than straight-run gasolines. So far, no gasoline has been found that will pass the accelerated aging test specified and develop excess gum in storage, although there is some suspicion that some gasolines which will not pass it may not develop excess gum in storage.

The test has been adopted tentatively, pending an investigation by the Bureau of Standards of accelerated aging tests which will duplicate gum stability in storage.

The Air Corps has subjected samples of straight-run and cracked gasolines to accelerated aging and tested the anti-knock rating of the aged against the unaged samples. In the case of a straight-run California Fighting Grade gasoline, the aged sample required less than 0.2 cc. lead to equal the unaged. In the case of a vapor-phase cracked gasoline which increased its gum value by approximately 1700 mg. on aging, over 10 cc. lead was required to bring the aged sample up to the unaged.

[7] "Gum in Gasoline," E. B. Hunn, H. G. M. Fischer, and A. J. Blackwood, *S.A.E. Journal*, January, 1930.

2 Anti-Knocks

The available anti-knocks at present are: Aromatics, organo-metallics, carbonyls, aromatic amines, and the alcohols. Of the organo-metallic compounds, only tetraethyl lead has been used commercially. Iron carbonyl has been used to some extent in Germany. Nickel carbonyl has been investigated as regards its anti-knock value, but beyond this does not seem to have been used in multicylinder engines. The aromatic amines, such as aniline, ortho-toluidine, xylidine, etc., have been the subject of considerable research and have been used to some degree for racing and special purposes, but have found no general application. Anhydrous ethyl alcohol in the smaller concentrations is, apparently, a better anti-knock than benzol. Owing to its high latent heat of evaporation, it increases volumetric efficiency and internally cools the cylinder unit, and on this account as been used largely for racing purposes in high concentrations, mainly in air-cooled motorcycle engines. In some racing-aircraft engines, overheating and failure have been avoidable only by the use of fairly heavy alcohol concentrations. Only anhydrous alcohol is soluble in gasoline, and even in mixture is exceedingly hydroscopic and picks up water from the atmosphere, with the result that the alcohol is almost entirely thrown out of solution and the anti-knock effect confined to one layer of the fuel.

The viewpoint and experience of the Matériel Division with the aforementioned anti-knock compounds are as follows:

(*a*) *Aromatics.* Aromatic compounds, particularly those with low freezing points, are mainly of use for adding to gasolines in cases where the base fuel cannot be brought up to requirements by the use of dopes alone. Aromatic compounds added to doped fuels when the aromatic concentration is of the order of 30 per cent have in several cases resulted in an increase of fuel consumption of the order of 3 per cent over that obtained with a doped fuel of similar anti-knock value and low aromatic content.

(*b*) *Organo-Metallics.* Tetraethyl lead in the form of Ethyl fluid has been rather extensively used by the Air Corps in the last year. This, particularly when added to highly naphthenic fuels such as the California gasolines, makes an exceedingly good fuel for hot-running, high-compression, supercharged engines. It has not been found possible to exceed a rating of about 95 Octane 5 Heptane with any gasoline and 6 cc. of lead at high cylinder temperature, and this only with the best of the California gasolines. When ratings in excess of this are required, it is the practice of the Matériel Division, for the present, to use benzol, toluene, or alkyl benzene in California gasoline with 6 cc. of lead added to the mixture. A detailed discussion of the operating results with Ethyl aviation gasoline is given later.

(*c*) *Carbonyls.* The experience of the Matériel Division is confined to iron carbonyl, and this only in knock-test engines. At 350 deg. fahr. jacket temperature, it was found that spark-plug missing occurred within 3 or 4 minutes after switching over to fuel containing approximately 7 cc. of iron carbonyl per gallon. Experiment with this material has been abandoned for the moment.

(*d*) *Aromatic Amines.* The Matériel Division has used commercial mixed xylidines and commercial ortho-toluidine in a few high-compression engines for racing and has done some single-cylinder endurance testing. The experience is too slight to draw conclusions from except that the single-cylinder tests showed a tendency to foul the engine, particularly the spark plugs. Tests made at 350 deg. fahr. jacket temperature at 900 r.p.m. in the Series 30 Ethyl Gasoline engine, using the temperature plug for determination of detonation, showed that 3 cc. of lead in a high-grade California Fighting Grade gasoline was equaled by 11 per cent of commercial ortho-toluidine and 89 per cent of the same gasoline. Thus, for the same anti-knock effect, ortho-toluidine would cost at least ten times as much as lead.

(*e*) *Alcohols.* The Matériel Division has no experience to date with alcohols as anti-knocks and for the present does not plan to investigate their possibilities.

The experience of the Matériel Division with anti-knocks to date would indicate that, as regards availability and usefulness in modern air-craft engines, tetraethyl lead has the greatest possibilities in raising general service-fuel standards. For limited use, to supplement lead, aromatics have a distinct field which would be greatly increased by increased production and availability of aromatic compounds, in particular those of low freezing point.

Furthermore, it is the opinion of the Matériel Division that in raising the anti-knock standard of service fuel to the highest possible standard of any general availability, dopes are not a remedy for the use of a poor base fuel. Rather, as good a base as possible should be employed and to this be added the maximum usable quantity of dope, and if further improvement in anti-knock value is required, aromatic compounds may be added. In this connection, a test of some interest may be quoted. A high-grade California gasoline plus 6 cc. of lead was tested against the same gasoline-lead mixture plus 30 per cent C.P. Benzol, i.e., 4.2 cc. of lead per gallon. The test was carried out at 350 deg. fahr. jacket temperature and detonation measured by the temperature-plug method. The gasoline-benzol-lead blend was decidedly inferior to the gasoline-lead blend, although exactly how much so was not determined. Thus, the last 1.8 cc. of lead produced more anti-knock effect than 30 per cent of benzol.

Tests of the same California gasoline containing 6 cc. of lead against a blend of 70 per cent of this gasoline, 30 per cent commercial toluene, and 4.2 cc. of lead showed a match by the same method as used for the benzol blend. A match as regards power and cylinder temperature was also obtained in a multicylinder liquid-cooled engine with 7.3 compression ratio and operating at a jacket temperature of 300 deg. fahr. The aromatic blend, however, gave a 3 per cent higher fuel consumption at best setting.

Tests in a highly supercharged water-cooled engine of 5.8 compression ratio, equipped with a gas-turbine supercharger showed that, with another California gasoline, the gasoline with 6 cc. of lead was superior to a blend of 80 per cent this gasoline, 20 per cent motor benzol, and 4.8 cc. of lead.

SECTION 3 FUEL REQUIREMENTS OF MODERN AIR-CRAFT ENGINES

The anti-knock value of the fuel required by aircraft engines of even similar type varies considerably. The fuel required will depend upon the compression ratio, the volumetric efficiency (including the use of supercharging to increase this factor), the engine speed, the design and size of the cylinder and piston unit, and the operating temperature of the cylinder unit.

The Curtiss D-12, water-cooled, 12-cylinder, vee engine of 1160 cu. in. capacity and 5.6 to 1 compression ratio, is a most remarkable engine as regards its ability to give high output on relatively poor fuel. This engine at 180 deg. fahr. jacket temperature has a peak b.m.e.p. of 138 lb. per sq. in. at approximately 1900 r.p.m. and develops this on average Mid-Continent D.A.G. (approximately 48 Octane-52 Heptane knock rating) at a specific fuel consumption of about 0.52 lb. per b.hp-hr. At 2300 r.p.m., 130 lb. b.m.e.p., and 435 b.hp. are developed, with a specific fuel consumption of approximately 0.5 lb. on Mid-Continent D.A.G. With 7.3 compression ratio and 180 deg. fahr. jacket temperature, approximately 4 cc. of lead is required in Mid-Continent D.A.G. (approximately 77 Octane-23 Heptane knock rating). 512 b.hp. or 152 lb b.m.e.p. is developed at 2300 r.p.m. on a specific fuel consumption of 0.45 lb. At 5 6 compression ratio and 300 deg. fahr. jacket temperature, 425 b-hp. or 127 lb. b.m.e.p. is developed at 2300 r.p.m. on a specific fuel consumption of 0.44 lb. with approximately 2 cc. of lead in Mid-Continent D.A.G. (approximately 73 Octane-27 Heptane knock rating). The same performance is obtained with 40 per cent of Motor Benzol and 60 per cent Mid-Continent D.A.G. At 7.3 compression ratio and 300 deg. fahr. jacket temperature, 488 b-hp. or 144 lb. b.m.e.p. is developed at 2300 r.p.m. on a specific fuel consumption of 0.41 lb., the fuel being California Fighting Grade, plus 6 cc. of lead (knock rating approximately 91 Octane-9 Heptane). In this case, by leaning the mixture out so as to produce a 3 per cent power drop from the maximum, a specific fuel consumption of 0.39 lb. has been obtained.

The Curtiss V-1570, 12-cylinder, vee, water-cooled engine is similar to the Curtiss D-12 engine, except that it has open-end sleeve aluminum-block cylinder construction in place of closed-end sleeve, has 1570 cu. in. capacity instead of 1160 cu. in., and the compression ratio is 5.8 to 1. At 2400 r.p.m. and 180 deg. fahr. jacket temperature, 620 b-hp. or 130 lb. b.m.e.p. is developed on Mid-Continent D.A.G. with approximately $^1/_2$ cc. of lead, with a specific fuel consumption of 0.47 lb.

With 8.3 compression ratio at 180 deg. fahr. jacket temperature, 700 b.hp. or 147 lb. b.m.e.p. is developed on a specific fuel consumption of 0.41 lb. with a Fighting Grade California Gasoline plus 6 cc. of lead, having an approximate knock rating of 88 Octane-12 Heptane, this fuel being barely good enough from the anti-knock standpoint, but the engine condition in this test was somewhat doubtful.

A somewhat modified version of this engine, with a geared supercharger and 5.8 compression ratio, gave the following performance at 180 deg. fahr. jacket temperature and 2400 r.p.m.:

848 b.hp. or 178 lb. b.m.e.p., specific fuel consumption 0.53 lb.

810 b.hp. or 170 lb. b.m.e.p., specific fuel consumption 0.45 lb.

The fuel used was a California Fighting Grade gasoline with 6.8 cc. of lead (approximate knock rating, 88 Octane-12 Heptane). The pressure in the intake manifold in the foregoing tests was 12 in. Hg. above atmospheric.

Another modified version of this engine, similar to the standard engine, except that it has smaller valves and somewhat different manifolds, gave the following performance:

600 b.hp. or 126 lb. b.m.e.p. at 2400 r.p.m. with 180 deg. fahr. jacket temperature on a specific fuel consumption of 0.49 lb.

At 300 deg. fahr. jacket temperature, 574 b.hp. or 121 lb. b.m.e.p. was obtained at 0.48 lb. specific fuel consumption and 578 b.hp. or 122 lb. b.m.e.p. at 0.53 lb. specific fuel consumption.

The fuel used in these tests was Mid-Continent D.A.G. with 3 cc. of lead (approximately 75 Octane-25 Heptane, knock rating) which was of course unnecessarily good for the tests at 180 deg. fahr. jacket temperature.

The Matériel Division has as yet to find any water-cooled engines that, on a given fuel, will either develop equal unsupercharged mean effective pressure or allow of equal compression ratio without supercharging, as do the Curtiss D-12 and V-1570 engines. Several water-cooled engines have been tested that will develop only 120 lb. b.m.e.p. or a little over on average Mid-Continent D.A.G. and that cannot use compression ratios in excess of 5.4 to 1 on this fuel at ground level.

Air-cooled engines, in general, at equal brake mean effective pressure demand considerably better fuel than the best of the water-cooled engines. In fact, the Air Corps has only one air-cooled engine in service that will give satisfactory full-throttle operation at ground level on Mid-Continent D.A.G. This

engine develops only 220 hp. and a little over 120 lb. b.m.e.p. at 1800 r.p.m.

One 9-cylinder, radial, air-cooled engine, of approximately 1750 cu. in. capacity, develops 130 lb. b.m.e.p. at 1900 r.p.m. with 5.2 compression ratio and a specific fuel consumption of about 0.52 lb. The fuel required is approximately $1^1/_2$ cc. of lead in average Mid-Continent D.A.G. At 8.0 to 1 compression ratio, 144 lb. b.m.e.p. was obtained at 1900 r.p.m. with 0.45 lb. specific fuel consumption. The fuel used was 70 per cent California Fighting Grade gasoline, 30 per cent Motor Benzol, with 6 cc. of lead in the mixture. The anti-knock value of the fuel blend used is not known. However, the California gasoline used has approximate knock ratings of 87 Octane-13 Heptane with 3 cc. of lead and 91 Octane-9 Heptane with 6 cc. of lead. The engine could not be operated at full throttle with the best California gasoline and lead alone; at least not with any lead concentration that the Air Corps considers worthy of test.

One supercharged, air-cooled, 9-cylinder, radial engine, in flight, gives very satisfactory operation on Mid-Continent D.A.G. plus 3 cc. of lead (approximately 75 Octane-25 Heptane knock rating) if the throttle is not opened fully below 5000 ft. altitude. This engine has 5.2 compression ratio and at 2300 r.p.m. develops a pressure at the intake valves of approximately 9.5 in. Hg above atmosphere. On the dynamometer with any fuel, this engine is liable to stick pistons in a few minutes at full throttle and 2300 r.p.m. if the specific fuel consumption be lowered below 0.6 lb. This is no reflection on the engine in question, as it is not designed for ground boosting, but rather as an altitude engine. A change to a piston design with a liberally ribbed interior which results in very considerable piston cooling by the oil in the crankcase (and sharply increases the temperature rise of the oil through the engine) resulted in full throttle dynamometer operation being possible. The engine, equipped with the ribbed pistons, was run for about 12 hours at full throttle, developing 620 b.hp. or 159 lb. b.m.e.p. on a specific fuel consumption of 0.51 lb., the fuel used being a California Fighting Grade gasoline with 6 cc. of lead and an approximate knock rating of 88 Octane-12 Heptane. This performance is of interest on two grounds (*a*) It shows the marked influence of design on fuel requirements, and (*b*) in comparison with the performance obtained from the 8 to 1 compression ratio, 1750 cu. in., 9-cylinder, air-cooled engine referred to above, with a limitation on the fuel used, supercharging offers greater possibilities for increase of output than does high compression alone.

The relation between the maximum output obtainable from the Curtiss V-1570 at 180 deg. fahr. jacket with 8.3 compression ratio and with supercharging, in both cases on approximately the same fuel and working close to the limit of the fuel, is also of interest in showing the advantage of supercharging over high compression for maximum output. This engine also shows that supercharging to high output can be obtained with relatively excellent fuel consumption.

The anti-knock value of the fuel required by an engine can be materially diminished by increasing the fuel consumption over that necessary for "best setting" (specific fuel consumption giving 1 per cent less than maximum power). In general, the policy of the Air Corps is against such a procedure, which, while it produces engines of low specific weight, tends to excessive total fuel consumption and neglect of cylinder design.

In the light of present knowledge the Air Corps proposes to specify a standard fuel and to rate engines in terms of the power they will produce on this fuel at specified maximum allowable fuel consumption at ground level or with an air density at the carburetor air intake equal to that at 5000 ft. altitude, depending upon the duty for which the engine is required. While the rated power will be obtainable at the stated r.p.m., under the conditions given, either increase of specific fuel consumption or of the anti-knock requirement of the fuel will be required when in full climb for most engines, as the resultant reduction of engine speed causes an increased tendency to detonation. Callender, King, and others[8] obtained the figures shown in Table 2, which shows this effect, on a Ricardo E-35 variable-compression engine. While the same fuel was used over the speed range, the usable compression ratio increased with engine speed.

TABLE 2

R.p.m.	Highest useful compression ratio
1200	4.45
1300	4.65
1400	4.90
1500	4.95
1600	5.00

The effect of engine speed in allowing increase of b.m.e.p. with a given fuel will likely be of decided value in the future, as the tendency is for engine speeds to increase.

As has been stated, the design of the cylinder unit has, under any given set of conditions, a very pronounced effect upon the output obtainable from a given fuel. Cooling of the cylinder head and barrel, valve cooling, piston cooling, spark-plug location, and combustion-chamber shape all have their influence. It is the policy of the Air Corps that the maximum of cylinder and engine development shall take place around a standard fuel and that engines shall be made to suit fuels, rather than fuels to suit engines.

Engines will be rated in terms of their performance on standard fuel and at specified fuel consumption, rather than in terms of what may be got out of them with a super-fuel and at excessive fuel consumption. This should tend to improve cylinder design and cooling and put an end to the rather prevalent system of cutting engine weight at the expense of fuel consumption, often with the result that, despite the reduction of engine weight, the total power-plant weight, with fuel for one hour's flight, is increased.

The Heptane-Octane anti-knock ratings of the fuels referred to in this section are, as can be gathered from the discussion on "Determination of Anti-Knock Value," Section 1, at the best only approximate, but represent the best average figures available for the fuels in question and at least mean more than quoting the amount of lead or benzol in D.A.G. or Fighting Grade. The percentages of Heptane and Octane referred to are all by volume, although weight percentages represent a more accurate and desirable method of using this scale.

The case of the liquid-cooled engine with a limitation on the maximum anti-knock value of the fuel available may well be considered. A high temperature of the cooling liquid is desirable, as this diminishes the size of the radiator required and thus the parasitic cooling drag. Practically all work with cooling liquids of high boiling point to date has been done at 300 deg. fahr. but it is possible and probable that the optimum jacket temperature will depend upon the type of engine and the type of airplane it is used in.

Increase of jacket temperature reduces the possible compression ratio and the degree of supercharging. The highest possible compression ratio is desirable as it improves fuel economy and reduces the specific heat rejection to the cylinder walls. A high degree of supercharging is desirable, as it produces the greatest increase of output on a given fuel, at the expense, however, of fuel economy and total heat rejection by the cylinder and piston unit.

It is obvious, therefore, that in any particular engine the opti-

[8] Aeronautical Research Committee (British) Reports and Memoranda No. 1062, H. M. Stationery Office.

mum condition for each installation will depend on a nice balance between radiator size as affected by both jacket temperature and compression ratio, fuel economy as affected by compresson ratio, and output as affected by both compression ratio and degree of supercharge, the latter having the major effect, of course.

In the case of a bomber, where the radiator drag is but a small percentage of the total for the airplane and where the maximum ground power available for take-off is required, it is possible that a jacket temperature of the order of 180 deg. fahr. will be most desirable. In this case, fuel economy is of importance for long range; therefore, the compression ratio will probably be such as to cause no undue sacrifice of range.

In the case of a pursuit airplane, where ground power for take-off is ample and speed and the ability to go to high altitude are of paramount importance, the minimum radiator size and the maximum degree of supercharge will probably be aimed at.

SECTION 4 CORROSION AND ATTACK DUE TO FUEL IN AIRCRAFT ENGINES

Corrosion problems due to fuel are a great deal more severe in aircraft engines than in automobile engines. The steel cylinder barrel almost always used in aircraft engines is largely responsible for this difference, as the cast-iron cylinder of the automobile engine is relatively much less susceptible to corrosion. In addition, many aircraft engines have unlubricated valve gears, with the result that exhaust-valve corrosion and sticking are a great deal more prevalent than in the average automobile engine with its oiled valve gear.

The use of doped fuels containing halogens in many cases results in a considerable amount of corrosion trouble with resultant difficulty in service that is not met with in normal undoped fuels. Corrosion having been a quite general experience with doped fuels, it has become a habit to attribute all such trouble to the use of this type of fuel. It is worthy of note, however, that as bad a case of engine corrosion as any yet experienced by the Matériel Division occurred in an engine that had been operated on 20 per cent benzol mixture, the benzol containing 0.37 per cent sulphur and causing heavy corrosion in the copper-dish test, large, loose flakes of copper sulphide being formed. This fuel blend caused rusting of the cylinder bores and produced a heavy dark-gray deposit in the exhaust ports of the aluminum head.

The corrosion problems occurring in a variety of types of aircraft engines as a result of the use of doped fuels are discussed below.

1 Cylinder Corrosion

The use of tetraethyl lead in conjunction with the theoretical quantity of bromine to convert all the lead present to lead bromide during combustion results in most cases in a slight amount of corrosion in the top part of the cylinder bore with normal cylinder-barrel material such as 0.40 to 0.50 carbon steel. This corrosion, which occurs while the engine is standing, usually extends from $^1/_2$ to 1 in. below the upper limit of piston-ring travel. That any operating difficulty results from this corrosion there is little or no evidence. Similar corrosion appears to occur at times with cast-iron cylinder bores, and yet no trouble is known to occur from this source in automobile engines operated on Ethyl gasoline. The higher the operating temperature of the engine, the the less is this corrosion as a rule. For a considerable period, Ethyl gasoline containing 50 per cent bromine in excess of that necessary to convert all lead present to lead bromide was in use. This excess bromine resulted in a great deal more corrosion than that caused by the use of the present mixture containing only the amount necessary for complete conversion to lead bromide.

Corrosion of the cylinder barrels due to the condensation of aqueous products of combustion which have blown by the piston rings and which condense on the cylinder walls below the pistons during standing causes some trouble. This would seem to be affected by the method of crankcase breathing. One radial, air-cooled engine which breathes through the hollow rear section of the crankshaft into the rear accessory drive housing has caused trouble in this respect, although there is no evidence that such trouble would not occur with undoped fuel. In the matter of crankcase breathing, it is worthy of note that some of the automobile companies make it an invariable practice to place the crankcase breather on the highest point of the case so that the aqueous products of combustion will be expelled on standing, due to the fact that their density is less than that of air. An air bleed into the bottom of the crankcase allowing the entrance of air to replace the blown-by products of combustion which may be discharged to atmosphere by reason of their relatively lower density is worthy of consideration on aircraft engines. This would be similar in effect to the crankcase ventilation systems used in automobile engines.

Corrosion of cylinder bores of cast-iron cylinder automobile engines as a result of condensation of products of combustion of undoped fuels within the combustion chamber is known to occur quite rapidly after shutting down, and in practice causes but little trouble.

In composite aluminum and steel cylinders, the use of tetraethyl lead in the fuel results in a sticky white liquid exuding from the aluminum portions exposed to products of combustion after the engine has stood some time. This liquid, which appears to be mainly an aqueous solution of aluminum bromide, rapidly corrodes carbon-steel cylinder bores, etc., that it may come in contact with if they are dry of oil. As a rule, the presence of oil is sufficient to prevent such corrosion, and in many cases a cylinder will not corrode after removal from an engine until it is washed off with gasoline. It is the practice, therefore, in the Air Corps to oil-slush cylinder unit parts that have been operated on doped fuel, after washing off with gasoline. Attempts have been made to eliminate cylinder corrosion by injecting pressure oil into the induction system while the engine is being shut down, the purpose being to spread an oil film over the inside of the cylinders and over the exhaust-valve stems in the case of unlubricated valve gears. This has been tried with a large air-cooled radial engine with unlubricated valve gear and no direct breathing from the crankcase. The engine has been several times flooded with oil while shutting down and with such quantity of oil as to cause very heavy smoking. No spark-plug fouling has occurred, and corrosion of the tops of the cylinder bores seems to be eliminated. Corrosion of the cylinder bores below the pistons due to condensation of products of combustion within the crankcase has not been eliminated, and rusting of exhaust-valve (cobalt chrome steel) stems occurred in every test, although reduced by the oil treatment.

Limited experience with an inverted 12-cylinder, vee, air-cooled engine with a completely lubricated overhead camshaft valve gear has, to date, shown an entire absence of corrosion due to the use of doped fuel. This is apparently due to the fact that oil drains down the cylinder bores after the engine is shut down. An entire absence of corrosion of valve heads and stems has been observed to date, although the cobalt-chrome valve steel used will corrode fairly rapidly in an unlubricated valve gear.

The Matériel Division is conducting and sponsoring experiment with corrosion-resisting material for cylinder barrels in composite aluminum cylinder construction. Troubles arise in composite aluminum and steel cylinder construction due to the fact that the coefficient of thermal expansion of the aluminum alloys used for the cylinder heads is approximately twice that of the carbon steel normally used for cylinder barrels. The use of corrosion-

resisting material for cylinder barrels at once suggests that the disparity of thermal expansion of the cylinder head and barrel can be, to a large degree, eliminated by the use of the austenitic stainless steels for barrels. The coefficient of expansion of aluminum is only 30 to 40 per cent greater than that of some of the austentic steels and cast irons. This results in the possibility of a great reduction of the differential expansions which cause much trouble in composite cylinder construction. The shrink of the cylinder barrels in the heads can be reduced, with the result that less stress is put in the head, and there is less chance of permanently stretching the head. In addition, the cylinder barrel is less liable to go bell-mouthed at the top of the bore when the shrink of the head on the barrel is relieved as the engine heats up to operating temperature. Piston conditions will be largely improved on account of the reduction of piston clearance allowable. This will improve piston cooling and tend to improve piston bearing conditions, due to reduced rocking of the piston. The reduction of piston rocking and lessening of bell-mouthing of the bore at the head end will further materially improve piston-ring conditions and wear.

The use of cylinder-barrel material with a higher coefficient of thermal expansion than that of normal carbon steel is not a new idea. Experiment with bronze sleeves in aluminum cylinders was carried out in England by Gibson[9] in 1916-18, but was abandoned, owing to excessive wear of the sleeves.

Most of the austenitic nickel-chromium stainless steels, containing 8 to 20 per cent nickel and 12 per cent and over of chromium, have been found to have very high resistance to attack by both condensed aqueous acid products of combustion from doped fuels and to the constituents in the hot gases tending to cause attack. In these respects the austenitic steels have proved superior to the stainless steels containing chromium only and which approximate in coefficient of thermal expansion to the normal carbon steels.

With increase of operating temperature in modern liquid-cooled engines and composite aluminum and steel cylinder construction, the use of cylinder-barrel material with a higher coefficient of expansion than that of the carbon steels would appear to be extremely desirable in order to reduce stresses in the cylinder heads, maintain liquid tightness of the seal between the head, and generally reduce differential expansion between the aluminum portions of the cylinder and the barrel. Thus, the added cost of the corrosion-resistant barrel would appear to be justified upon other grounds than the use of doped fuel. Forged and cast austenitic nickel-chromium steels and austenitic cast-iron containing nickel and copper are being experimented with. One European aircraft-engine constructor reports that attempts some three years ago to use austenitic nickel-chromium stainless steel cylinder barrels resulted in rapid scoring of the barrel, despite the use of castor oil. It is reported that austenitic cast-iron cylinder barrels have already been successfully used in automobile engines, and instead of scoring readily, the material rapidly work-hardens to a hard glaze. Tests carried out for the Matériel Division of austenitic cast-iron and forged-steel barrels for composite aluminum cylinder liquid-cooled engines have to date shown:

(*a*) That the cast iron rapidly develops a hard high glaze. The physical strength is so much lower than that of carbon steel, however, that a barrel that will not fail mechanically cannot be obtained with the space and design limitations of the engine in question.

(*b*) That in the same engine as used for the tests of cast-iron barrels, the forged austenitic steel barrels eliminate the leakage experienced with carbon-steel barrrels at 300 deg. fahr. jacket temperature. They are, however, exceedingly difficult to machine and present problems due to scoring and excessive piston-ring wear.

The importance of differential expansion in the cylinder and piston unit is shown by the vast amount of experiment that has gone on in the automobile-engine field directed to reduction of clearance between the cylinder bores and aluminum pistons. It is noteworthy that the use of aluminum alloy with considerably reduced thermal expansion is making some headway for pistons.

It would appear that austenitic cylinder-barrel material is more readily applicable to liquid-cooled than to air-cooled engines, as the thermal conductivity of such material is only of the order of 30 per cent of that of normal carbon steel. In the case of the air-cooled engine with fins integral with the barrel, the fin thickness and weight would of necessity need to be approximately trebled. The use of fins of higher conductivity attached to the barrel with a sound thermal bond, or the reversion to a cylinder construction, using an integral aluminum cylinder head and finned barrel with a shrunk-in austenitic steel cylinder sleeve, would appear possible. The last-mentioned cylinder construction proved to be unsatisfactory with carbon-steel barrels, due almost entirely to differential expansion. In any case, the cylinder corrosion troubles due to the use of doped fuel in air-cooled engines with lubricated valve gear largely appear to be capable of solution without the use of corrosion-resistant cylinder-barrel material. Many air-cooled engines now in use in the Air Corps are using doped fuel with negligible trouble from cylinder corrosion. In most of the large air-cooled engines in use in the Air Corps, the elimination of doped fuel in favor of any readily commercially available anti-knock fuel would result in overheating and other troubles which would be a great deal more serious than those resulting from the use of dope.

2 Valve Corrosion and Attack

The use of fuels doped with tetraethyl lead will cause, and in many cases has caused, a great deal of operating trouble due to corrosion of exhaust valves. This seems to have two phases: rusting due to condensed acid products of combustion which occurs on the stem and seat of the valve and erosion or attack of the seat and other portions of the valve head by hot products of combustion. The first cause is much the more serious as it causes sticking and often, as a result, rapid wear of the valve guide and stem.

Corrosion can be entirely eliminated by the use of suitable material in unlubricated valve gears. Materials unsuitable for use with unlubricated valve gears can be made to function satisfactorily with lubricated valve gears without great difficulty in the majority of cases. The use of some of the austenitic nickel chromium valve steels appears to be an almost complete answer to corrosion due to fuel doping with tetraethyl lead, even with unlubricated valve gears.

Nitrided Silchrome No. 2 steel is probably the most unsatisfactory valve steel as regards use with Ethyl gasoline that the Matériel Division has as yet had experience with. In an aluminum cylinder, liquid-cooled engine with aluminum-bronze valve seat inserts and completely lubricated valve gear, this material was rapidly attacked on the seats of the valves. The attack was sufficiently rapid to require frequent replacement of the valves. Whether this attack was due to condensed products of combustion or to the hot gases is not known. The same material when used in an air-cooled engine with a partially lubricated valve gear caused a great deal of trouble with valve sticking. This sticking was unknown when undoped fuels were used.

Tungsten steel with analysis within the range used for high-

[9] "Resume of Experimental Work on Air-Cooled Cylinders at the Royal Aircraft Establishment," A. H. Gibson, D.Sc., Internal Combustion Engine Sub-Committee Reports No. 24, H. M. Stationery Office.

speed tools rusts extremely rapidly in unlubricated valve gears when used with Ethyl gasoline. This, however, is hardly of importance, as its use had been almost entirely abandoned on account of its tendency to burn and scale. Tungsten steel was in use in some modern engines in conjunction with internal valve cooling which, by reducing valve temperature, largely prevented scaling. Its use in this case was due to its remarkable wear resistance, but it had to be rapidly abandoned when Ethyl gasoline was used in the engines in question.

Cobalt chrome steel has given a great deal of trouble in unlubricated valve gears with Ethyl gasoline, particularly on the sea coast, and may be regarded as generally unsatisfactory for such use on account of rusting. As far as experience is available, this material appears to be satisfactory for use in lubricated valve gears. Silchrome steel, with and without tungsten (approximately 2 per cent), has proved satisfactory in lubricated valve gears, but rusting of valve seats is at times evident, though no operating trouble has yet been traced to this cause.

All in all, the austenitic nickel-chromium valve steels, some containing tungsten in small quantity, appear to be the best for use with doped fuels. These steels, which have found considerable favor apart from use with doped fuel, have the advantages of remarkable strength at high temperature, are extremely tough at all temperatures if the silicon content is 1 per cent or below, and most of them have high resistance to corrosion and to erosion and scaling by hot products of combustion of doped and undoped fuels. They have the disadvantages of low proportional limit which sometimes results in stretching, cannot be hardened as can cobalt chrome and silchrome steels, and thus do not resist wear as well, and further machining is difficult in the case of hollow-stem aircraft-engine valves. The difficulties of lack of wear resistance can be almost entirely overcome as regards the valve stem by lubrication and reduction of side thrust. Wear on the tip of the stem can be overcome by welding on a hard tip or fitting a hardened plug.

One rather curious effect of the use of Ethyl gasoline in an air-cooled, radial engine has developed in extended endurance with a considerable amount of supercharging. After a large number of hours' running, excessive cylinder temperature and preignition occur, and on removal of the cylinder a deposit is found on the exhaust-valve head in the combustion chamber. On removing this deposit, the cylinder temperature returns to normal and the preignition is absent. The valve steel used contains 7.5 per cent Ni, 12.5 per cent Cr, 2.5 per cent Si, and the deposit is apparently due to lead-bromide attack (see under Exhaust Disposal system), as it is apparently almost entirely magnetic iron oxide. In the later discussion of attack of materials by lead bromide at high temperature, it will be noted that the steel used for those valves is not by any means the best as regards resistance to this attack. Attack does not occcur in the engine in question in normal service, even with a considerable amount of running with supercharging. Therefore, although the trouble is rare, every attention should be given to exhaust-valve cooling in the design of engines for use with doped fuel, particularly in the case of engines with high cylinder temperature and supercharging.

In any engine designed for the use of doped fuel it is desirable that ample valve-gear lubrication be provided. This should be of the circulating oil-splash type. With most of the best of the modern valve steels, ample valve and valve-gear lubrication is an almost complete answer to valve corrosion, as a result of the use of doped fuels.

3 Exhaust Disposal System

Shortly after a general adoption of Ethyl gasoline in service by the Air Corps, numerous cases of airplanes being set on fire by hot particles blown from the exhaust pipes occurred while idling taxying, warming up, or shutting down the engine. In no case did these fires occur in the air, being confined to conditions when the air blast over the wings was sufficiently low to allow the hot particles to settle on the wing surfaces.

Investigation showed that the particles causing the fires were flakes of iron oxide, mainly the magnetic oxide (thus proving that the scale was formed at high temperature). The question of the relative attack of exhaust piping by doped and undoped gasoline and of the relative resistance of a variety of materials to such attack was investigated by the Ethyl Gasoline Corporation. The first method of investigation was to burn doped and undoped gasoline under identical conditions in blow torches, the flame being passed through $1^1/_2$-in. outside diameter by 24-in. long pipes and being sufficiently intense to maintain a zone of 6 in. length at red heat. The results of these tests were as follows:

(*a*) *Mild Steel.* With undoped gasoline: Tube extensively scaled, but scale adherent and none blown out during the 20-hr. test. With Ethyl gasoline: Slightly more scale than with undoped gasoline. Scale decidedly less adherent and some blown out of the discharge end of the pipe during the test. With undoped gasoline plus ethylene dibromide: It was thought possible that the corrosion might be due to the ethylene dibromide in the Ethyl fluid burning to free hydrobromic acid. The amount of ethylene dibromide present in the Ethyl gasoline used in the foregoing test was therefore added to undoped gasoline and a third test was run. This showed corrosion similar to that experienced with undoped gasoline rather than that with Ethyl gasoline.

(*b*) *Monel Metal.* The attack with both undoped and doped gasoline was imperceptible.

(*c*) *Austenitic Nickel-Chromium Steel, 18% Cr, 9% Ni, 0.1% C.* Imperceptible attack with either undoped or doped gasoline.

(*d*) *Mild Steel Calorized.* With undoped gasoline: No perceptible attack. With Ethyl gasoline: No attack in hot zone of tube. Discharge end shows fairly heavy formation of loose, rusty scale, of which about 50 per cent was magnetic.

As the attack did not appear to be due to acid products of combustion, tests were made of the corrosion effects of lead bromide at high temperature. Pieces of a variety of metals about 1 in. sq. were treated with 0.3 gm. of lead bromide and heated to a temperature above the melting point of lead bromide, but below red heat. The heating was continued until all lead bromide was volatilized off, this usually taking about 2 hr. This test is probably too drastic, but the results in general accord with the tests on tubes and experience with various materials in service. The results are as follows:

(*e*) *Mild Steel.* Heavy and very rapid scaling; scale non-adherent.

(*f*) *Mild Steel, Chromium-Plated.* Attack just as heavy and rapid as with mild steel.

(*g*) *Monel Metal.* Very slight attack; deposit produced by attack quite adherent.

(*h*) *Pure Nickel.* Almost imperceptible attack.

(*i*) *Pure Aluminum Sheet.* Fairly heavy attack; deposit adherent. Lead bromide largely reduced to metallic lead.

(*j*) *Nickel-Chromium Steel. 18% Cr, 9% Ni, 0.1% C.* Attack intermediate between Monel metal and mild steel, but relatively slight. Scale less adherent than with Monel metal.

(*k*) *Nickel-Chromium Steel. 18% Cr, 9% Ni, 2½% Si, 0.1% C.* Attack less than in (*j*) and very much localized, producing spots of not very adherent scale, about 0.01 in. thick.

(*l*) *Nickel-Chromium Steel. 17% Cr, 2% Ni, 2.75% Si, 0.2% C.* Attack less than in (*k*), approximately that of Monel metal, but more localized.

(*m*) *Chromium Iron. 13% Cr, 0.1% C.* Attack similar to that of (*j*) but more localized; scale more adherent also.

The Matériel Division has also conducted some crude tests of

lead-bromide resistance at high temperature. Strips of various materials were heated to a bright-red heat and powdered lead bromide was repeatedly dropped on the upper surface and allowed to volatilize off, the treatment being continued for about 10 min., as a rule.

(*n*) *Mild Steel.* Exceedingly rapid attack with the production of heavy, loose, black scale within 5 min. of treating with lead bromide. Mild steel similarly heated without lead bromide showed almost imperceptible scaling.

(*o*) *Nickel-Chromium Steel, 11% Cr, 34% Ni, 4% Si, 0.25% C.* Continued heating for over half an hour produced only a slight, tightly adherent film of black scale.

(*p*) *Cobalt-Chrome Valve Steel, 18% Cr, 1.2% Co, 1.2% Mo, 1.4% C.* Fifteen minutes' heating produced a loose, powdery, non-adherent, reddish-black scale about 0.003 in. thick. This steel, when used in unlubricated valve gears, is heavily attacked whereas it shows almost no attack in lubricated valve gears. The attack by lead bromide is slightly less than that shown by material (*q*). Therefore it would appear that the attack experienced in valve service with cobalt steel is mainly rusting.

(*q*) *Nickel Chromium Valve Steel, 7.5% Ni, 12.5% Cr, 2.5% Si, 0.3% C.* Attack somewhat more pronounced than in the case of (*p*); scale non-adherent. This is a well-known valve steel that gives very satisfactory service for valves and valve seat inserts with heavy lead concentrations, showing neither rusting and, very rarely, scaling. This steel in service, as regards rusting, gives vastly better results than (*p*).

(*r*) *Nickel-Chromium Valve Steel, 19% Ni, 13% Cr, 2% W, 0.40% C.* Better than any steel except (*o*) tried in the Matériel Division tests.

(*s*) *Invar. 33% Ni, Balance Fe.* Attack very slight. Similar to material (*q*).

(*t*) *Heat-Treated Aluminum Bronze, 11% Al, 5% Fe, 5% Ni, 0.1% Mg, Balance Cu.* Rapid attack with the production of non-adherent black scale.

(*u*) *Extruded Aluminum Bronze, 10.5% Aluminum, Balance Copper.* Exceedingly heavy attack with the production of non-adherent black scale which cracks off in cooling. Attack worse than in the case of mild steel under similar treatment.

(*v*) *Cast-Aluminum Alloy, 4% Cu, 2% Ni, 1.5% Mg, Less Than 1.25% Si and Fe, Balance Al.* Slightly pinholed portion of aluminum piston. Heated at below red heat, but to the softening point. Heavy attack and production of relatively large patches of metallic lead. Where the exhaust system does not get sufficiently hot to produce mechanical failure, cast-aluminum exhaust stacks of this alloy have given exceedingly satisfactory service with Ethyl gasoline, no significant attack being experienced.

While the test of heating in the presence of lead bromide as used by both the Matériel Division and the Ethyl Gasoline Corporation is, as previously stated, probably too drastic, it provides approximate data as to the relative resistance of materials to lead bromide at high temperature. The results obtained accord, in general, with attack experienced in various engine parts. The resistance of austenitic nickel-chromium steels and the violent attack of aluminum bronze in particular parallel experiences in hot-running, air-cooled engines as regards valves and valve-seat inserts.

As regards material for exhaust piping, materials (*g*), (*j*), and (*k*) would appear the most promising at the moment, and the final choice will probably depend upon the ease of fabrication and cost, although a variety of considerations enter into the question of the most suitable material apart from corrosion resistance. Complicated and elaborate exhaust disposal systems, such as ring manifolds on radial, air-cooled engines and the extensive exhaust piping used on exhaust-turbine superchargers in particular involve a number of problems other than resistance to temperature and corrosion. Some of the problems involved are discussed below:

(*a*) *Coefficient of Thermal Expansion.* It is not known if the mild steel generally used at present has the most suitable coefficient of expansion. A low coefficient of expansion will, in general, tend to reduce thermal stresses due to temperature differences in the pipe structure itself, particularly at welds, but may cause increased stress as a result of attachment to the engine.

At average operating temperatures of ring manifolds, chromium steel or chromium iron has approximately the same coefficient of expansion as mild steel. Monel metal has approximately 35 per cent greater, and the austenitic nickel-chromium steels, such as materials (*j*) and (*k*), have approximately 65 per cent greater expansion.

(*b*) *Ease of Drawing, Forming, Beating, Etc.* Monel and the austenitic nickel-chromum steels mostly seem to be more difficult to handle in the foregoing respects than dead-soft mild steel, but to present no great difficulties in the fabrication of complicated shapes to those used to working them. The shops at the Matériel Division rather prefer dead-soft annealed austenitic nickel-chromium steel, such as material (*j*), to soft mild steel, as regards forming and beating.

(*c*) *Welding.* In the present state of knowledge, welding would appear to be the simplest method of building up complicated exhaust systems. None of the most suitable materials appears to weld as readily as mild steel.

It is desirable that a material for such use should produce non-spongy welds, that the welds should not be brittle, and that brittleness should not be produced in the metal adjacent to the weld. All the stainless steels discussed appear to be liable to brittleness, either in the weld or in the adjacent metal, unless heat treatment after welding be used. It is also desirable that the welds should have a tensile strength as close as possible to that of the surrounding material. Monel metal appears to braze readily with a spelter consisting of 80 copper 20 zinc which has a melting point of approximately 1600 deg. fahr., which should be more than adequate for any exhaust disposal system worthy of use in aircraft. Even if 80–20 brazing be insufficient, it can readily be reinforced with riveting. None of the stainless steels, either of the straight chromium or the nickel-chromium type, appears to braze well, if at all.

(*d*) *Strength at High Temperature.* Other things being equal, it is desirable that the material should lose as little strength as possible with increase of temperature. From the standpoint of fire hazard in crashes the temperature of the exhaust disposal system at any point should be held below 600 deg. fahr., but this hazard is largely being forgotten or disregarded in the case of radial air-cooled engines. In the case of exhaust-turbine supercharger exhaust piping, local temperatures considerably in excess of 600 deg. fahr. appear at the present to be unavoidable. Therefore, it is desirable that the hot strength of the material used should be as high as possible, in case of accidental overheating, although soft mild steel has to date given little trouble in this respect. The austenitic nickel-chromium steels have the highest strength at elevated temperature of any commercially available material. Monel metal at 1000 deg. fahr. is superior in tensile strength to low-carbon mild steel.

The attack of the exhaust disposal system by the products of combustion of Ethyl gasoline does not, in a suitably designed system, cause relatively greater wastage or attack that is of importance from the viewpoint of life of the equipment. The attack is only of importance from the standpoint of the fire hazard introduced. Any increased rate of wastage of exhaust systems of automobile engines, due to the use of Ethyl gasoline rather than undoped gasoline, would appear in general to be negligible.

Further, the use of corrosion-resistant material for exhaust systems cannot be charged to doped fuel alone, as the commonly used mild steel has been far from satisfactory without the use of

doped fuel, particularly in the case of ring manifolds on large air-cooled engines. Ring manifolds for such engines have been the subject of much investigation in order to reduce burning, corrosion, and scaling, particularly for seaplane use. A variety of stainless steels, very heavy nickel plating of mild steels, and other methods of producing resistance to corrosion and scaling have been worked on. Fortunately, the materials that provide adequate resistance to Ethyl gasoline also are very satisfactory as regards burning, scaling, and salt-water corrosion.

4 Valve-Seat Insert Attack

In air-cooled engines with aluminum-bronze valve seat inserts, mostly of material (*u*), sinking of the exhaust valves into the inserts with fair rapidity is at times experienced with Ethyl gasoline. This occurs either in full-throttle ground testing or in flight, if cooling is inadequate. With some engines, it seems to be a general occurrence under almost any conditions of running and is probably due to inefficient exhaust-valve cooling.

No case of such valve-seat sinking has yet been observed with liquid-cooled engines using cooling-liquid temperatures varying between 180 and 300 deg. fahr. This would indicate that its occurrence is largely a function of valve seat insert and valve temperature.

The tests of aluminum bronze, described in Section 4, subhead 3, show that this material is violently attacked by lead bromide, whereas the austenitic nickel-chromium steels, which have similar coefficients of thermal expansion, are mostly highly resistant. A coefficient of thermal expansion as close as possible to that of aluminum alloy is desirable in order that the inserts shall remain tight in aluminum cylinder heads. Extended full-throttle tests by the Air Corps of materials (*q*) and (*r*) for exhaust-valve seat inserts in an air-cooled engine using gasoline with 6 cc. of tetraethyl lead per gallon showed that both materials were superior to aluminum bronze, such as material (*u*), but that the latter was in reasonably satisfactory condition after 90 hours' running without valve attention. The bronze inserts showed very slight black scaling, whereas the steel inserts were glazed. The valves used in this case were of cobalt-chrome steel, internally cooled, and of approximately 55 Rockwell C hardness on the seats. Similar material to (*r*) eliminated valve-seat sinking in European air-cooled radial engines of 200 hp., operating on Ethyl gasoline in Canada. In this case, valve-seat sinking of the order of $^1/_8$ in. in 50 hours of flying occurred with aluminum-bronze seats and solid cobalt-chrome steel valves. This trouble was apparently due to overheating, caused by faulty installation conditions. Dynamometer tests of this type of engine with inadequate cooling showed that out of a variety of insert materials, including aluminum, bronze and two or three valve steels, the only one immune from sinking was austenitic nickel-chromium steel, and it is understood that since the adoption of this material, no further cases of trouble have occurred.

A rather serious disadvantage of the austenitic nickel-chromium steels for seat inserts is that after considerable service the seating work hardens to a glaze that no ordinary seat cutter will cut, and Carboloy or similar cutting material will probably be required for refacing.

Monel metal would appear to be worthy of trial as a valve-seat insert material. Its resistance to corrosion and lead-bromide attack is high. Its coefficient of thermal expansion (0.15×10^{-5} per deg. cent., 25 to 300 deg. cent.) is between that of bronze and ordinary steel. Ordinary steel inserts can, by suitable precautions, be made to stay tight in an aluminum head. Thus, Monel metal should present no difficulty on this score. The thermal conductivity of Monel metal is 0.06 in c.g.s. units, approximately twice that of the austenitic nickel-chromium steels, which is of some advantage in a seat insert. Whether Monel metal will glaze so that it cannot be recut with ordinary seat cutters will be determined by experiments now in progress.

5 Valve Gear

In general, the use of Ethyl gasoline tends to somewhat increase the corrosion of valve-gear parts, such as valve springs, camshafts, rockers, etc. Such corrosion, due to the condensation of products of combustion within the valve-gear housing, is by no means unknown even with undoped fuel, heavy pitting of valve springs and camshafts being not uncommon. The greater acidity of the products of combustion of Ethyl gasoline shows a tendency to increase such rusting and pitting. The remedies for this type of corrosion are: (1) The elimination of pockets which hold condensed products of combustion within the valve-gear housings; (2) removing the fumes from the valve housing as rapidly as possible; (3) oiling all parts of the gear as liberally as possible; and (4) avoiding such overcooling of the valve-gear housing as tends to increase condensation. A further remedy applicable to upright vee or in-line engines, the valve gears of which cannot in general be very liberally oiled owing to leakage of oil down the intake and exhaust valve stems, appears to be some oiling scheme, such as reservoirs which would slowly discharge oil accumulated during running over the valve gear, as the engine cools after shutting down.

In the case of inverted vee engines with overhead camshaft valve gears, the limited experience available suggests that valve-gear corrosion is negligible as the valve gears can be very heavily sprayed with oil without danger of an excess passing to the valve ports via the valve guides.

6 Spark Plugs

The use of Ethyl gasoline has certain effects on spark plugs which do not occur with undoped fuels. Lead deposits, probably largely lead bromide, occur on the insulator and on the inside of the shell. These deposits, in the case of high-class mica plugs while disturbing in appearance, appear to cause little or no trouble. Furthermore, lead deposits almost invariably result in an entire lack of carbon deposits and, on the whole, are much less troublesome than the latter.

Test of 12-cylinder vee engines with half the cylinders running on Ethyl gasoline (3 cc. lead) and half on benzol mixture showed that electrode burning was less with Ethyl gasoline than with benzol mixture. Tests of Ethyl gasoline containing only the theoretical amount of bromine to convert all lead present to lead bromide and of gasoline with similar lead concentration (3 cc.) and 50 per cent excess bromine showed no appreciable difference in electrode attack, although less deposit on the insulators with the higher bromine concentration. Tests with 75 per cent of the theoretical bromine necessary to convert the lead present to lead bromide and a lead concentration of 6 cc. showed heavy slag-like deposits on the spark plug cores and no advantage in reduction of engine corrosion.

While in continuous or endurance running, Ethyl gasoline appears to reduce burning of the spark-plug electrodes, in general flight service, with the engine usually in operation for less than 10 per cent of the time, plug electrodes seem to waste more than they do on undoped fuel. This would appear to be due to the condensation of acid aqueous products of combustion, and prevention is being sought in the use of electrode materials other than the standard manganese nickel.

The foregoing remarks as to the effects of Ethyl gasoline on spark plugs apply only to mica plugs. The Air Corps has only a limited experience with the use of Ethyl gasoline and porcelain spark plugs. This experience, however, showed tendencies to electrode attack and fluxing of the insulators.

The foregoing conclusions with regard to the use of mica plugs apply only to lead concentrations up to 6 cc.

7 Corrosion, Conclusions

The foregoing discussion of the corrosion difficulties of doped fuel in aircraft engines may appear to indicate that the difficulties are serious and hardly worth attempting to overcome. However, it is the viewpoint of the Matériel Division that doped fuel of some type is here to stay for high-performance military aircraft engines and that the difficulties attending the use of such fuel can be overcome, as they have been in automobile engines. Further, some engines now in service in the Air Corps use doped fuel with negligible operating difficulty. Therefore, the present policy of the Air Corps is to require that new engines developed for its use shall be capable of operation on gasoline containing 6 cc. of tetraethyl lead per gallon with little or no more trouble than given by an undoped fuel of similar anti-knock value.

SECTION 5 VAPOR LOCK

The Matériel Division has kept in close touch with the work of the Fuels Research Sub-Committee of the A.P.I. and S.A.E. on vapor lock of aviation gasolines. Some work on the measurement of gasoline temperatures at various points of fuel systems in flight is being carried out by the Matériel Division for the committee.

Some vapor-lock trouble is experienced with the present military fuel systems and average gasoline obtained to Air Corps Specification 2-40F. This is largely due to the fuel pumps having to lift gasoline from the tanks rather than being drowned, although some trouble is experienced even with gravity systems.

The Bureau of Standards, which is carrying out the work for the aforementioned committee, has found that the "corrected" A.S.T.M. 10 per cent point is very closely related to the gasoline temperature at which vapor locking will occur at sea-level pressure. Examination by the Matériel Division of a large number of samples of gasolines giving reasonably satisfactory service in the Air Corps and meeting Specification 2-40F showed that the average corrected 10 per cent point was 65 deg. cent. Therefore the Air Corps, in its recently issued specification for Aviation Fighting Grade Anti-knock gasoline, has eliminated the 5 per cent point specified in Federal Specifications and has substituted a corrected 10 per cent point with temperatures limits of 62 to 72 deg. cent. This is pending further investigation of the vapor-lock problem and improvement in fuel systems.

Vapor locking in aircraft is apparently almost entirely confined to the fuel system (pipes, pump, etc.) and almost never occurs in the carburetors. Therefore improvement in fuel systems, and in particular the use of drowned fuel pumps, should allow the use of gasolines with lower 10 per cent points.

From the supply standpoint, lowering of the 10 per cent point is desirable, as some of the stabilized Mid-continent casing-head gasolines with lead added make excellent fuels for hot-running engines. Furthermore, lowering of the 10 per cent point will facilitate starting. Until fuel systems are improved, however, any lowering of the 10 per cent point cannot be considered by the Air Corps. Even with improved fuel systems, it is possible that it will prove undesirable to lower the 10 per cent point, as such lowering may produce excessive boiling of the fuel in the tanks of supercharged airplanes which climb to 30,000 ft. altitude with extreme rapidity. The fuel in the tanks under these conditions will, at altitude, be practically at ground-level temperature and therefore more likely to boil, unless steps are taken to cool it off with increasing altitude.

Attempts by the Matériel Division to use fuel with a corrected 10 per cent point of 43 deg. cent. in a pursuit airplane having a drowned pump and a cockpit temperature of 45 deg. cent. resulted in pronounced vapor-locking trouble and the engine cutting out repeatedly at 7000 to 8000 ft. altitude.

SECTION 6 LUBRICATING OIL FOR AIRCRAFT ENGINES

In the past, the ideas of the Air Corps as to the necessary qualities of lubricating oils were largely the result of the wide use of the Liberty engine and oil tests conducted with it. The advent of engines with much higher specific performance and in particular higher cylinder temperature, which need heavy oils even in winter, has led to rather drastic revisions of specifications. The study of the requirements of oil for winter use and for engines with higher cylinder-wall temperature resulted in the issue of Air Corps Specification 3556, which is a tentative specification for oil for service-test purposes directed to studying and securing better oils for the modern equipment now coming into service. Considerable study of oil for high-performance engines is now under way, and more is contemplated.

The ideal properties of a lubricating oil for aircraft-engine purposes appear to be as follows:

(*a*) Maximum oiliness, particularly at high film temperature
(*b*) Low viscosity coefficient
(*c*) Minimum tendency to decompose and gum in use
(*d*) Low pour point for winter use.

Oiliness is of pronounced importance in aircraft-engine lubrication, and the Matériel Division has almost no information regarding this property of engine lubricating oils except that castor oil possesses it to a higher degree than any other oil yet tested. It is possible with castor oil to operate engines that will stick pistons on mineral oil in a few minutes' running at full throttle. No information on the oiliness of different mineral oils is available to the Matériel Division, although it is reported that differences have been observed in this respect in engine tests of otherwise almost similar oils. Some oil refiners state that very complete dewaxing reduces oiliness, but it would seem that determination of this property under engine conditions is an exceedingly difficult problem.

A low viscosity coefficient is desirable as this results in an oil that not merely thins out less at high temperature but thickens up less at low temperatures. In a given oil, provided an adequate supply is reaching the surfaces to be lubricated, the ability to maintain lubrication appears to be approximately proportional to the absolute viscosity. Thus in engines operating at high cylinder temperature, it is desirable that the decrease of viscosity with increase of film temperature should be as low as possible. Viscosities of oils for aircraft use are measured at 100 and 210 deg. fahr., whereas the temperature of the oil film in air-cooled cylinders is at times in excess of 350 deg. fahr. Thus the importance of a low viscosity coefficient is obvious. The importance of low viscosity coefficient, as regards its influence upon engine friction when starting in cold weather, has been thoroughly investigated by Messrs. Irwin and Frank[10] of the Matériel Division, and engine friction has been shown to be almost entirely a function of the viscosity coefficient in oils of similar viscosity at 210 deg. fahr.

Provided oil is reaching the surfaces to be lubricated in sufficient quantity and is of adequate viscosity, the most common cause of failure in engines with high cylinder temperature is produced by carbonaceous deposits in the piston-ring grooves, which ultimately result in the rings sticking, with resultant blow-by and piston failure.

The Power Plant Branch of the Matériel Division has made some preliminary efforts to investigate the phenomena of piston-ring sticking. As ring sticking in a single-cylinder, aircraft engine usually results in piston failure and, further, the regulation of

[10] "Relationship of Laboratory Tests and Cold-Weather Motor Operation of Various Oils," E. R. Irwin and G. W. Frank, Matériel Division Report, Serial No. 2933.

temperature conditions with such equipment is decidedly difficult, it was decided to use a Series 30 Ethyl Gasoline Corporation Knock-Test engine. In order to accelerate the test, a cast-iron piston was used in conjunction with a jacket temperature of 350 deg. fahr. After considerable experiment the following procedure was evolved: The engine was run at 900 r.p.m. at full throttle with a standardized fuel at approximately maximum-knock mixture strength, the spark advance was regulated to produce a reading of 525 deg. fahr. ±25 deg. on the Matériel Division type 3 temperature plug, and the cylinder-head temperature was held within a limit of 20 deg. fahr.; 800 cc. of the oil to be tested was charged into a washed and dried crankcase. A piston and ring assembly, the weight of which had been obtained to within 10 mg., was installed and the engine was started up, and after reaching standard temperature conditions, it was held under these conditions for 7 hours. At the conclusion of the 7-hour period, the piston was removed, a second carefully weighed piston and ring assembly was installed, and the test was continued under similar conditions for a second 7 hours. At the conclusion of the 14 hours of testing, the oil was carefully evacuated from the crankcase and held for chemical and physical examination. Each piston, after removal, was washed off with casing-head gasoline, dried and weighed, the carbon and other deposit removed from the top of the crown, and the assembly again weighed. The piston assembly was then enclosed in a bomb, containing carbon solvent, and the temperature raised to approximately 300 deg. fahr. for about 2 hours. The piston rings were then removed and the entire piston and rings scraped free of all deposits. The rings were then replaced, the piston reweighed, and the weight compared with the original weight when installed. In cases of very excessive deposit in the top ring groove, this deposit was, in some cases, removed and weighed.

Table 3 gives the original physical properties of the oils used in the tests.

TABLE 3

Oil No.	Saybolt viscosity at 210°F., sec.	Saybolt viscosity at 100°F., sec.	Conradson carbon residue
1	100	1140	0.3
2	100	1200	1.6
3	102	1140	1.3
4	100	2400	0.6
5	121	1650	0.3

Table 4 gives the properties of the oils after draining from the crankcase at the conclusion of the tests.

TABLE 4

Oil No.	Dilution, per cent	Saybolt viscosity at 210°F., sec.	Saybolt viscosity at 100°F., sec.	Conradson carbon residue	Precipitation number
1	7.0	95	1160	0.9	0.05
2	0.2	133	2220	2.7	0.08
3	0.7	148	2290	2.8	0.08
4	2.0	119	3110	2.0	0.50
5	1.0	146	2400	1.3	0.06

Table 5 gives the results of oxidation tests on four of the oils used.

TABLE 5

	Saybolt viscosity at 210°F., sec.			Conradson carbon residue			Precipitation number		
		Oxidized			Oxidized			Oxidized	
Oil No.	Unused	7 hr.	17 hr.	Unused	7 hr.	17 hr.	Unused	7 hr.	17 hr.
1	100	116	149	0.3	0.8	1.9	0	0.0	0.0
2	100	118	281	1.6	3.0	6.5	0	0.2	7.0
3	102	128	226	1.3	2.6	5.2	0	0.0	0.0
4	100	137	...	0.6	2.5	...	0	4.0	...

Oxidation test consists of bubbling 0.5 cu. ft. of air per hour through a test tube containing 40 cc. of the oil under test, the tube being immersed in an oil bath at 420 deg. fahr., the temperature of the oil being 390 to 400 deg. fahr.

Table 6 gives the weights of total deposit and of total deposit less the weight of deposit on the crown.

TABLE 6

Oil No. 1	
First 7-hr. period:	
Top ring completely free at conclusion of test.	
Total carbon deposit on piston	2.13 gm.
Total carbon deposit less that on top of crown	1.34 gm.
Second 7-hr. period:	
Top ring completely stuck for 360 deg. of circumference at conclusion of test.	
Total carbon deposit on piston	2.59 gm.
Total carbon deposit less that on top of crown	1.94 gm.
Oil No. 2	
First 7-hr. period:	
Top ring completely free in groove on completion of test.	
Total carbon deposit on piston	1.27 gm.
Total carbon deposit less that on top of crown	0.53 gm.
Second 7-hr. period:	
Top ring completely free in groove on completion of test.	
Total carbon deposit on piston	0.98 gm.
Total carbon deposit less that on top of crown	0.82 gm.
Oil No. 3	
First 7-hr. period:	
Top ring completely free in groove.	
Total carbon deposit on piston	1.16 gm.
Total carbon deposit less that on top of crown	0.68 gm.
Second 7-hr. period:	
Top ring sticky in groove, but could be pried loose for all but 45 deg. of circumference.	
Total carbon deposit on piston	1.20 gm.
Total carbon deposit less that on top of crown	0.93 gm.
Oil No. 4	
First 7-hr. period:	
Top ring free in groove, but 0.40 gm. of deposit in groove behind ring.	
Total carbon deposit on piston	2.20 gm.
Total carbon deposit less that on top of crown	1.89 gm.
Second 7-hr. period:	
Top ring completely stuck for 360 deg. of circumference.	
Total carbon deposit on piston	3.12 gm.
Total carbon deposit less that on top of crown	2.82 gm.
Oil No. 5	
First 7-hr. period:	
Top ring quite free in groove at conclusion of test.	
Total carbon deposit on piston	1.89 gm.
Total carbon deposit less that on top of crown	1.36 gm.
Second 7-hr. period:	
Top ring completely stuck in groove for 360 deg. of circumference.	
Total carbon deposit on piston	1.85 gm.
Total carbon deposit less that on top of crown	1.61 gm.

From the results shown in Table 6, the total deposit less the deposit on the top of the crown appears to bear a very close relationship to the relative ring-sticking tendencies of the oils tested.

Neither the original properties of the oils, their condition after test, nor their resistance to oxidation appear to be a guide to ring-sticking properties, although the oxidation test would seem to give an indication, in the case of extremely bad oils.

Castor oil, remarkable for its oiliness factor, is probably by far the worst oil used in aircraft engines as regards ring-sticking tendencies.[11]

Two outstanding results are shown by these tests: (*a*) That the Conradson carbon value of the unused or the used oil is no guide to its ring-sticking and carbon-depositing tendency at high cylinder temperature; (*b*) that the naphthenic-base oils do not give softer deposits than the paraffin-base oils as far as these tests go. Oil No. 4 is a very largely naphthenic oil and gave the hardest deposits in the ring grooves of any oil tested.

Oils Nos. 2 and 3 are both Pennsylvania products. No. 3 is said to be a blend of bright stock and neutral, whereas No. 2 is said to be completely vacuum-distilled. It is notable that oil No. 2 is the only one which did not cause a stuck top ring in the last 7 hours of the 14-hour test period.

[11] "The Lubrication of Aircraft Engines," F. A. Foord, Proceedings of Royal Aeronautical Society, 1929.

The test procedure used may be too drastic and too accelerated, but nevertheless it is felt that it bears a closer relationship to the use of oils in modern aircraft engines with high cylinder temperatures than do most of the published tests at jacket temperatures of the order of 180 deg. fahr. A large program of similar tests on widely differing oils with both cast-iron and aluminum pistons and a similar test procedure to the foregoing is planned in the future.

Low pour point is necessary for oils for winter use, particularly in the case of the heavier oils required, even in winter, by engines of high cylinder temperature. This property of oils was investigated by the Matériel Division[10] in conjunction with the viscosity coefficient as regards the influence of both upon engine-starting friction and pumpability.

The Matériel Division recently conducted cold-weather starting tests on Liberty engines with the three oils shown in Table 7.

TABLE 7

Oil No.	Pour point, °F.	Saybolt viscosity at 210°F., sec.	Saybolt viscosity at 100°F., sec.	Viscosity coefficient
6.....	25	122	1500	12.30
7.....	5	124	2280	18.40
8.....	−15	113	1440	12.75

The oils had been thoroughly circulated through the engines before starting the tests, and the airplanes were allowed to stand out all night to get thoroughly cold. The air temperature at the time of the tests was 23 deg. fahr.

With oil No. 6, the engine started on the fifth attempt, and oil pressure was obtained in 3 min. from starting. The temperature of the oil into the engine rose to 41 deg. fahr. after 30 min. idling and to 50 deg. fahr. after 45 min.

With oil No. 7, the engine was extremely stiff and needed breaking loose by hand, and ten attempts were required to start it. After a start was obtained, the oil temperature and pressure reactions were similar to those of oil No. 6

With oil No. 8, a start was obtained on the fourth attempt, and oil pressure was obtained in 1 min. The oil temperature rose to 41 deg. fahr. in 20 min. idling and to 50 deg. fahr. in 30 min.

While considerable further winter testing of oils with widely different viscosity coefficients and pour points is required, nevertheless the foregoing tests are indicative of the importance of viscosity coefficient and pour point upon engine-starting friction and oil pumpability at low temperatures. As regards the work on piston-ring-sticking tendencies of oils, only the engine testing is due to the Power Plant Branch, all physical and chemical testing of the oils used being under the supervision of E. R. Irwin, Materials Branch of the Matériel Division.

SECTION 7 CARBON REMOVERS

The experience of the Matériel Division in its tests of oils for piston-ring sticking has led to the conclusion that carbon solvents are, or shortly will be, available which have an exceedingly powerful effect in removing or loosening carbon deposits behind piston rings, on the top of piston crowns and from the interior of combustion chambers. As the reliability of aircraft engines increases, and consequently the period between overhauls lengthens, the use of such carbon solvents will probably be of value. The Matériel Division has been watching the results of the use of carbon remover in a large fleet of automobiles and trucks. In this fleet, carbon remover has been in use for three years. Cylinder heads are commonly not removed in 20,000 miles of running and over, gummed intake valves can be eliminated without lifting cylinder heads, and stuck piston rings, which were frequently found on overhaul, are, with regular use of carbon remover, virtually unknown.

If the regular use of carbon solvent in aircraft engines with high cylinder temperature will serve to reduce or eliminate piston-ring sticking, its use will be more than justified. Carbon deposits in the combustion chambers of aircraft engines are usually not troublesome. However, at times they cause difficulty. In the endurance test referred to under "Valve Seat Insert Attack," heavy, hard deposits had collected at the tops of the cylinder bores, and as a result the top lands of the pistons were reduced in diameter by as much as 0.060 in. in places after 90 hours' full throttle running. Such deposits could almost certainly be eliminated by the use of carbon solvent, and their regular removal should, in addition to improving piston conditions, tend to smother full-throttle running and better maintenance of full power.

The Matériel Division is finding carbon solvent useful in removing the extensive carbon deposits that occur inside the crowns of liberally ribbed pistons of hot-running engines. These deposits interfere with piston cooling and are almost impossible to remove by scraping on overhaul, but can be readily removed even after only a 1-hour treatment with carbon remover without heating. For this purpose the Matériel Division is selecting a relatively non-toxic carbon remover owing to the inevitable exposure to fumes and skin absorption.

SECTION 8 DETONATION

It is with much trepidation that even mention is made of what detonation is or what causes it. However, the available evidence resulting from the researches of a number of workers on the fundamental aspects of the subject indicates that the cause of detonation is preoxidation of the charge during the suction and compression strokes before the ignition spark occurs. Non-knocking fuels and knocking base fuels with lead added have been shown to be materially less oxidized at the instant before the spark passes than are knocking fuels. This leads to the conclusion that, if the fuel could be injected into the cylinder late in the compression stroke, such oxidation would be materially diminished, and high compression, supercharging, and high cylinder-wall temperatures would probably be possible with fuels that knock exceedingly readily in the normal carbureted engine. The injection would of course have to be so arranged that sufficient time was allowed before the occurrence of the spark to produce complete mixing and evaporation of the injected fuel.

Note

All references to D.A.G. or Fighting Grade throughout this paper refer to straight-run gasolines, unless otherwise specified.

Acknowledgment

The author wishes to acknowledge the assistance of E. R. Irwin and G. W. Frank, of the Matériel Division, in the matters of supply of data and checking. Thanks are due to Graham Edgar, of the Ethyl Gasoline Corporation, and to several engine constructors in this country and abroad for data and engine experience with materials and a variety of fuels.

Discussion

W. F. Parish.[12] Many data in the history of the development of industrial machinery will contribute largely toward immediate development of the aircraft engine, which seems to be reaching the limit of its performance with the present available fuels and mineral lubricants. Any machine, in the early stages of its development, requires a period of experimentation that will result in its continuous beneficial evolution. But this often is carried to a point at which the machine gets out of balance with the lub-

[12] Consulting Lubricating Engineer, New York, N. Y. Mem. A.S.M.E.

ricant used. As machines are developed, their speed is increased, they are increased in size, or in the power developed, or in that required per unit of weight. Their bearing pressures and the temperatures at which they operate are also increased on account of their weights and speeds and the mode in which the machine is built. Under such evolution, the machine may continue to develop to a point at which the lubricants available no longer meet the severe operating conditions demanded. The operating troubles are then such that the machine is no longer of commercial value. Unless the factors which have thrown it out of balance are corrected, the machine is of no further practical use, and some other form of equipment will supplant it.

Evolution of New Machinery

The value of a new machine will always be measured in terms of its more perfect and continuous operation. In effect, this means that it must be lubricated more effectively over long periods without difficulty. The trend of evolution has been instanced many times in the past, one being that of the early steam engines which were designed for crankcase-bath lubrication. In this particular type of engine the conditions of operation were such that the oils put into the crankcase emulsified, decomposed, oxidized, and the lighter ends distilled off. This left a heavy residue which failed as a lubricant because oil conductors would become filled with solids and the bearings continually would melt because of lack of oil and on account of interrupted oil films. The difficulties of maintaining such engines in operation proved insurmountable, even when an attempt was made to provide lubrication by introducing oil and water combinations. Such mixtures, when at all suitable in proper proportions, would soon be thrown out of equilibrium by the evaporation of the water. The cycle of gradual destruction would then again begin. All of such types of engines are now obsolete, because they could not be lubricated properly and therefore were not commercial.

Textile Spindle as an Example

The original textile spindle later had a lubricating bath which was introduced to secure more perfect lubrication. The available lubricants were oils that oxidized very rapidly and caused gumming when confined in a bath, which resulted in stoppage of the spindles. The apparatus for the application of the lubricant unbalanced the lubricant and the requirements of the machine. These factors could not be brought back into equilibrium until new lubricants were found that would not oxidize. When the desired perfect balance was finally secured, the principle of bath lubrication, using a mineral lubricant and bearings of suitable design, has greatly advanced the art of building machinery.

Inherent Difficulties Stated

The inherent difficulties with the present type of internal-combustion automotive gasoline engine, including both aircraft and marine types, are that portions of unburned fuel come into contact with the lubricant to some variable degree. Other portions of the lubricant are thrown into contact with the heated surfaces at such high temperatures that they reach the cracking point of the lighter fractions of the oil, resulting in the deposition of carbon residues. These two conditions bring about a gradual change in the lubricant. The method in vogue for the last 10 years, in an attempt to solve this apparently unbalanced condition, has been to increase the viscosity of the oil. As the development of the engines has proceeded along lines of increasing compression, speed, and power, the engines have become hotter; therefore it has been thought that thicker lubricants were required as a consequence. Little doubt exists that much of the additional heat in these engines is furnished by the increased fluid friction of the heavy lubricants. We probably are fostering a vicious cycle in having hot engines that are then lubricated with a heavier oil which, in turn, will make engines still hotter. In this valuable paper we have heard that thick, high-viscosity oils used in the engines under certain conditions are stated to become still thicker. This is due to cracking and the elimination of the lighter fractions of the lubricant. The final result is that the oil holds while in circulation a gradually increasing amount of material of the nature of carbon residue and the gums from partially burned oil. The addition of this matter eventually modifies the surface tension of the oil film. The film then ruptures, and abrasion of the surfaces follows. Gums, which act as binders of the residues and dirt that gets into the system, form behind the rings and put them out of commision. A condition such as this shows clearly that the limits of the lubricant have been reached. It shows also that the development of the engine has been carried to a point at which the available lubricants as then applied are no longer able to withstand the severe conditions.

Remedy Lies in Thinner Lubricants

If the aircraft-engine development is to proceed beyond the present point, it is obvious that we must secure cooler operating engines, and much can be done by using the thinner lubricants and changing the entire method of oil application. New forms of apparatus for cooling, filtering, and possibly rectifying the oil must be developed, and possibly also new methods of film maintenance at such points as work under the most severe conditions. No other way seems to be left open if we are to proceed with engine development. Improvements in methods of lubricant application have already been shown to be the practical remedy for the development of today's successful steam turbine, Diesel engine and many types of production machinery. These machines are, as a result, perfectly balanced, and thus are never heard of by the engineering societies as constituting an engineering problem.

Mr. Heron. As regards military aircraft engines, there is little evidence that dilution of the lubricating oil is of consequence. If excessive priming, washing the oil off the cylinder walls when endeavoring to start, can be described as dilution, then it does exist, but the dilution experienced with automobile engines does not enter the aircraft-engine lubrication problem.

The Air Corps for the present does not intend to allow the use of lubricating oils of higher viscosity than 125 sec. Saybolt at 210 deg. fahr. and 1810 sec. maximum at 100 deg. fahr., and is in agreement with Mr. Parish that the continual tendency to make hotter engines and raise oil viscosities is a vicious cycle.

The Air Corps believes, in the light of present knowledge, that if an engine needs a heavier oil than Grade 120, Specification 3556, to secure satisfactory operation, either the engine or the installation should be so modified as to produce satisfactory operation on that oil.

Encouragement by the Air Corps of the use of heavier oil would doubtless result eventually in the adoption of 200-sec. oil (at 210 deg. fahr.) of low viscosity coefficient.

The Matériel Division has no evidence to support Mr. Parish's statement that the heavier oils cause engines to run hotter. Heavier oils admittedly increase friction, but experience does not show that they increase operating temperature of the cylinder unit; in fact, rather the reverse.

While piston-ring sticking due to carbon deposits occurs in service operation of multicylinder engines in the Air Corps, this is not, as Mr. Parish states, due to the presence of considerable gum in the body of the oil in the tanks. Oil is at present completely drained from the lubrication system and replaced with fresh oil every 10 hours. Examination of the used oil does not show more than slight change; nevertheless, in hot-running the oil has decomposed and coked behind the piston rings even with such frequent change of oil.

The remedy for lubrication troubles lies very largely in design, although the best available oils must, of course, be used. Maintaining the oil fed to the engine at a suitable temperature will secure adequate bearing lubrication and prevent film breakdown there. The case of the film or partial film on the cylinder wall is another matter, however, as the final temperature of the oil on a cylinder wall at a temperature of 350 deg. fahr. would not appear to be materially affected by the temperature at which it is fed into the engine. If anything, the film temperature would appear to be reduced by increased oil-entrance temperature, as under such conditions a increased supply of oil usually reaches the cylinder walls and pistons, and thus oil cools them.

While much can be done in improvement of lubrication by better film maintenance and design to secure cooler running pistons, etc., nevertheless it is hardly possible to agree with Mr. Parish that hot-running engines must be abandoned on account of oiling difficulties. To abandon the high-temperature engine would mean giving up air-cooled and liquid-cooled engines with high cooling-liquid temperatures, and the progress of development does not point thus. The Air Corps has recently run two types of 525 hp. 9-cylinder air-cooled radial engine (both of 6 in. cylinder bore) for 146 hours without piston-ring sticking or lubrication trouble. Marked increase of specific output in both of these engines would probably produce lubrication trouble and ring sticking, but increased oil supply, improved cylinder and piston cooling, and possibly frequent removal of carbon deposits with carbon solvent would probably result in satisfactory operation with increase of output.

So far as reduction of carbon deposits is concerned, the use of oil of lower viscosity does not appear to be a remedy. Using the ring-sticking test method described in the paper, with oils of the same type, but one of 75 sec. Saybolt viscosity at 210 deg. fahr. and the other of 150 sec. at 210 deg. fahr., little difference in tendency to deposit carbon was noted.

Mr. Parish cites the Diesel engine among other types of machinery in which the lubrication problems have been satisfactorily solved. Robert Sulzer[13] has shown that in a two-cycle Sulzer Marine Diesel engine of 600 mm. bore, the top piston ring comes in contact with a portion of the cylinder liner which is at a temperature of 480 deg. fahr., and found the edges of the piston crown (liquid-cooled piston) to reach 530 deg. fahr. The piston-ring temperatures and the mean temperature of the cylinder liner were, however, very considerably lower than those occurring in modern high-temperature aircraft engine. Liner temperatures of 480 deg. fahr. at points where lubrication must be maintained do not occur in modern air-cooled aircraft engines which are worthy of consideration for military use and efficiently installed. That lubrication can be maintained under such conditions for periods of service vastly longer than those required of any aircraft engine would indicate that high temperature alone does not render efficient lubrication impossible.

With regard to filtering and reclamation of aircraft-engine lubricating oil, it is of interest to note that in the series of piston-ring sticking tests now being conducted by the Matériel Division, a reclaimed and acid-treated Mid-Continent oil has proved as good as any oil tested. This oil was reclaimed by heating, followed by filtration in a commercial reclaimer, and was then treated with sulphuric acid in the laboratory. The effect of the acid treatment was to reduce markedly the carbon deposits occurring in comparison with that produced by the reclaimed oil without acid treatment.

The worst oil by far as yet tested is "Nujol." This inferiority may be due to insufficient viscosity to maintain ring sealing and resultant gas blow-by, causing rapid gum and coke formation.

[13] "Temperature Variation and Heat Stresses in Diesel Engines," *Engineering* (London), April 2, 1926, and Proceedings of Institution of Naval Architects.

GRAHAM EDGAR.[14] Several points in Mr. Heron's interesting and valuable paper appear to the writer to warrant comment:

(1) With regard to the methods of testing fuels for anti-knock value, the writer believes Mr. Heron's conclusions absolutely sound. Once it is admitted (and there seems no doubt whatever of the actual facts) that the conditions under which a test is carried out may alter the relative anti-knock value of two fuels, it becomes clear that a rough idea must be obtained of the relative anti-knock value of various fuels *under the conditions of practical operation*, and then a set of conditions must be chosen on the test engine to duplicate as accurately as possible, the *average* values obtained under operating conditions. This is true for automobile fuels as well as for aircraft fuels. Fortunately for the automobile-fuel situation, motor gasolines seem much less affected by test conditions than aircraft fuels, so that it is a simpler problem to test them.

As experimental data on multicylinder engines are accumulated, it will be possible to specify more intelligently the ideal conditions of operation; but Mr. Heron's specifications represent at least an intelligent approach to this difficult problem,.

(2) Mr. Heron's data on the performance of high-compression and supercharged engines certainly illustrate the vast improvements which are possible with fuels of very high anti-knock value, and undoubtedly justify the stand taken by the Matériel Division that it will adopt the best possible base gasoline of wide availability and will further improve such fuel with the maximum permissible amount of anti-knock.

(3) With regard to the difficulties experienced by the Matériel Division with the use of Ethyl fluid in certain aircraft engines, the writer agrees with Mr. Heron that it would not appear to be a very difficult problem to eliminate these difficulties entirely, or to reduce them to negligible factors, by investigations by the aircraft-engine manufacturers on suitable materials for valves, valve seats, exhaust systems, etc. When Ethyl gasoline was first introduced for automotive use, some difficulties were met with certain types of valve material under conditions of severe operation, but with improvements in valve materials, together with improvements in the composition of Ethyl fluid, complaints alleging any injurious effect of Ethyl gasoline on any part of the automobile engine have become most exceptional. Under the widely different conditions of aircraft operation, and with different materials of construction, it is not surprising that new problems have arisen.

It is fortunate, also, that the answer to the problems arising from the use of Ethyl fluid in aircraft fuels appears to lie in the use of materials of construction and details of design which are advantageous for use with any fuel, at least in the great majority of cases.

MR. HERON. *Paragraph* (1). It has to be admitted that the accumulation of the relative performance of widely varying types of fuel in multicylinder engines is proving a slow process.

The Matériel Division is considering attempting, as an alternative, to carry out some tests on a highly supercharged air-cooled single-cylinder engine, the cylinder to be used being that of a modern super-performance radial engine.

Paragraph (2). The engine performance quoted in the paper has since been exceeded on two types of supercharged engines, and while none of the figures given could probably be maintained at present for endurance running, it is almost certain that such performance will be possible for lengthy periods in the next year or two.

Paragraph (3). Steady progress is being made with the solution of operating difficulties attending the use of Ethyl gasoline in the

[14] Ethyl Gasoline Corporation, Yonkers, N. Y.

Air Corps. Exhaust-disposal-system corrosion appears to be eliminated completely; nickel-chromium steel with 18 per cent Cr, 9 per cent Ni, and 0.1 per cent C appears to be the best solution. Cracking at the welds is being experienced with Monel metal exhaust rings. However, cylinder corrosion has yet to be entirely eliminated, the austenitic steel barrel presenting as yet many difficulties.

H. K. Cummings.[15] Mr. Heron is to be commended for his recognition that the knock problem in aircraft engines is not the same as that in motor-vehicle engines. The desire to obtain precise, or closely reproducible, measurements of one of the causes or effects of detonation too often obscures the real issue—measurement of that aspect of detonation which is objectionable. Measurements of detonation of aircraft and of automobile fuels may well require quite different apparatus and technique. The use of automobile fuel has an acquired dislike for the noise accompanying detonation, wholly apart from any damage which may be ascribed to the detonation. In the case of airplane fuels, overheating and mechanical shock are the objectionable features, because of their effect on the engine. With this in mind, it is apparent that in rating the detonation of fuels the mixture ratio should be adjusted to that giving the maximum intensity of the objectionable feature of the detonation reaction, rather than arbitrarily adjusting the carburetor for maximum power or, say, maximum sound intensity in the case of aircraft fuels.

While some form of temperature measurement would appear to be indicated as the most logical means for estimating the detonation of aircraft fuels, a comprehensive investigation should first be undertaken with the object of determining what type of surface shows the closest correlation to operation conditions. It is possible that an indirectly cooled surface may not even qualitatively reflect the condition of the directly cooled surface. The Bureau of Standards found cylinder-head-wall temperatures in a detonation-test engine to be practically unaffected by mild autoignition which it is believed originated from the indirectly cooled exhaust-valve surface. In this case therefore, temperature measurements on a directly cooled surface failed to distinguish the onset of a dangerous condition of an indirectly cooled surface. The opposite condition may possibly occur also.

Referring to the section on lubricating oils, it may be worth noting that Sir William Hardy believes wax desirable because of its indirect influence in promoting oiliness; that is, making it possible for the component causing oiliness to be selectively absorbed.

In connection with the carbon-deposition tests, it would be of interest to know whether the same two piston assemblies were used in each set of tests. Oil flow past the piston is one of the major factors influencing the rate of carbon deposition. One piston may wear the cylinder differently than another; hence the order in which different assemblies were used may be of importance, as well as the number of different assemblies used.

While the results shown in Table 6 do not appear to support the Conradson test as an indication of the carbon deposit, it should be remembered that the oil flow past the piston is very largely a function of the viscosity of the oil on the cylinder walls. Oil No. 4 undoubtedly was at a disadvantage from this viewpoint, and the conclusion regarding the relative carbon depositing tendency of the napthene-base oil might be modified if oils having equal viscosity at 350 deg. fahr. were used. The observation that the naphthene-base oil gave hard carbon deposits is in accord with results obtained by W. H. Herschel in engine tests at the Bureau of Standards some years ago.

Mr. Heron. Mr. Cummings has tersely stated the difference between the effects of detonation in automobile and aircraft engines; i.e., that in the former it is mostly a matter of offense to the ear and in the latter mainly a matter of overheating.

As he states, when making ratings, the mixture ratio should be adjusted so as to produce the maximum intensity of the objectionable feature; namely, sound intensity for automobile engines and overheating for aircraft engines. With the use of the temperature plug it has been found that mixture ratio giving maximum plug temperature coincides with that producing maximum sound intensity and also with that producing a maximum bouncing-pin reading. This is somewhat at variance with the general assumption that maximum knock-mixture strength is also that giving maximum power. While maximum power-mixture strength, or rather the mixture ratio giving 1 per cent less than maximum power, as a rule, in an aircraft engine, gives maximum cylinder temperature, it does not, however, produce maximum exhaust-valve temperature. Maximum exhaust-valve temperature is, as a rule, produced by a mixture ratio considerably leaner than that giving maximum power. As has been stated in reply to Dr. Becker, the temperature-plug readings in general follow those of the cylinder head in the Series 30 Ethyl Gasoline Engine; thus, the temperature plug would appear to measure effects at variance with the conditions producing exhaust valve overheating in aircraft engines.

It is agreed that a comprehensive investigation is needed of the best method of temperature rating of fuels as regards sensitivity and relation to operating conditions in multicylinder engines.

In general, in aircraft engines the overheating of pistons, exhaust valves, and spark plugs, which are all indirectly cooled, is of much greater importance than that of the directly cooled surfaces of the cylinder.

With reference to Sir William Hardy's views on wax promoting oiliness in a lubricating oil, the Matériel Division has made some preliminary tests with the Stephens Consistometer and finds that the addition of wax raises the temperature at which film breakdown occurs.

In the tests of ring-sticking and carbon-depositing properties, the same two piston and ring assemblies were used in all tests and were used in the same order in each test. Two pistons were used in order to check the progressive decomposition of the oil. Furthermore, in the case of oil No. 4, the use of a single piston for the 14-hour test period resulted in the top piston ring being so severely stuck that it could be removed only by heating in carbon remover for two days, followed by heating the ring and piston crown with an oxyacetylene torch. Mr. Cummings states that the rate of oil flow past the piston is one of the major factors causing carbon deposition. In the ring-sticking test method used by the Matériel Division increase of oil supply to the piston not only reduces carbon deposits in the ring grooves, but also on the inside and top of the piston crown. In high-temperature multicylinder aircraft engines the best-known method of avoiding ring sticking with a given oil and without design change is to increase the rate of oil passage by the rings.

Mr. Cummings remarks that oil No. 4 was at a disadvantage in the comparative tests shown in Table 6 on account of the fact that its viscosity at cylinder-wall temperature is lower than that of the other oils tested. This is possibly true, but the test was devised to investigate the ring-sticking qualities of typical aircraft-engine oils and a naphthenic oil having the same viscosity at 350 deg. fahr. or thereabouts, as the other oils tested would hardly be of much use for aircraft purposes, if such an oil could be procured.

Further testing under identical conditions has failed to show much connection between viscosity of oils of a given type and their tendency to stick rings and deposit carbon.

The test method used does not always give reproducible results,

[15] Chief, Automotive Power Plants Section, Department of Commerce, Bureau of Standards, Washington, D. C.

and further work on it to improve the reproducibility is necessary. The results in general, however, check up with observations as to ring sticking, carbon deposit, etc., experienced with the same oils in hot-running aircraft engines.

A. E. BECKER.[16] This paper contains such a wealth of valuable information that it is impossible to do justice to it in a discussion based on a hasty reading. The paper requires careful study and analysis to appreciate the full extent of the constructive work which Mr. Heron is doing on the aviation-fuel problem.

Mr. Heron's knock-rating work at high temperatures is distinctly of the pioneer type. Through his courtesy we also have had an opportunity to make some comparative measurements by the bouncing-pin and temperature-plug methods (described in the paper) in our laboratory. These measurements were made at 350 deg. fahr. on an engine similar to the Ethyl Gasoline Corporation's Series 30 Knock-Testing Engine and with the same fuels given in Table 1 of Mr. Heron's paper. For purposes of comparison, the data are given (see Table 8).

TABLE 8

Fuel	Engine speed	Throttle opening, deg.	Compression pressure, lb. per sq. in.	Spark advance, deg.	Cc. lead to equal 50 per cent benzol By bouncing pin	By temperature plug	Plug temperature, °F.
P.P. No. 10 (Mid-Continent D.A.G.)	600	10	99	20	1.7	1.3	510
	600	11½	109	20	1.9	1.8	555
	835	11	84	32	1.1	0.4	568
	835	14	105	32	2.2	0.8	613
P.P. No. 104 (California Fighting Grade)	600	10½	102	20	1.5	0.5	544
	600	13	118	20	1.2	0.9	589
	835	12	91	32	0.7	0.1	578
	835	15	113	32	1.7	0.6	645

It will be noted that these data check those of Table 1 in a general way. From the two sets of data it is obvious that the bouncing-pin method always results in more tetraethyl lead being required in one sample to match a second sample than is required when the temperature method of comparison is used. If the samples can be taken as typical of all fuels, it follows that the use of the bouncing-pin method will always result in being on the safe side when meeting a given anti-knock standard. It is suggested that a more delicate potentiometer over the temperature range met during testing might result in better differentiation between samples by the plug method. A shortcoming of this latter method is the tendency for carbon to deposit on the face of the plug in a manner similar to the description in the paper of the depositing of carbon on the exhaust valves. Just as the removing of this carbon from the exhaust valves causes a lowering of cylinder temperature and the prevention of preignition, so also the removing of the carbon from the face of the temperature plug results in the plug recording somewhat higher temperatures.

The writer can also verify what Mr. Heron says in regard to heptane-iso-octane equivalents. Two fuels which have the same heptane-iso-octane equivalents when compared at 210 deg. fahr. are not necessarily either equivalent to each other or to the same heptane-iso-octane mixture at 350 deg. fahr. On the other hand knock ratings made in our laboratory with heptane-ethyl alcohol, heptane-benzene, and heptane-iso-octane blends correlate perfectly with h.u.c.r.'s obtained by Mr. Boyd for similar blends on his variable-compression engine. Likewise a fair degree of correlation has been obtained between our knock rating scale and those of the Texas Company, Vacuum Oil Company, Atlantic Refining Company, and Standard Oil Company of New York, measurements in all cases having been made at 212 deg. fahr., although the test methods and engines were not always the same.

Extensive work similar to that just described must be done at high temperatures before it can be determined just which method will most nearly result in rating fuels in practically the same order as they are now being rated at 212 deg. fahr. Further, much additional work with multicylinder engines, as proposed by Mr. Heron, must be carried out to enable a conclusion to be made regarding airplane-fuel-knock engine-testing conditions which will correspond to average airplane-engine operating conditions. In arriving at a solution of the problem, variable-compression work, similar to that which Mr. Boyd has been doing and as suggested by Mr. Heron, should be carried out at these higher temperatures with different fuels.

It is stated in the paper that maximum power, minimum fuel consumption, and minimum cylinder temperatures are obtained simultaneously when sufficient anti-knock compound has been added to the base fuel. This statement is at variance with the generally accepted notion that minimum fuel consumption always occurs at a much leaner mixture than that which results in maximum power.

The idea advanced in the paper that engines should be built to conform to a standard fuel is good. However, this should not be promoted to the extent that it would prevent the use of any large supply of good anti-knock fuel which might at some future time become available as a result of new processes or otherwise. The writer believes that the author of the paper kept this possibility in mind when he made the statement about building engines to suit fuels rather than fuels to suit engines.

Mr. Heron states the case in regard to vapor lock very well when he says the lowering of the 10 per cent point is desirable. Every effort should be made to so design fuel systems and carburetors that fuels of lower 10 per cent point can be used, since it will result in both larger supplies of fuel being available and in better anti-knock characteristics.

The author is certainly to be congratulated upon the comprehensiveness of the work which he has done on a problem which is extremely difficult. The writer feels sure that the many suggestions he has made will lead to fruitful results during the next few years.

MR. HERON. The data and remarks submitted by Dr. Becker are of decided interest. Examination of the engine test results show that, in comparison with those shown in Table 1, the average divergence in cubic centimeters of lead and in percentage of lead content is decidedly less for the temperature-plug determinations than it is for the bouncing-pin results.

Dr. Becker's argument in favor of the bouncing pin is of course sound so long as only gasoline containing lead is being purchased and is being tested against a standardized aromatic blend. It would seem that comparative tests of aromatic blends with lead added against California and cracked gasolines both containing lead by bouncing-pin and temperature-plug methods should be made.

The accumulation of carbon upon the temperature plug and its effect in raising its temperature applies also to the cylinder, piston, and exhaust valve when deposits accumulate on these portions of the engine. In any knock-test method of comparing against a standard, it would seem that the effects of such deposits should affect relative ratings much less than do engine speed and knock intensity.

Rather than use a potentiometer for recording the temperature of the plug in place of a millivoltmeter, it would appear that a plug design or test conditions showing greater sensitivity should be aimed at. The visual indication of temperature changes on a millivoltmeter when switching from fuel to fuel or when the engine condition is unsteady and unsuitable for carrying out knock tests

[16] Fuel and Lubrication Section, Research Laboratories, Standard Oil Development Company, Elizabeth, N. J.

is helpful to the operator and is far less trouble than the continual balancing of a potentiometer.

The Matériel Division has no particular ax to grind in favor of the temperature plug and is at present using the knock meter and bouncing pin on the Series 30 Ethyl Gasoline Engine and finds that this combination is much the most rapid and convenient method for rating fuels of which it has any experience.

It may be said for the temperature method:

(*a*) That is measures the tendency of a fuel to heat indirectly

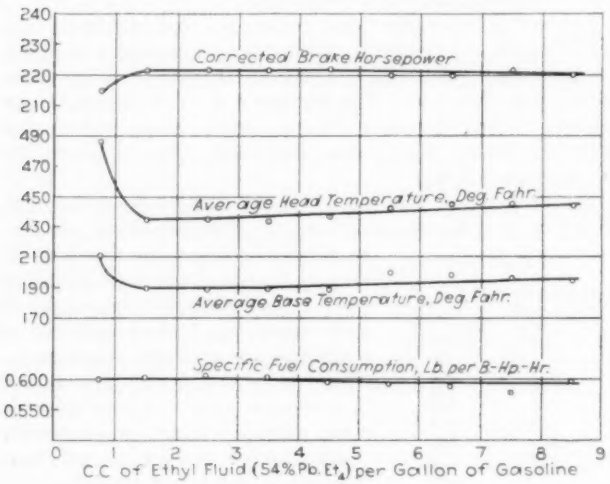

FIG. 4

cooled surfaces within the cylinder unit. In the case of an aircraft engine it is the overheating of indirectly cooled parts of the cylinder unit, such as pistons, spark plugs, and exhaust valves, resulting from the use of fuel too low in anti-knock value which causes failure. Incidentally, the relation of the temperature-plug readings to the readings of two other sets of thermocouples in the cylinder head of the Ethyl Gasoline Series 30 Engine has been checked. One couple was almost in the exhaust-valve seat and the other right below the bouncing pin. Under condition of constant spark advance and throttle opening, the relation between the readings of cylinder-head temperature and plug temperature was approximately constant. However, change of spark advance changed the relation between plug and head temperature; i.e., at different spark advances and constant plug temperature the cylinder-head temperature varied somewhat.

(*b*) That it is exceedingly simple and very reliable.

(*c*) That it provides a means of measuring at least the relative heating effect of a fuel at engine speeds in excess of those at which the bouncing pin will operate satisfactorily.

(*d*) At 900 r.p.m., its sensitivity to small lead or benzol concentration changes is at least equal to that of the bouncing pin at any engine speed yet used by the Matériel Division on the Series 30 Ethyl Gasoline Engine.

The Matériel Division has rated a number of straight-run California gasolines in terms of lead requirement to equal a standard California gasoline plus 3 cc. of lead. Ratings have been made at 900 r.p.m. and 350 deg. fahr. jacket temperature with the temperature plug and these checked against ratings made at 600 r.p.m. and 300 deg. fahr. jacket temperature with the bouncing pin. The agreement is surprisingly close and mostly within the limits of reproducability with either of the test methods.

With reference to carrying out variable compression engine tests at different jacket temperatures, it would appear desirable for aircraft fuels that:

(*a*) The engine used should have a cylinder closely approximating that of the most advanced type of liquid-cooled aircraft engine.

(*b*) That the tests should be carried at an engine speed of the order of that of modern aircraft engines at full power; i.e., 2000 r.p.m. or over.

In lieu of a variable compression engine, the use of a modern aircraft-engine cylinder with a variable amount of supercharging might well be considered. There is good ground for this suggestion as the trend with modern aircraft engines is rather to use up a given improvement in fuel by supercharging than by any considerable increase of compression ratio.

With regard to obtaining minimum fuel consumption, maximum power, and minimum cylinder temperature simultaneously when sufficient anti-knock compound has been added to the fuel under test, the minimum fuel consumption referred to in the paper is the fuel consumption giving 1 per cent less than maximum power (best setting), and once sufficient anti-knock compound has been added to the base fuel, this consumption is not reduced by further additions of anti-knock compound. That "best setting" consumption was referred to, was so stated in the paper—possibly not clearly, however.

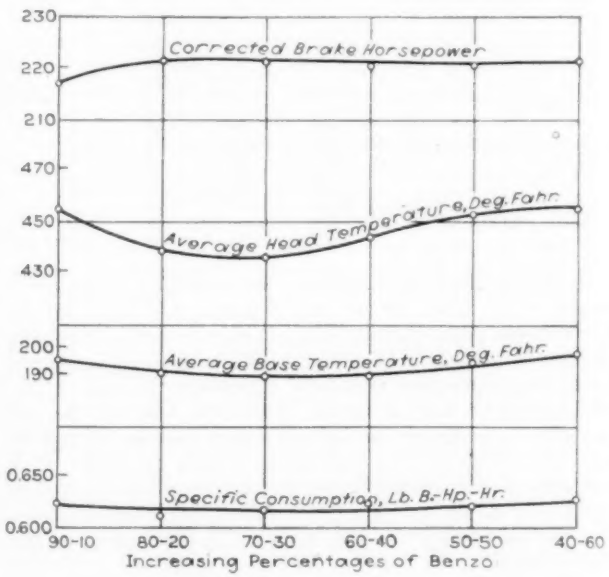

FIG. 5

Typical results of the effects of variation of lead and motor benzol concentration in average Mid-Continent D.A.G. upon power and cylinder temperature at "full rich" (not best setting) carburetor setting are shown in Figs. 4 and 5. These tests were carried out with a Wright J-5, 9-cylinder, air-cooled engine of 790 cu. in. cylinder capacity at 1800 r.p.m. and with 6.5 to 1 compression ratio. No particularly good data are available in support of the statement that the "best setting" consumption falls as the anti-knock concentration is progressively increased from the point where the fuel is definitely lacking in sufficient anti-knock to that necessary to secure maximum power with minimum fuel consumption.

When the fuel is deficient in anti-knock value, to be able to run at full throttle the air-to-fuel ratio has to be deceased to secure elimination of detonation. As the anti-knock value is increased, the mixture ratio for full-throttle running can be increased and the fuel consmption thus decreased. It would appear obvious that, as the fuel consumption for full power without detonation is decreased, the consumption for 1 per cent less than full power will be similarly decreased.

While it is Air Corps policy that engines shall be built to suit standard fuels rather than to supply each engine type with an appropriate fuel, nevertheless, as Dr. Becker suggests, the fuel standard will be raised as often as developments make this possible, and engine output will of course keep step with the fuel improvement.

While lowering of the 10 per cent point is of course desirable, the Air Corps is at present having such trouble with vapor lock as to render it desirable to specify a Reid vapor-pressure requirement on all gasoline for its use. The substituting of a Reid vapor-pressure test for the lower temperature limit of the 10 per cent evaporated point is necessitated by the fact that some gasoline deliveries apparently contain propane. For the present, pending improvement in fuel systems, it appears that a Reid vapor pressure of 6.5 lb. per sq. in. at 100 deg. fahr. cannot be exceeded.

ROBERT E. WILSON.[17] It is very fortunate for both engine manufacturers and users and those who supply its fuel and lubricants that an able and unbiased body like the Air Service is effectively prosecuting such important lines of research. The writer concurs heartily in Mr. Heron's statement that engines should be built to give good performance on certain standard fuels, and also his conclusion that in the light of present knowledge we must use tetraethyl lead in substantial quantities if we are to get real super-compression fuels. Making the standard fuel equivalent in anti-knock to 3 cc. of lead in California Fighting Grade gasoline certainly gives such a fuel—one which will make possible such performance and economy that engine manufacturers will have an adequate incentive to use metals which will withstand any danger of corrosion by Ethyl fluid or its products of combustion. Automobile engines give no trouble from this source, and there is no reason why aviation engines cannot be made equally satisfactory.

The Army Air Service has fostered two other things which will be of great assistance in making super-compression fuels generally available at a reasonable price. One is that the use of high-temperature liquid cooling by products such as glycol should greatly increase the ease of avoiding knocking with straight hydrocarbon fuels, most of which tend to lose their anti-knock value rather rapidly at the very high temperatures encountered in air-cooled engines. It must be remembered that even a very small local hot spot in an engine (for example, the exhaust valve) will greatly increase the tendency of a given fuel to knock.

The other helpful factor is the recommendation of a stability test instead of an inaccurate and over-strict copper-dish test for gum. The existence of the latter specification has made it practically impossible to use any cracked product in aviation fuels, in spite of the fact that cracked products generally have better anti-knock properties, and can be refined to a point where they give no actual trouble from gum. Our own company developed such a stability test several years ago, and has found the results obtained therewith a reliable guide to the behavior of a fuel in storage and service.

MR. HERON. While, as Dr. Wilson suggests, the avoidance of local hot spots is easier with high-temperature liquid-cooled engines than with air-cooled engines, nevertheless the best of the air-cooled engines have exhaust-valve cooling that is at least good as the best of the available water-cooled engines. As far as the existing data go, they would suggest that the glycol-cooled engine will give greater mean effective pressure on a given fuel than will the air-cooled engine. However, the comparison is not very exact, as it is based on an air-cooled engine with 195 cu. in. cylinders, having very excellent exhaust-valve cooling and running at 1900 r.p.m., and liquid-cooled engines with 96 and 131 cu. in. cylinders running at 2300 and 2400 r.p.m., both having less efficient exhaust-valve cooling than the air-cooled engine.

Dr. Wilson's views on cracked fuels for aviation and the accelerated aging test for gum are of decided interest, coming as they do from such a wealth of experience. The Air Corps' experience of cracked gasolines is as yet slight. In addition to the flight tests described in the paper, it is now receiving a fair volume of gum-stable cracked undoped D.A.G. to its Specification No. 2-40-F and has had no trouble to date with this fuel.

The lead response of cracked gasolines tested by the Air Corps has so far proved disappointing, despite the very high anti-knock value of some of these gasolines in the undoped condition.

The Air Corps wishes to encourage the use of cracked fuels of high anti-knock value, as it is only by their use on a fairly wide scale that their suitability for aircraft use can be determined.

Aluminum Alloys for Aircraft-Engine Piston and Cylinder Heads[1]

By A. J. LYON,[2] DAYTON, OHIO

The paper contains results of a great amount of valuable research on aluminum alloys for aircraft-engine piston and cylinder heads that has not heretofore been covered, and the findings should be valuable to all aircraft-engine designers. Two alloys have heretofore been recommended, but the Materiel Division at Wright Field has developed a series of new alloys, and the paper describes the method of manufacture, the effect of numerous alloying constituents on their properties, the strength at elevated temperature, their stability, and the methods of heat treatment, with comparison with the present standard alloys.

ALUMINUM-ALLOY PISTONS for automobile engines were first used in Belgium and France as early as 1912. Shortly after the World War, pistons were made in the United States for automobile engines by the permanent-mold process which involves casting in metal molds with removable iron cores. The alloys used for this purpose were mostly of the 10 per cent copper-aluminum type. With the development of heat-treating processes, small amounts of magnesium and iron were made to the foregoing alloy, in which form it is known as S.A.E. No. 34, or Lynite 122. There are also compositions containing nickel, manganese, and various other alloying constituents, the most important being the aluminum-copper-magnesium-nickel alloy "Magnalite."

The complicated designs and size of many aircraft-engine pistons and practically all cylinder heads make it impractical to use the permanent-mold process for the casting of these parts. Dry- or green-sand castings are generally used for air-cooled cylinder heads, while pistons are made either in green-sand molds or in semi-permanent molds, the latter being a metal mold with a sand core. Aluminum alloys cast in sand have a lower strength and hardness than when cast by the permanent-mold process, so that materials satisfactory for use in automobile-engine pistons are in many cases not suitable for aircraft engines. The U. S. Army Air Corps has directed considerable attention to the study of properties of piston and air-cooled cylinder-head materials, and it specifies the two following alloys in the heat-treated condition for this purpose:[3]

Alloy Lynite 122, or S.A.E. No. 34—Copper, 10 per cent; magnesium, 0.25 to 0.50 per cent; iron, 1.25 to 1.50 per cent; aluminum plus impurities, remainder.

Alloy Y, or Magnalite—Copper, 4 per cent; nickel, 2 per cent; magnesium, 1.50 per cent; aluminum plus impurities, remainder.

Neither of these materials is satisfactory in all respects. The aluminum-copper-magnesium alloy is especially difficult to cast sound in the form of the heavy sections that often are encountered in air-cooled cylinder heads, and the aluminum-copper-iron-magnesium alloy is unsatisfactory on account of its relatively high specific gravity, low strength when cast in heavy sections, and the softening of the alloy due to exposure to the operating temperatures of aircraft engines. The Matériel Division at Wright Field has developed a series of alloys which have a more desirable combination of properties than these alloys listed, and this paper describes the method of manufacture, effect of numerous alloying constituents on their properties, strength at elevated temperature, their stability, and methods of heat treatment, with comparison with the present standard alloys.

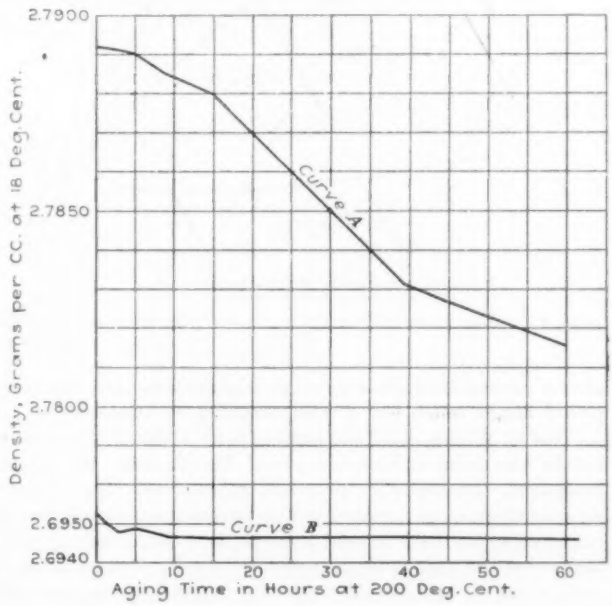

FIG. 1 EFFECT OF AGING AT 200 DEG. CENT. ON DENSITY OF COPPER-ALUMINUM ALLOY AND ON MAGNESIUM-SILICON-ALUMINUM ALLOY
(Curve *A*, 4.5 per cent copper-aluminum alloy, quenched at 500 deg. cent.; curve *B*, 0.58 per cent magnesium, 0.4 per cent silicon and aluminum alloy, quenched at 500 deg. cent.)

THE HIGH-STRENGTH ALUMINUM ALLOYS

The foregoing alloys can be classified as high-strength aluminum-casting alloys on a basis of tensile strength and hardness. The strength is in the range of 30,000 to 40,000 lb., and the

Presented at the Fourth National Aeronautic Meeting, Dayton, Ohio, May 19 to 22, 1930, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

Brinell hardness is in excess of 100. The ductility is lower than the alloys commercially used in the general run of sand castings. Alloys of this later class have tensile strengths ranging from 18,000 to 25,000 lb. per sq. in., and their hardness is less than 90. The high-strength aluminum-casting alloys must be subjected to a heat-treating process which involves soaking at an elevated temperature, quenching, and aging.

Either copper or magnesium, with sometimes both constituents, is used in all the high-strength aluminum alloys. Copper forms a compound $CuAl_2$ which has a maximum solid solubility in aluminum of approximately 5 per cent copper at the eutectic melting point (540 deg. cent.). At 500 deg. cent. the solid solubility is reduced to 4.5 per cent copper, and at 250 deg. cent. it is less than 3 per cent. Magnesium combines with the silicon, always present in aluminum as an impurity, to form the compound Mg_2Si which has a solid solubility in aluminum of 1.6 per cent at 580 deg. cent., the melting point of the eutectic formed by the aluminum and the compound Mg_2Si. Like the copper compound, the solubility decreases rapidly with temperature. By quenching from a relatively high temperature, the hardening constituents are held in solid solution, and tests made immediately after the quenching operation show improvement in hardness, strength, and ductility over the material in the cast condition. Upon aging the quenched alloys, either at atmospheric temperatures or at higher temperatures, the compounds $CuAl_2$ and Mg_2Si act alike and are precipitated in the form of finely divided particles which are accompanied by still further increase in strength and hardness and by a decrease in elongation. In the commercial heat-treated aluminum-casting alloys, copper is used either alone as a hardening constituent or with magnesium. When both elements are present in the alloy, the solubility of the copper compound is reduced at both high and low temperature; likewise, the solubility of magnesium silicide is less in the presence of copper than it is in pure aluminum. In magnesium silicide alloys, magnesium, in addition to the amount required to unite with the silicon to form the compound Mg_2Si, reduces the solubility at both high and low temperatures, and in the Cu-Al alloys excess copper has the same effect. There are certain other alloying constituents which affect the solid solubility of these hardening compounds in aluminum, the most important of which, from a commercial standpoint, is nickel, which has little effect on the hardening effect of magnesium silicide, but increases the solubility of the copper compound both at high and low temperatures, and as a result reduces its hardening effect. Gayler and Preston ("The Age Hardening of Some Aluminum Alloys," Journal of the Institute of Metals, Vol. 41) studied the effect of the precipitation of the compounds $CuAl_2$ and Mg_2Si upon the hardness and density of several alloys containing copper and magnesium. The graphs in Fig. 1, taken from the data published by the foregoing authors, indicate that alloys which are hardened by the precipitation of magnesium silicide (curve *B*) undergo a less volume of change than those hardened by the precipitation of the copper compound (curve *A*). This is of importance from the standpoint of stability of dimensions of parts exposed to elevated temperatures in use. Curve *B* for the magnesium silicide alloy shows no decrease in density after five hours at a temperature of 250 deg. cent., while curve *A* for the aluminum-copper alloy shows that the density of volume changes during a period of fifty hours' exposure to the same temperature. It would follow that parts cast in the copper alloy should be annealed for prolonged periods in order to insure stability of dimensions, while an alloy which is hardened by the precipitation of magnesium silicide can be subjected for a much shorter period and thereby rendered immune to further "growth." The charts shown in Fig. 2 have been taken from the work of Bingham and Haughton on the age hardening of aluminum-copper-nickel-magnesium alloys, "Alloying Constituents and Age Hardening of Some Ternary and Quaternary Alloys." The Journal of the Institute of Metals, No. 2, 1926, Vol. 36, p. 144, shows that 2 per cent nickel in the alloy containing 4 per cent copper completely eliminates the precipitation of the compound $CuAl_2$, while the 10 per cent copper magnesium-aluminum alloy owes its increased hardness and strength upon aging to the precipitation of both the compounds Mg_2Si and $CuAl_2$.

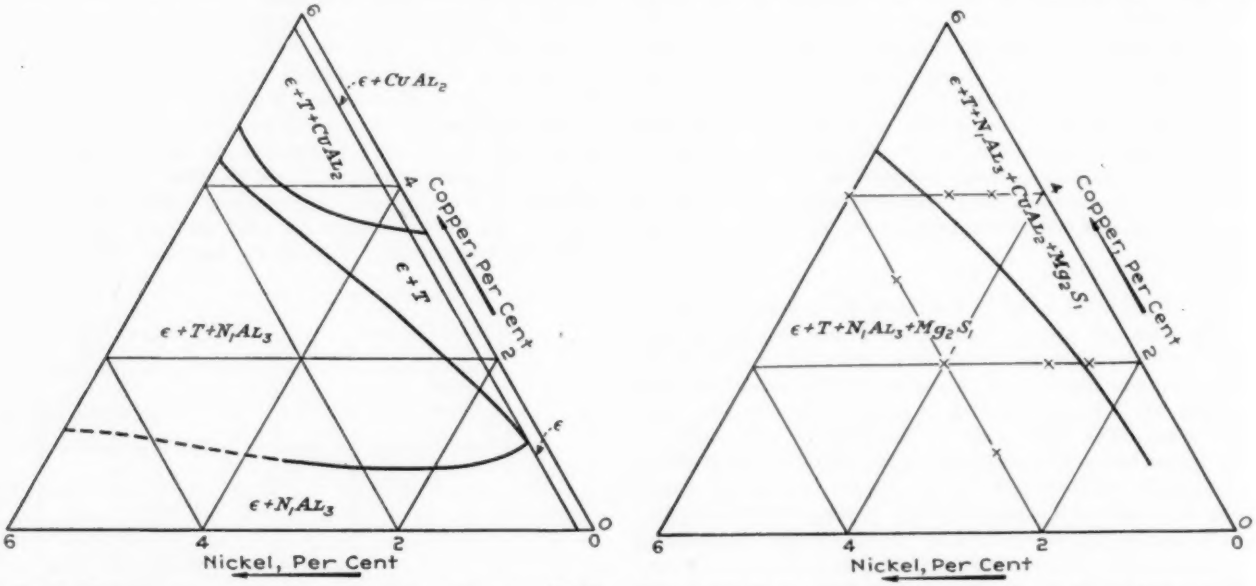

FIG. 2 CONSTITUTION AT 500 DEG. CENT. (FOR *A*) AND AT 200 DEG. CENT. (FOR *B*) OF A COPPER-NICKEL-ALUMINUM ALLOY CONTAINING 1 PER CENT MAGNESIUM

EFFECT OF SMALL AMOUNTS OF NICKEL ON THE PROPERTIES OF THE ALUMINUM-COPPER MAGNESIUM ALLOYS

A high-strength alloy developed by the Material Division for parts requiring a good combination of strength and elongation

has been described by Daniels, Lyon, and Johnson in the Transactions of the American Institute of Mining and Metallurgical Engineers, 1925, Vol. 71, p. 864. This alloy theoretically contains copper magnesium and silicon in the proportions that produce the maximum hardening and strengthening effect upon heat treatment. Test specimens cast in green sand, conforming to the dimensions of the American Society for Testing Materials, quenched at 510 deg. cent. and aged at 150 deg. cent. for 24 hours, gave the following physical properties:

Tensile strength, lb. per sq. in.	32,300
Elongation, per cent in 2 in.	3.2
Brinell hardness, 500 kg., 10 mm.	74

The composition of the foregoing alloy was: Cu 3.0, Mg 0.5, Si 0.3, Fe 1.2, Al remainder. Increasing the silicon content to 0.6 per cent to allow for silicon in the iron compounds, the following average results were obtained:

Tensile strength, lb. per sq. in.	41,370
Elongation, per cent in 2 in.	0.5
Brinell hardness, 500 kg., 10 mm.	101

It was concluded that an alloy of this type could be used for pistons and cylinder heads with the advantages of a lower specific gravity than the 10 per cent copper-magnesium alloy and with better casting properties than the 4 per cent copper and 2 per cent nickel-magnesium alloy. Small amounts of nickel were added for the purpose of determining the effect of this element upon the physical properties. The following results were obtained on standard test specimens soaked at 525 deg. cent. for 5 hours, quenched in cold water, and aged at 150 deg. cent. for 24 hours:

Nickel,[1] per cent	Tensile strength, lb. per sq. in.	Elongation, per cent in 2 in.	Brinell hardness
Nil	42,690	0.5	105
0.25	42,590	0.5	109
0.50	42,450	0.5	111

[1] Cu 3.0, Fe 1.2, Mg 0.5, Si 0.6, Al remainder.

The physical properties are not affected by small additions of nickel where the alloys are quenched from a temperature below 530 deg. cent., but as little as 0.5 per cent nickel is shown in Fig. 3 to have a pronounced effect upon the strength and hardness of the heat-treated alloys when quenched from higher temperatures. It was also observed that these alloys could be heated to a higher temperature without danger of "burning" than those of the same composition except for the nickel content. Another possible advantage of the nickel is to lessen "growth" by preventing the precipitation of the compound $CuAl_2$. The charts of Fig. 2 show that 0.5 per cent nickel does not quite place the alloy containing 3 per cent copper in the field where there is no precipitation of the copper compound when aged or annealed at 200 deg. cent. However, hardness tests made on forged alloys with the nickel content ranging from 0.2 to 2.0 per cent by Bingham ("The Constitution and Age-Hardening of Some Ternary and Quaternary Alloys," Journal of the Institute of Metals, 1926, Vol. 36), show that from the practical standpoint 0.4 per cent nickel suppresses the age hardening of the copper-aluminum alloys. It was found in this investigation that 0.5 per cent nickel is sufficient to lessen "growth" caused by the precipitation of the compound $CuAl_2$, but not enough to appreciably affect the casting properties of the alloy, as described under another heading.

Iron and Silicon in the Aluminum-Copper-Nickel-Magnesium Alloys

Iron and silicon occur as impurities in all grades of aluminum ingot used in the manufacture of aluminum alloys. Where grade 1 primary aluminum is used, the iron and silicon from this source do not exceed 0.5 per cent. However, in the remelting of the alloys in connection with the manufacture of casting, additional iron is picked up from ladles, stirring rods, and melting pots. There is a conflict of opinion on the beneficial effects of added iron in excess of that which occurs in the form of an impurity, but it is generally conceded that it has a beneficial effect on the strength of alloys at elevated temperatures and in the casting of parts that are subject to cracking during solidification. In the high-strength aluminum alloys, containing copper and magnesium, neither iron nor silicon appreciably affects the solid solubility of the hardening constituents

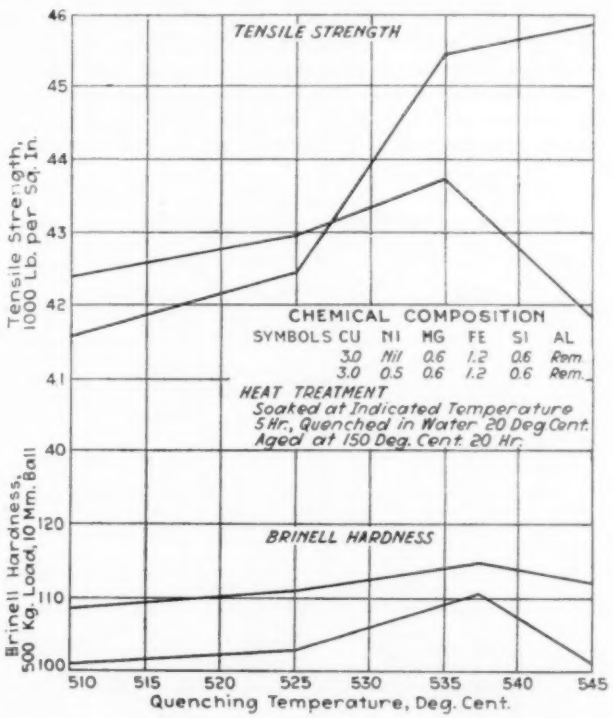

Fig. 3 Effect of Nickel on the Strength and Hardness of Aluminum-Copper-Magnesium Alloys

($CuAl_2$ and Mg_2Si) and therefore does not affect the age-hardening of these alloys in the same manner as does nickel or excess magnesium. Iron forms the compound $FeAl_3$ with aluminum which has a limited solubility and forms a eutectic with aluminum at about 1.7 per cent iron. Silicon is soluble in aluminum in the solid state up to approximately 1 per cent. Iron in the presence of silicon forms a number of compounds and series of solid solutions which appear in the microstructure of aluminum alloys in various crystal forms.

Gwyer and Phillips ("The Constitution of Alloys of Aluminum With Silicon and Iron," Journal of the Institute of Metals, 1927, Vol. 38) have described three constituents that are present in aluminum-iron-silicon alloys as cast and annealed at 500 deg. cent.: $FeAl_3$, which occurs in the as-cast alloys in the form of elongated masses of needles and plates; Beta, as a constituent which resembles Chinese script and which is a solid solution of iron and silicon; *X* constituent, which occurs in the form of needles and contains various proportions of iron and silicon in solid solutions. The latter two constituents are formed as a result of a reaction between the compound $FeAl_3$ silicon and aluminum during the freezing of the alloys and to a certain extent by prolonged annealing of the solid alloys at high tempera-

tures. E. H. Dix, of the Aluminum Company of America, also has furnished valuable data on the occurrence of iron and silicon in aluminum, and in general his findings are in agreement with those of the English investigators. Geyer, Phillips, and Mann, ("Alloy of Aluminum With Copper, Silicon, and Iron," Journal of the Institute of Metals, 1928, Vol. 40, p. 346) also have shown the presence of a quaternary eutectic formed by $CuAl_2$, the constituents Beta and X, primary silicon, and aluminum.

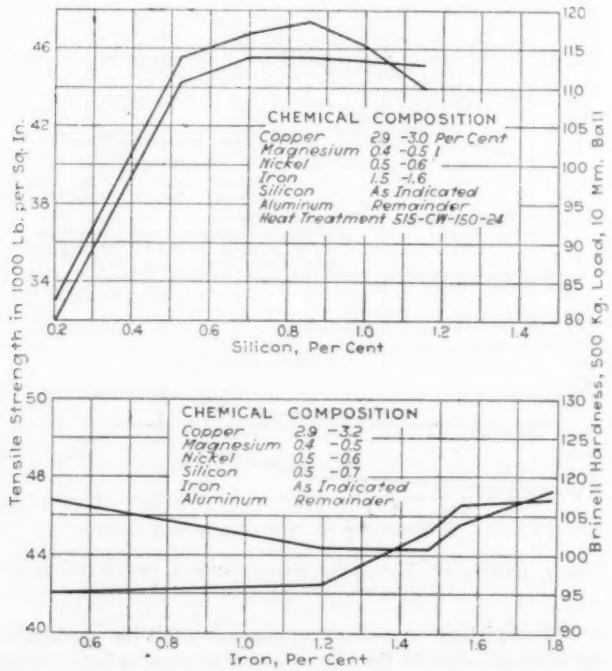

FIG. 4 EFFECT OF IRON AND SILICON ON THE TENSILE STRENGTH AND HARDNESS OF ALUMINUM-COPPER-MAGNESIUM ALLOY, QUENCHED FROM A TEMPERATURE OF 525 DEG. CENT.

The melting point of this eutectic is approximately 520 deg. cent. and is important in connection with the heat treatment of all high-strength aluminum alloys containing silicon, iron, and copper.

Archer and Jeffries ("New Developments in High-Strength Aluminum Alloys," Transactions of the American Institute of Mining and Metallurgical Engineers, 1925, Vol. 71, p. 839) have shown the effect of iron in a wrought aluminum-copper alloy to be harmful, but with the addition of approximately 1 per cent silicon to a 4 per cent copper-aluminum alloy containing 1 per cent iron, the tensile strength was increased 35 per cent without greatly affecting the elongation.

A study of the effect of iron and silicon in the cast aluminum-copper-nickel-magnesium alloys was made in connection with this investigation, and the results are shown in Figs. 4 and 5 and in Table 1. The best combination of strength and hardness of this type of alloy is developed with 0.6 to 0.8 per cent silicon, with an iron content of approximately 1.5 per cent. The results given in Table 1 are for two alloys of the same composition except for the iron content and show that the use of iron in this type of alloy is desirable.

In alloys containing 1.5 per cent iron the temperature to which the alloys can be heated without "burning" and rendering the material unfit for use is rapidly reduced with increasing silicon, as shown by the graphs in Fig. 5 and the results given in Table 2.

From the results of the foregoing experiments two composi-

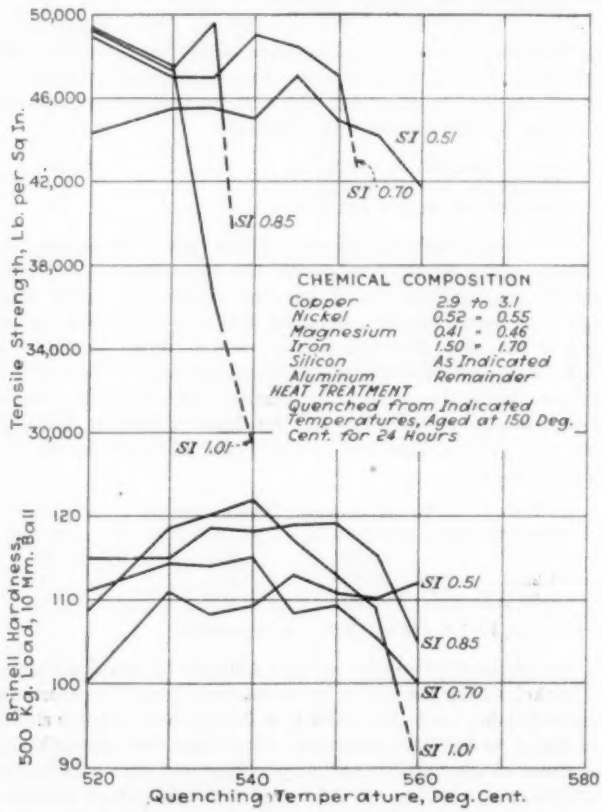

FIG. 5 TENSILE STRENGTH AND HARDNESS OF 3 PER CENT COPPER-MAGNESIUM-NICKEL-ALUMINUM ALLOYS, SHOWING THE EFFECT OF SILICON ON THEIR HEAT TREATMENT

tions were selected representing the upper and lower practical limits for silicon in the aluminum-copper-nickel-magnesium alloys for use in pistons and cylinder heads. For the purpose of identification, these alloys have been given the symbols X and Z, and their chemical compositions follow:

	Cu	Ni	Fe	Si	Mg	Al
Alloy X	3.0	0.5	1.5	0.6	0.5	Rem.
Alloy Z	3.0	0.5	1.5	1.0	0.5

515	41,020	49,270	49,370	49,000	100	111	115	108
526	45,610	46,900	4,710	46,180	111	114	114	118
532	46,600	47,030	49,760	37,280	108	114	118	120
538	46,080	49,400	28,340	20,000	109	115	117	122
543	47,310	48,570	21,300	16,400	113	108	119	117
549	45,060	47,570	20,330	19,950	111	109	119	113
555	44,120	19,540	19,520	19,360	110	105	115	110
560	41,740	12,440	5,287	3,992	112	97	106	89

[1] Aged 24 hr. at 150 deg. cent.
[2] Cu 2.90–3.08, Fe 1.47–1.73, Ni 0.52–0.55, Mg 0.41–0.48, Al remainder.

Effect of Copper

For the purpose of determing the limits of the copper in this type of an alloy, the copper content was varied in the range 3 to 5 per cent with the following results for sand-cast specimens quenched from 525 deg. cent. and aged for sixteen hours at 150 deg. cent.:

Copper[1] per cent	Tensile strength, lb. per sq. in.	Brinell hardness, 500 kg., 10 mm.
3	46,970	116
4	43,740	113
5	44,340	122

[1] Ni 0.5, Mg 0.5, Fe 1.8, Si 0.5, Al remainder.

The foregoing results show that the physical properties at atmospheric temperatures are not appreciably affected by the variations in the copper content. The heat treatment and the properties resulting therefrom of the 5 per cent copper alloy are affected by iron, silicon, and nickel in the same manner as the 3 per cent copper alloy, as shown in Fig. 6. An alloy of the following compositions was chosen from this series for the purpose of investigating its properties:

Alloy symbol	Chemical composition
W	Cu 5.0 per cent
	Ni 0.5 per cent
	Mg 0.5 per cent
	Fe 1.5 per cent
	Si 0.6 per cent
	Al Rem.

Effect of Magnesium

Two heats were made of exactly the same composition and containing iron, nickel, copper, and silicon in amounts corresponding to the specifications of experimental alloy X. Magnesium (0.5 per cent) was added to one of the heats, while none was added to the other. Standard cast-to-size test specimens were cast in green sand, then heat-treated. One lot of specimens from the foregoing composition was tested after aging at room temperature for 24 hr. and another lot after aging at 150 deg. cent. for the same length of time. The results given in Table 3 show that the specimens aged at room temperature are of the same order as those obtained by Hyman (Journal of the Institute of Metals, 1925, Vol. 34), who recommends an alloy of similar composition to alloy X for general purposes where combinations of high strength and ductility are required in castings. The results given in Table 3 for the specimens aged at 150 deg. cent. show a tensile strength 20 per cent higher than ordinarily obtained on Y alloy and Lynite 122 and show conclusively that the hardening and strengthening are due almost entirely to the precipitation of the compound magnesium-silicide. Small variations in the magnesium content can be expected in the mixing of the alloys, and the effect on the strength and hardness is shown in the following tabulation:

Magnesium,[1] per cent	Tensile strength, lb. per sq. in.	Brinell hardness, 500 kg., 10 mm.
0.4	47,220	107
0.5	46,715	108
0.6	45,880	109

[1] Cu 3.0, Ni 0.55, Fe 1.6, Si 0.99, Al remainder.

The foregoing results were obtained on sand-cast specimens quenched from 515 deg. cent. and aged for 24 hours at 150 deg. cent.

Method of Alloying

Aluminum ingot for the manufacture of aluminum alloys may be obtained commercially in the following grades that conform to U. S. Army Specifications:

Grade	Chemical composition Al	Cu	Fe-Si	Mn and other impurities
Special	99.5	0.1	0.4	....
Grade A	99.0	...	0.8	0.25
Grade B	98.0	...	1.5	0.50

Grade A aluminum as used in the mixing of the high-strength alloys usually contains approximately 0.5 per cent of iron and 0.3 per cent or less of silicon. The relationship of the iron and silicon contents of alloys X, Z, and W has been shown to be of great importance, so in order to control the composition accurately, an intermediate alloy containing both elements is used in mixing the alloys. The compositions of these hardeners are as follows:

Alloy	Fe	Si	Mg	Al
X and W	8.0–10.0	4.0–6.0	5.0–6.0	Rem.
Z	8.0–10.0	6.0–8.0	5.0–6.0	Rem.

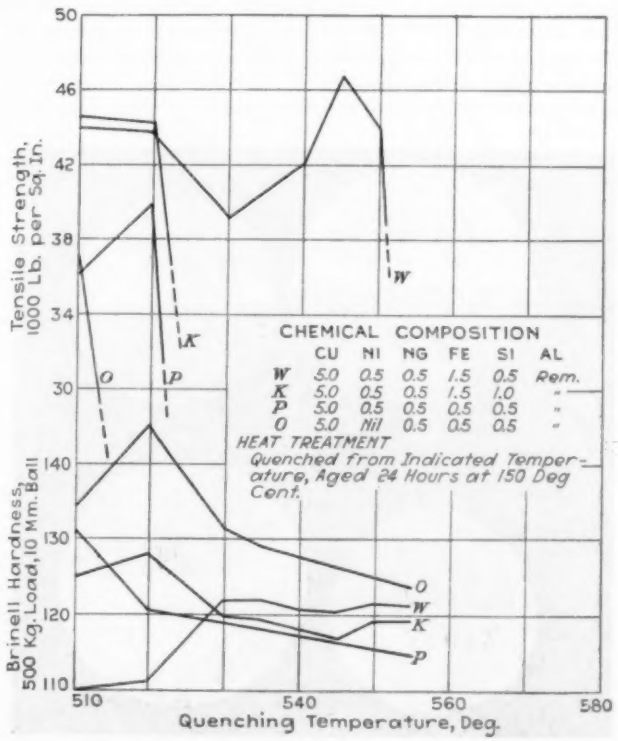

Fig. 6 Tensile Strength and Hardness of 5 Per Cent Copper-Magnesium-Aluminum Alloys and the Effect of Iron, Silicon, and Nickel on Their Heat Treatment

These hardeners can be mixed in crucible-type furnaces and the composition of the alloying elements be controlled within the foregoing limits. The variation in the final alloy is less than 0.1 per cent. The copper and nickel are introduced in the alloys in the form of a Cu-Ni-Al hardener containing the following proportions of copper and nickel:

Alloys X, Z, and W	Copper, 30 to 40 per cent Nickel, 5 to 8 per cent

In connection with the manufacture of Y alloy it has been stated that it is desirable to introduce the magnesium directly into the final alloy rather than to add it by means of a magnesium-rich alloy of aluminum, but in the manufacture of alloys, X Z, and W there was no difference in the casting properties of the alloys made by the direct addition of magnesium and those made by introducing the nickel with the iron and silicon. The iron-silicon-magnesium intermediate alloy breaks readily under the hammer for the purpose of weighing and when cast into iron molds is free from segregation. It has a relatively low melting point and readily goes into solution in aluminum at a temperature of 800 deg. cent. Experiments with several compositions of nickel, copper, magnesium, and aluminum proved that the addition of magnesium in this manner was unsatisfactory. Nickel with magnesium produces intermediate alloys that go into solution very slowly, and excessive dross is formed upon the surface of the molten metal.

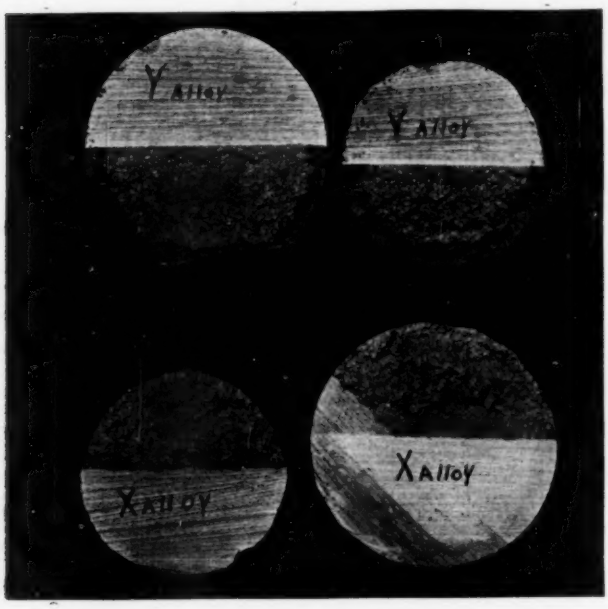

FIG. 7 PHOTOGRAPH SHOWING POROUS RIM NEAR SURFACE OF Y-ALLOY CASTINGS AND THE ABSENCE OF THIS DEFECT IN ALLOY X

CASTING PROPERTIES

The soundness of castings of alloy W is superior to the other two experimental alloys X and Z, but all are greatly superior to Y alloy. Cylinders 3 in. in diameter and 6 in. in length cast in green sand, as shown in Fig. 7, were poured at 675 deg. cent. from the following alloys:

	Composition					
Alloy symbol	Cu	Ni	Mg	Si	Fe	Al
Z	3.0	0.5	0.7	1.0	1.5	Rem.
X	3.0	0.5	0.5	0.7	1.5	Rem.
W	3.0	0.5	0.5	0.7	1.5	Rem.
122	10.0	Nil	0.3	0.2	1.3	Rem.
LCD	2.5	Nil	0.7	0.6	1.5	Rem.
Y	4.0	2.0	1.5	0.3	0.4	Rem.

From the surface of these cylinders, $^1/_8$ in. was machined, and the cylinder was light-etched in a solution of sodium hydroxide, and others were fractured and the appearances were compared. The surface of the cylinder cast in Y alloy contained numerous gas cavities of considerable depth and size. The alloy LCD was the best of the series, while alloys Z, X, W, and 122 were about of the same order, except that "pinholing" was more pronounced on the 122 cylinder. Fractures of specimens from alloy Y contained a porous, discolored rim approximately a $^1/_4$ in. deep, which contained numerous cavities. Alloys X, Z, and W show this defect to a much less degree, and it can be eliminated by the fluxing of the metal; and alloys 122 and LCD, which do not contain nickel, were free from it. Fig. 8 shows a comparison of the fractures of alloys Y and X. Chemical samples taken from the surface of the cylinders referred to and which were cast in Y alloy show the normal amount of nickel and magnesium, but the copper was 1 per cent less than the average sample, showing that segregation occurs in heavy cast sections.

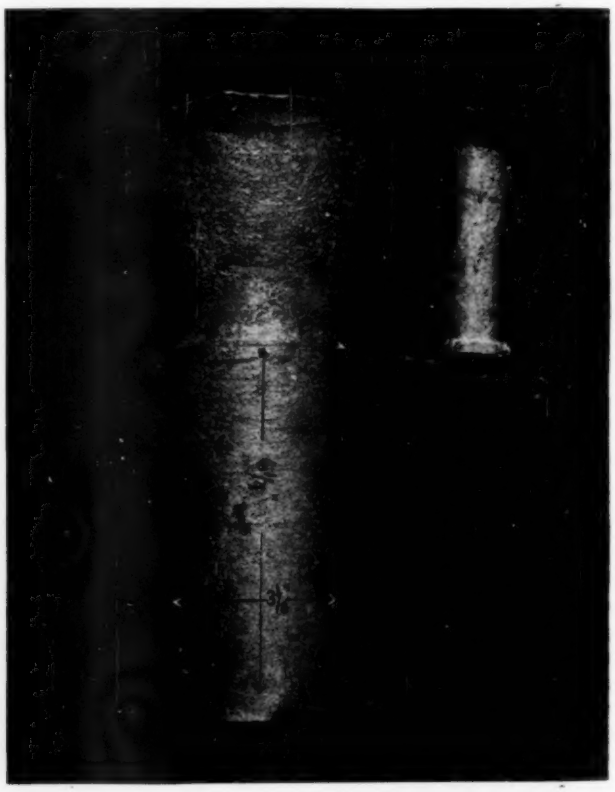

FIG. 8 PHOTOGRAPH SHOWING METHOD OF CASTING CYLINDER USED FOR COMPARING CASTING PROPERTIES (SEE FIG. 7) AND FOR GROWTH MEASUREMENTS (SEE FIG. 14)

A further comparison was obtained between the casting characteristics of alloys Z, X, W, and Y by substituting the former alloys in a piston of complicated design that had given trouble in the foundry and machine shop because of gas holes, cracks, and distortion. These alloys produced sound castings when cast with the same method of gating and chilling as Y alloy, except that alloy X required slightly heavier risers as the solidification shrinkage is higher and the pouring heads and risers "pipe" to considerable depth. Increasing the copper

Reheated at 260° C., 25 hr	32,530	29,810	25,300	2.0	0.5	0.5	74	83	77

Composition as mixed	Cu	Fe	Si	Ni	Mg	Al
X	3.4	0.75	0.6	0.7	0.7	Dif.
Y	4.0	0.5	0.3	2.0	1.5	Dif.
Lynite 122	10.0	1.5	0.3	Nil.	0.25	Dif.

content of alloy X from 3.0 per cent to 3.5 per cent and the nickel content from 0.5 per cent to 0.7 per cent and decreasing the iron produced a marked improvement without affecting the physical properties, and castings molded in exactly the same manner as for Y alloy showed no evidence of "shrinks" or "draws." All castings in the experimental alloys were sound, as was shown by cutting the pistons into sections and by the use of X-ray analysis. The rejections due to imperfect castings alone averaged about 50 per cent in Y alloy for this particular piston, while in the experimental alloys the rejections due to foundry defects in the experimental alloys were practically nil.

Heat Treatment

The heat treatment of alloys X, Z, and W is similar to the process for Y alloy and Lynite 122 with the exception of the temperature to which the materials can be heated for quenching. The soaking period, or the time the material must be held at the quenching temperature in order to effect solution of the hardening constituents, is comparatively short, and no appreciable gain in the physical properties is obtained for periods over five hours, as is shown in Table 3. The results given in Table 2 and the graphs shown in Figs. 5 and 6 indicate that the maximum properties of the alloys containing 0.6 and 0.8 per cent silicon can be developed over a considerable range of temperature, which is a distinct advantage in commercial heat-treating practice. The maximum temperature to which Y alloy can be heated without "burning" is 530 deg. cent., and small variations in temperature have a very pronounced effect upon the physical properties, as shown by the following results:

Quenching temperature, deg. cent.	Tensile strength and Brinell hardness of alloys, lb. per sq. in.			
	122	Y	W[1]	X[1]
505	36,900–116	34,200–100	42,380–117	47,150–111
515	39,100–134	37,900–106	43,900–111	49,270–115
525	37,800–124	44,350–111	39,160–124	46,900–114
538	22,300–112	20,000–110	42,860–121	49,400–115
549	23,600–106	20,100–109	43,300–122	47,570–109
560	21,600–101	18,000–102	21,150–102	12,440– 97

[1] Silicon 0.70; maximum quenching temperature.

The aging or temperature to which the alloys must be reheated after quenching to develop the maximum hardness and strength can be accomplished at temperatures ranging from 150 to 260 deg. cent. Aging temperatures higher than 150 deg. cent. require a much shorter time to produce the maximum hardness and strength, as shown in the following tabulation for the alloy:[4]

Aging temperature, deg. cent.	Aging time, hr.	Tensile strength, lb. per sq. in.	Elongation, per cent in 2 in.	Brinell hardness
150	2	37,510	3.7	89
150	8	39,420	1.0	95
150	16	44,800	1.0	105
150	24	48,960	0.8	113
150	48	47,150	0.5	113
205	1/2	44,520	0.7	103
205	1	45,220	0.7	110
190	5	47,930	1.0	111
260	1/2	44,540	0.5	108

Aging treatments of 16 and 24 hours at 150 deg. cent. were used in the experimental work in connection with the development of these alloys unless specified otherwise. For commercial practice, however, an aging treatment of 5 hours at 190 deg. cent. is recommended for pistons. The quenching temperature should be in the range of 510 to 530 deg. cent., as shown.

In many of the present types of aircraft engines it is the practice to shrink the aluminum alloy head upon a steel cylinder barrel at a temperature of approximately 375 deg. cent. The following physical results obtained on sand-cast test specimens quenched at from 500 to 515 deg. cent. and reheated to 375 deg. cent. illustrate the superiority of X-type alloy for this purpose:

Alloy	Reheating temperature, deg. cent.	Time at temperature, hr.	Tensile strength, lb. per sq. in.	Elongation, per cent in 2 in.	Brinell hardness
X[1]	375	1/2	27,200	2.8	61
Y	375	1/2	30,042	0.8	78
122	375	1/2	22,100	0.9	61
Z[2]	375	*1/2	30,080	2.5	71

[1] Si 0.5 per cent. [2] Si 1.0 per cent.

Comparing the foregoing results with the chart shown in Fig. 13 and with Table 4, it may be seen that the alloys are in their stable condition and that little change should occur in the foregoing properties upon reheating to the operating temperatures of aircraft-engine cylinder heads for prolonged periods of time. These results further show that cylinder heads that are subjected to the shrinking operation during assembly should not be artificially aged. A further advantage of alloy X is that it can be straightened after the quenching operation in the same manner as castings made from the high-strength alloy commercially known as Lynite 195, while the ductility of alloys Y and Lynite 122 is too low in the as-quenched condition to correct for any distortion that occurs during the quenching operation.

Tensile and Hardness Tests

In all cast metals and alloys the rate of solidification has a pronounced effect upon the mechanical properties, but in alloys that tend to segregate when cast in heavy sections the strength drops off more rapidly than with alloys that do not. For the purpose of comparing the properties of alloys used for sand castings it is desirable to know the effect that mass and thickness of section have upon the physical properties, as the rate of cooling and of solidification of the molten metal decreases as the size of the casting increases. In Figs. 9 and 10 the tensile strength and the hardness of the experimental alloys, X, Z, and W are compared with the two standard alloys now used by the Army Air Corps (Lynite 122 and Y alloy). These graphs were prepared from results obtained on test specimens cast in green sand ranging from 1/2 in. in diameter to 1.5 in. in diameter over the reduced section. The methods of gating were the same in all cases and the pouring temperatures were held constant at 675 deg. cent. A series of specimens, with the exception of the Lynite 122 specimens, were soaked at 510 deg. cent. for 5 hours, quenched in water, and artifically aged for 24 hours at 150 deg. cent., and then tested. The Lynite 122 specimens were soaked

[4] Chemical composition: Cu 3.08, Ni 0.55, Fe 1.57, Si 0.69, Mg 0.54, Al remainder. Sand-cast standard test specimens were quenched from 520 deg. cent.

at 500 deg. cent. to avoid burning. Another series were cast and allowed to stand for 30 days at room temperatures and then tested.

The superiority of all experimental alloys when cast in heavy sections such as are encountered in pistons and cylinder heads is readily shown. In particular, it may be seen by comparing the experimental alloys with Lynite 122 and Y alloy that the $^1/_2$-in. sections show a difference in strength of about 10,000 lb. per sq. in., or 25 per cent, in favor of the former, while for the $1^1/_2$-in. specimen the tensile strengths of X, W, and Z alloys are 75 per cent higher than Lynite 122 and Y alloy.

For the specimens cast and aged for 30 days at atmospheric temperatures, the graphs in Fig. 9 show that alloys X and Z

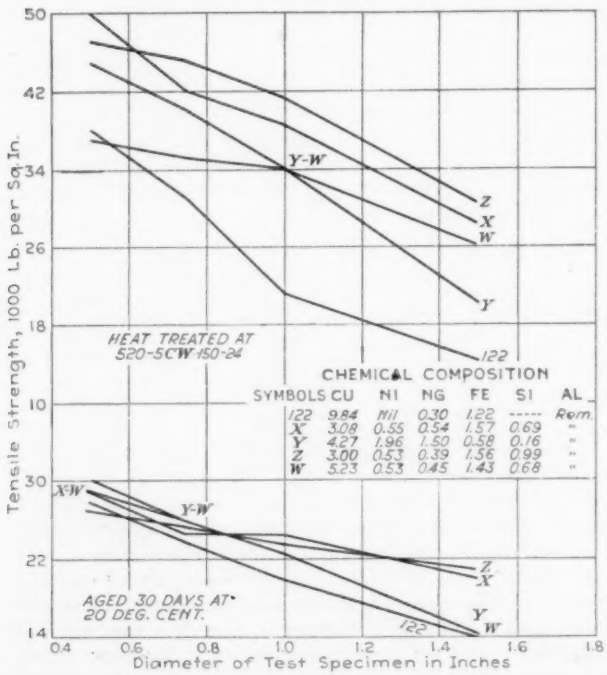

Fig. 9 Tensile Strength of Aluminum Piston and Cylinder-Head Alloys, Showing the Effect of Section Thickness

retain their strength in the larger sections better than the other three alloys, and it will be observed that there is a sharp break in the curve for Y alloy at a point corresponding to the 1-in. specimens. This is explained by the segregation of the copper and the formation of the rim of porous metal as shown in the photograph of Fig. 8. This condition is pronounced in the $1^1/_2$-in. specimens, and (as noted under another heading) is characteristic of heavy sections cast in all of the Al-Cu-Ni-Mg alloys. It is due to the occurrence of nickel and magnesium together, and lowering the magnesium content alone of Y alloy does not eliminate this porous rim of metal near the surface of all heavy sections.

The hardness results given in Fig. 10 show that the heat-treated experimental alloys are superior to the high-copper alloy, and in addition reveal an interesting phenomenon in the specimens cast from Y alloy. The hardness of the heat-treated specimens increases with increasing thickness and is explained by the manner in which this alloy solidifies. The equilibrium relations of the constituents in this type of alloy are very complex and involve the decomposition of constituents that separate from the partly solid alloy into other constituents at a lower temperature of the still partly solid alloy. Bingham and Haughton ("Constitution of Some Alloys of Aluminum with Copper and Nickel," Journal of the Institute of Metals, 1923, Vol. 29, p. 94) describes a constituent Tau (see Fig. 2) as a ternary compound or solid solution, containing copper, nickel, and aluminum, which is formed by a reaction between the compound $NiAl_3$ (solid) and the remaining liquid at a temperature of approximately 585 deg. cent. This constituent is very hard and has the property of dissolving both the compounds $NiAl_3$ and $CuAl_2$. The rate of solidification, therefore, would be expected to have a bearing on the amount of this constituent formed and on the final hardness of the alloy. It should be borne in mind that in dealing with cast alloys equilbrium conditions are more closely approximated under conditions of very slow cooling. From the practical standpoint this partly explains the variations of physical results that are often obtained on sand castings of Y alloy. The author further is of the opinion as a result of work on the stability of the properties of this alloy that $NiAl_3$, as well as Mg_2Si, plays an important part in the age-hardening of this type of alloy. There is evidence that mag-

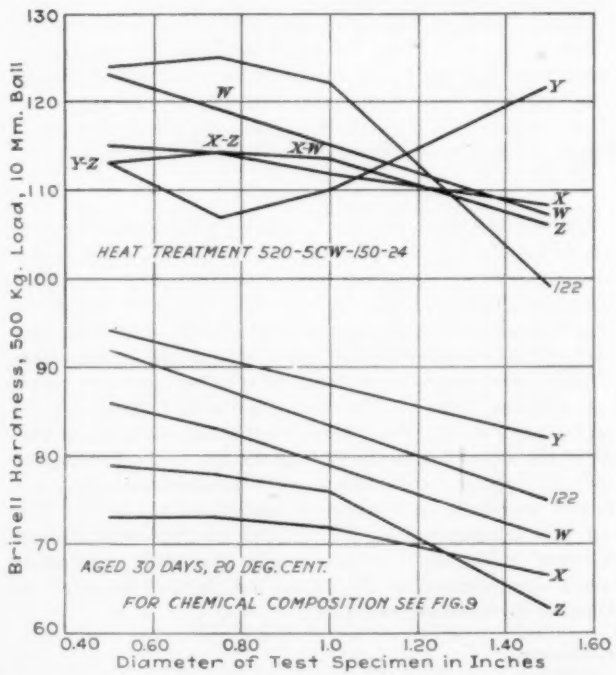

Fig. 10 Brinell Hardness of Aluminum Piston and Cylinder-Head Alloys, Showing the Effect of Section Thickness

nesium affects the solid solubility of the former constituent, and in an alloy of Y composition it is the principal age-hardening element rather than Mg_2Si.

Tension Test and Hardness Tests at High Temperatures

Tension tests were made on the experimental alloys X, Z, and W, and for the purpose of comparison, specimens cast from alloy Y and Lynite 122 were tested under the same conditions. The methods employed were the same as those used in the tests previously published for the two latter alloys by J. B. Johnson ("Materials for Aircraft Parts Subjected to High Temperatures," presented at the Annual Meeting, New York, N. Y., December 5 to 8, 1927, of The American Society of Mechanical Engineers.) These tests are of the "short-time type" as described by R. L. Templin and C. Braglio ("Temperatures Affect Aluminum Alloys," *The Foundry*, January 1, 1929). Templin and Braglio results for Y alloy and Lynite 122 in the "as-cast" condition are in agreement with the results obtained by the Air Corps and show

that Y alloy is slightly superior to Lynite 122 in the temperature range of 200 to 250 deg. cent. Templin and Braglio do not show results for Lynite 122 in the heat-treated condition, but Johnson has shown that the same superiority exists in the quenched and aged material. The results of the present tests shown in Fig. 11 indicate that at 260 deg. cent. and above alloys Y and X have the same tensile strength, but that the latter alloy has the advantage of a higher strength below 260 deg. cent. The strengths of alloys Z and W are, for practical purposes, of the same order.

The curves in Fig. 11 show that increasing amounts of either silicon and copper adversely affect the strength at high temperatures. Comparing alloys X and Z, it may be seen that the addition of less than $^1/_2$ per cent silicon causes a reduction in strength of approximately 7000 lb. per sq. in. at 600 deg. cent., or on a percentage basis a reduction of over 30 per cent. Copper, like silicon, in this type of alloy improves the casting properties and also is beneficial from the standpoint of machinability. Its effect upon the tensile strength at high temperature is less than that of silicon, and for this reason the composition of the Al-Cu-Ni-Fe-Mg alloy that gives the best combination of strength ductility at atmospheric and high temperatures, together with good casting properties, is as follows, the percentages corresponding closely to the composition previously given for alloy X:

Cu	3.4 to 3.8 per cent
Fe	0.75 to 1.75 per cent
Si	0.6 to 0.8 per cent
Mg	0.5 to 0.7 per cent
Ni	0.6 to 0.8 per cent
Al	Remainder

Stability of Properties

"Short-time" tensile and hardness tests at temperatures in the range of from 200 to 320 deg. cent. do not represent the actual strength and hardness of the aluminum alloys that age-harden after quenching. Continued exposure to temperatures in the foregoing range causes a decrease in strength and hardness proportional to the time of exposure within certain limits. In order to obtain the actual properties at these temperatures of an aluminum alloy containing copper or magnesium in the heat-treated condition it would be necessary to soak for long periods before testing. The results of the tensile and hardness tests at high temperatures, shown in Figs. 11 and 12, represent accurately the comparative strength of the alloys, but their actual strength in the stable condition at 260 deg. cent. would be from 15 to 30 per cent lower, depending upon the alloy. The graphs in Fig. 13 show the results of hardness tests upon disks $^1/_2$ in. in thickness and 6 in. in diameter cast against a chill in green sand, heat-treated and aged, and then reheated to 260 deg. cent. and tested for hardness at atmospheric temperature at intervals of time ranging from 1 to 120 hours. After each period of heating at 260 deg. cent., the specimens were quenched in order to eliminate the aging during cooling from the reheating temperature to atmospheric temperature. The tensile and hardness tests given in Table 4 were made on standard cast-to-size specimens heat-treated and aged to maximum strength and hardness and then reheated at 260 deg. cent. in the same manner as the disks. The results of the hardness tests show that Y alloy has a higher stable hardness than the experimental alloys or Lynite 122. The strength of alloy X is practically the same as Y alloy, and both are superior to Lynite 122, while X alloy has the advantage of higher ductility in the stable condition.

In the temperature range of from 320 to 375 deg. cent. the Al-Cu and Al-Cu-Ni-Mg alloys reach a stable condition after short periods of exposure. The high-temperature tests in Figs. 11 and 12 represent quite closely the actual strength of the alloys exposed to these temperatures for long periods of time. Experiments on a 5 per cent copper aluminum alloy showed that quenching and aging for 1 hour at temperatures in the range of from 315 to 375 deg. cent. placed the alloy in a stable condition and that reheating at lower temperatures produced no further change in the physical properties. Under the heading of "Heat Treatment" it has been shown that alloy X has a good combination of strength and ductility when heated to 375 deg. cent. after quenching and that the properties of the alloy in this condition are stable, as the age-hardening of this alloy is governed by the

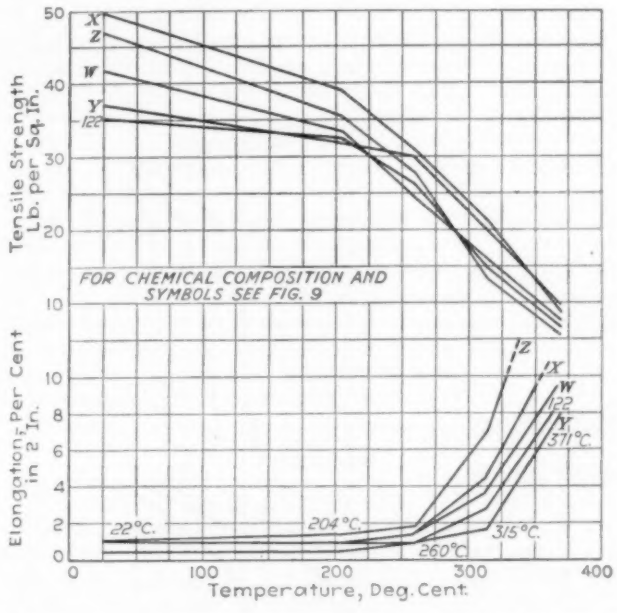

Fig. 11 Tensile Tests of Cylinder Head and Piston Alloys at High Temperatures (Sand Cast and Heat Treated)

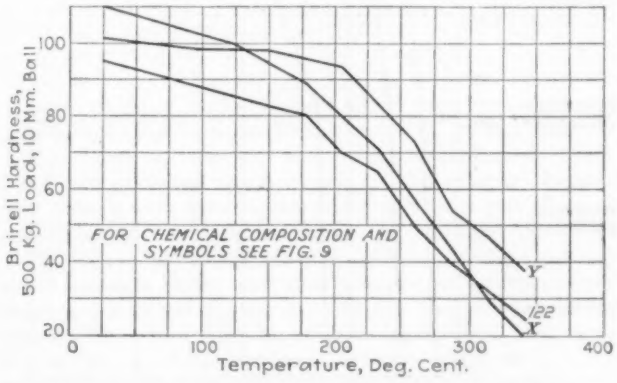

Fig. 12 Brinell Hardness of Piston Alloys at High Temperatures (Sand Cast and Heat Treated)

same principle as for the 5 per cent Cu-Al alloy. As stated elsewhere, the superior ductility of X alloy over the standard alloys, coupled with its property of retaining its tensile strength at high temperature, indicates that X alloy can be substituted for either of the standard alloys in cylinder heads to considerable advantage.

Hardness tests on pistons taken from various types of engines which had been run from 10 to 100 hours have shown that the hardness of the heads is approximately the same as the stable hardness values shown in Fig. 13 and Table 4 for alloys Y and Lynite 122. The skirts and piston-pin bosses of these pistons suffered no reduction in hardness and indicated that the operating

temperature was not high enough to cause softening during the ordinary life of a piston. Although at the writing of this report there are no test results available on pistons cast in X alloy that have been run in an engine, the laboratory tests indicate that this alloy can be used in pistons as well as for cylinder heads, and when compared to Lynite 122 it has approximately the same hardness in the stable condition, with the advantage of higher strength at both atmospheric and high temperatures and a lower specific gravity.

Specific Gravity

The specific gravities of alloys X and Z are of the same order

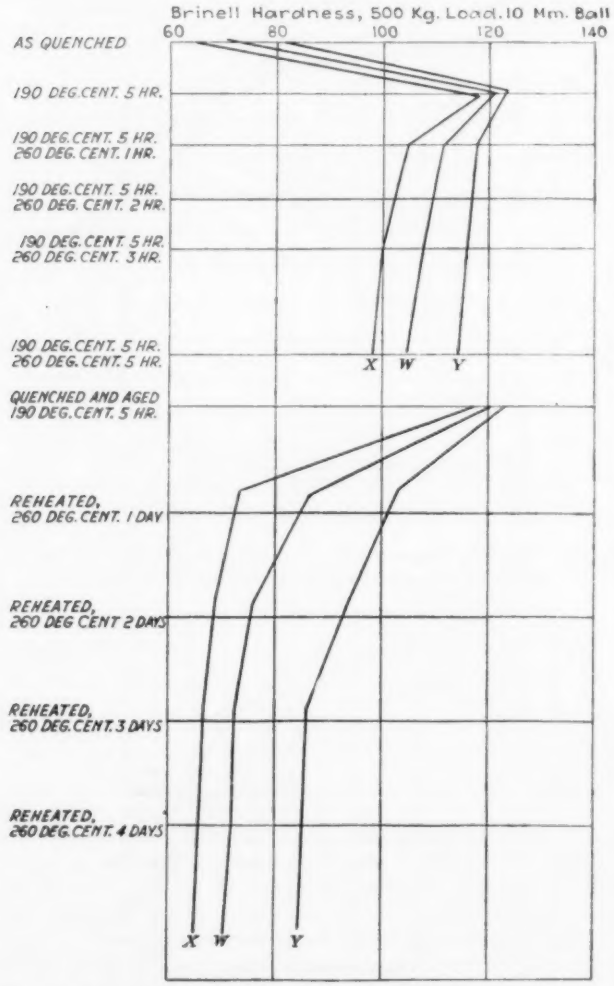

Fig. 13 Brinell Hardness of Piston Alloys at Atmospheric Temperatures (Sand Cast, Heat Treated, and Aged)

as the Y alloy and when compared to Lynite 122 afford a means of an appreciable saving in weight. The following shows a comparison of specific gravities:

Symbol	Specific gravity, grams per cc.	Percentage
122	2.91	100.0
Y	2.73	93.5
W	2.77	95.3
X	2.72	93.6
Z	2.73	93.5

The results listed were obtained on sand-cast specimens cut ¾ in. in diameter from the enlarged ends of standard tensile specimens and weighted in air and in water to the nearest 0.001 gram. The method of casting and pouring temperatures was the same, so that the results may be considered comparable. A saving of 6 per cent in weight can be obtained by the use of X alloy in place of Lynite 122, which amounts to a saving of 8 or 9 lb. in the cylinder heads alone of a conventional 400-hp. air-cooled engine.

Thermal Expansion

Coefficients of expansion measurements on this series of alloys have not been made, but a rough estimate can be made from comparison with similar alloys and from existing data showing the effect of alloying constituents. The coefficient of expansion for pure aluminum at 200 to 300 deg. cent. is 27.5×10^{-6} per deg. cent. (See Circular of the Bureau of Standards No. 346, p. 57.) The addition of copper up to 5 per cent has little effect upon the linear expansion at 300 deg. cent., but additions of silicon to the low-copper aluminum alloy appreciably reduce it.

The average coefficient of linear expansion in the range of from 20 to 300 deg. cent. for alloys containing copper in amounts less than 5 per cent, together with magnesium, silicon, and manganese, ranges from 25.0 to 27.0×10^{-6}. Available data show that alloys with 10 per cent or more of copper have a slightly greater coefficient of expansion than alloys of the low-copper or Y-alloy type.

For design purposes the coefficient of expansion for alloy X should be same as for alloy Y and Lynite 122, approximately 26.0×10^{-6} per degree cent.

Thermal Conductivity

The use of aluminum alloys in pistons and cylinder heads is advantageous from the standpoint of thermal conductivity as well as a means of saving weight. The following values taken from the eleventh report of the Alloy Research Committee, the Institution of Mechanical Engineers, shows the relation between the conductivity of pure aluminum and of cast iron:

Aluminum	0.50 to 0.52 cal. per cm. per sec.
Cast iron	0.09 to 0.11 cal. per cm. per sec.

The thermal conductivity of the 5 to 8 per cent copper-aluminum alloys sand cast and annealed has been recently shown by Griffiths and Schofield ("Conductivity of Aluminum Alloys and Bronzes," Journal of the Institute of Metals, 1928, Vol. 39) to be 82 per cent of that of the pure metal. Additions of copper lower the conductivity still further, and these authors give a value of 73 per cent of the pure metal for a 12 per cent copper aluminum alloy. Likewise, the addition of such elements as nickel, iron, or magnesium lowers the conductivity of the low-copper aluminum alloys. Griffiths and Schofield give a value of 73 per cent of the conductivity of pure aluminum for Y alloy, which corresponds to 0.40 cal. per cm. per sec., which is in accordance with the results previously obtained on this alloy and given in the eleventh report of the Alloy Research Committee.

An aluminum alloy containing 5 per cent copper, 2 per cent iron, and 0.5 per cent magnesium and one containing 9 per cent copper and 2 per cent nickel were found to have the same conductivity as Y alloy; so for practical purposes the thermal conductivity of alloy X should be about the same.

It should be borne in mind, however, that all the published data are for the as-cast or annealed alloys, and the effect of quenching from elevated temperatures such as employed in the heat treatment of the high-strength aluminum alloys would be to reduce the thermal conductivity, and the subsequent annealing of them would tend to restore the conductivity of the alloy to that of the as-cast and annealed condition.

Stability of Dimensions

The commercial casting alloys of aluminum increase permanently in size when in use. This permanent increase in dimensions in termed "growth," and its magnitude varies with the alloy and the temperature to which it is exposed in service. Leslie Aitchison (*Metal Industry*, May 16, 1924) attributed "growth" of pistons to stress set up during the solidification and cooling of the casting and mentions that after machining no growth takes place. He recommends annealing at 400 deg. cent. before the final machining operations as a means of dissipating the stresses. Zay Jeffries ("Journal of the Society of Automotive Engineers," 1920, Vol. 7, p. 295) has stated that all the aluminum-copper alloys suffer a change in volume when heated to 300 deg. cent., no matter how the alloys are cooled in ordinary method of production, but that this volume change can be made permanent at room temperature.

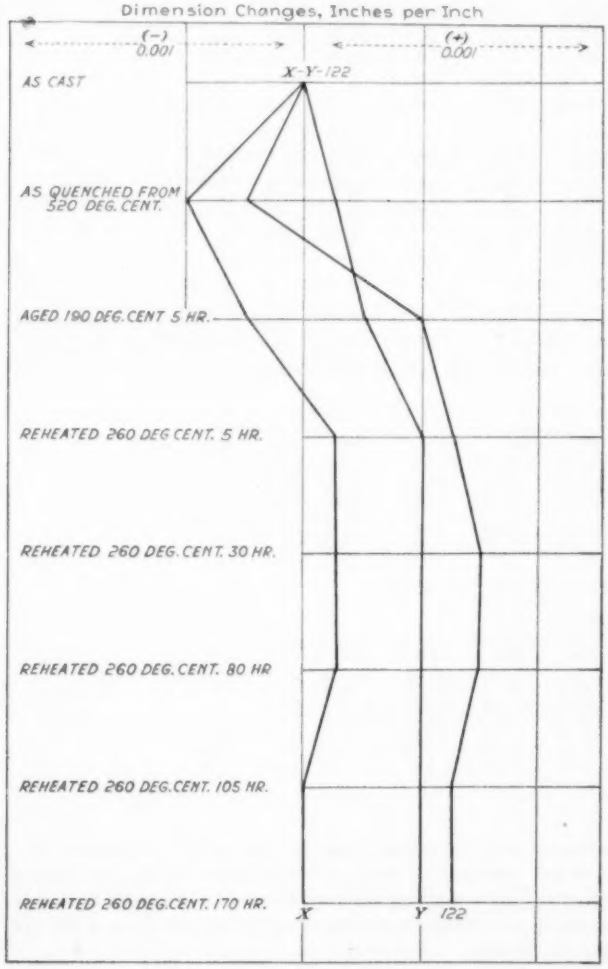

Fig. 14 Graph Showing Stability of Dimensions of Piston Alloys (Sand Cast and Heat Treated)

The laboratories of the Matériel Division have made growth measurements on pistons approximately 6 in. in diameter cast from Lynite 122, quenched and aged for 16 hours at 150 deg. cent., increased 0.007 in. after reheating to 260 deg. cent. for 5 hours. Pistons cast in Y alloy showed little or no growth, and in no instance has it been found to exceed 0.005 in. per inch. The chart in Fig. 14 shows the results of a series of careful measurments on a solid cylinder 6 in. in length and 3 in. in diameter, cast in alloys X, Y, and Lynite 122. It is shown that X alloy and Lynite 122 suffer a slight contraction when quenched from elevated temperatures. Y alloy shows a slight increase in volume which may be attributed to the natural aging that occurs during the period of three hours that the specimens were allowed to stand at atmospheric temperature in order to obtain equilibrium conditions of temperature.

After artificial aging or annealing at 190 deg. cent. for 5 hours, it is shown that all three of these alloys increase approximately 0.002 in. per inch after reheating to 260 deg. cent. for 5 hours. Longer periods at this temperature produced no further change in alloys X and Y, but Lynite 122 showed a slight increase. This is in accordance with the density changes shown in the graphs of Fig. 1. It was further shown that continued exposure to a temperature of 260 deg. cent. caused the alloys first to grow and then to shrink very slightly, which also is in accordance with the findings of the National Physical Laboratory (England). It is apparent that the growth of the aluminum casting alloys is very closely allied with their age-hardening characteristics and is due to the precipitation of the hardening constituents. From the practical standpoint, alloys aged to maximum hardness suffer little or no change in dimensions upon reheating, and short exposures to the upper limits of the age-hardening temperature range (150 to 260 deg. cent.) are more effective in producing stability of dimensions than are longer periods at lower temperatures.

Discussion

E. H. Dix, Jr.[5] In discussing this paper it will be necessary to confine remarks primarily to a comparison of alloys of the high-copper (122) type with those of the Y-alloy type of the older composition range, because the alloys discussed by the author are so new that the writer has not had sufficient experience with them to justify comments.

The Y alloy was introduced in this country as a material for pistons and cylinder heads largely because it seemed to retain its strength and hardness at elevated temperatures better than most other aluminum alloys. This characteristic is also possessed by alloys of the 122 type, but the fact has not received as much publicity, and as a result the Y alloy has come to be considered as the outstanding aluminum alloy for high temperature applications. Elevated temperature tests made at Wright Field[6] and published results by Mr. R. L. Templin[7] indicate that there is very little to choose between these two alloys as regards strength at temperatures of aircraft-engine operation.

The tests so far referred to are of the short-time type in which the specimen is pulled soon after temperature conditions have reached a practical equilibrium. In the case of heat-treated alloys subjected to high-temperature applications, such tests do not tell the complete story. A truer picture may be obtained by heating the alloys to the highest temperature to which they will be subjected during processing and engine operation, for a long period of time prior to making the high-temperature tests. Such results comparing the 122 and Y alloys have been obtained by Mr. D. A. Paul, working with Mr. Templin at the Aluminum Research Laboratories. Unfortunately the tests were made on sand-cast bars of 122 and forged bars of Y alloy, which of course makes the comparison less favorable for 122 alloy than if the results had been available

on Y alloy in the cast form also. The results given herewith were obtained on bars which had been annealed for 48 hours at 650 deg. fahr. prior to testing. This temperature is probably the maximum which would ever be reached by cylinder heads or pistons in aircraft engines, but a similar effect would be produced by annealing for a much longer time at a somewhat lower temperature. The tensile and yield strengths for 122 alloy at 500 deg. fahr. and above are superior to of Y those alloy.

elements. A theoretic computation for the specific gravity of X alloy gives a value of 2.79, which checks closely with a few actual determinations which we have made on an alloy of this composition.

The author and the Wright Field organization are to be congratulated for the full realization, which is evident from a reading of the paper, of the importance of the casting qualities of a new alloy to be used for cylinder heads. Before a cylinder head may be used it must be cast, and not matter how desirable an alloy may be from other viewpoints, if it cannot be handled in the foundry, it is useless. The author has carried his investigation through the preliminary laboratory stage. The next

(c) Stabilized 3 hr. at 600 deg. fahr.

It is the writer's opinion that the requirements for a satisfactory piston alloy are somewhat different from those of a cylinder. Growth, expansivity, and extreme lightness are not quite so important in cylinders as in pistons. Casting characteristics and mechanical property requirements are also sufficiently different for the two applications, so that it is possible to obtain an alloy suitable for pistons which may not be entirely satisfactory for cylinder heads and vice versa. In this connection, a new piston alloy which is just emerging from the development stage and is being used by some of the automobile, truck, and aircraft companies should be mentioned. This alloy has 15 per cent less expansivity than the alloy of the 122 type, and because of other characteristics may be fitted with 20 per cent less clearance.

The specific gravity as given by the author for X metal appears to be rather low for the preferred composition. The specific gravity of pure aluminum is 2.70, so that it is difficult to understand how an alloy containing as much as 3.6 per cent copper, 1.25 per cent iron, and 0.7 per cent nickel could have a specific gravity as low as 2.72 when there is only 0.7 per cent silicon and 0.6 per cent magnesium to compensate for the heavier added necessary step of course must be an actual production run. It is not sufficient to make a few cylinder heads, but rather, before the alloy may be accurately evaluated, it must be run in production in comparison with other known alloys on a difficult type of casting.

Again, it is not possible at this time to compare the casting qualities of X alloy with 122 alloy, but it may be pertinent to compare 122 with Y alloy. Within recent years the foundries in this country have had opportunity to obtain considerable experience in casting Y alloy in comparison with 122, and the author believes that all foundrymen who have had this experience feel that in the case of a difficult casting they prefer to use 122 alloy. It is true that a number of foundries have had excellent success with the Y alloy, but this is in spite of its casting characteristics rather than because of them. One of the chief difficulties in handling the Y-alloy type in the foundry is its tendency toward dross formation. Because of this it must be handled with special care, and even with the most careful control, there is always a greater percentage of leaky castings caused by dross inclusions.

It seems almost unnecessary to remark that the search for

a better alloy for cylinder heads and pistons which has resulted in this paper is a sign of the times. There is no organization in the country so well able to see the future needs of the aircraft engine industry as the Matériel Division at Wright Field. It is to be hoped that the excellent work of the author and others of the organization will continue toward this end.

G. D. WELTY.[8] High-silicon alloy (20 per cent silicon, balance aluminum) has been used rather extensively abroad as a piston material for a number of years. It is about 10 per cent lighter than the standard 10 per cent copper alloy used for pistons in this country and about 5 per cent lighter than Y alloy. In addition to this its coefficient of thermal expansion is some 18 or 20 per cent less than either of the two alloys mentioned. It is, however, exceedingly difficult to machine and is too soft to meet requirements in this country satisfactorily.

The 132 alloy referred to in Mr. Dix's discussion has been developed to overcome these difficulties. It contains about 14 per cent silicon, with smaller amounts of nickel, copper, and magnesium. Its specific gravity is 2.71, only slightly greater than that of pure aluminum, and its expansivity about 80 per cent that of 10 per cent copper alloy or of Y alloy. In addition to this, 132 alloy machines far more easily than the 20 per cent silicon alloy and may be heat-treated so as to produce hardness from 100 to 130 Brinell. It is particularly desirable for aircraft pistons, both on account of its low expansion and its low gravity, which not only reduces reciprocating weight and inertia forces, but which permits an additional weight saving on account of the smaller counterbalances required. The material is being used for pistons by a number of leading aircraft, bus, and automobile-engine manufacturers.

AUTHOR'S CLOSURE

The author wishes to express his interest in the contributions submitted by Messrs. Welty and Dix and to thank them for the discussions on alloys for pistons and air-cooled cylinder heads for aircraft engines. In reference to Mr. Welty's remarks, it is desired to point out that the application of high-silicon alloys for this purpose must be confined to designs that can be adapted to permanent mold castings; as in sand castings primary silicon separates during the freezing of the alloys in comparatively large crystals and increases the difficulty of machining. The data submitted by Mr. Dix on the physical properties of Lynite 122 at elevated temperature are of great interest, and it is hoped that he will be able to publish more data of this nature. In regard to the theoretic computation for the specific gravity of X alloy, it is well known that the methods of casting, pouring temperatures, size of castings, etc. have a decided effect on the density of aluminum base alloys. The values quoted for the specific gravity in the subject paper should be considered as comparative only. In connection with the use of Y alloy in aircraft-engine pistons, the Air Corps has found from experience that its principal advantage over Lynite 122 lies in its property of retaining its hardness to much greater degree under actual operating conditions. Y-alloy pistons are also appreciably lighter than pistons cast in Lynite 122.

on Y alloy in the cast form also. The results given herewith were obtained on bars which had been annealed for 48 hours at 650 deg. fahr. prior to testing. This temperature is probably the maximum which would ever be reached by cylinder heads or pistons in aircraft engines, but a similar effect would be produced by annealing for a much longer time at a somewhat lower temperature. The tensile and yield strengths for 122 alloy at 500 deg. fahr. and above are superior to of Y those alloy.

A theoretic computation for the specific gravity of X alloy gives a value of 2.79, which checks closely with a few actual determinations which we have made on an alloy of this composition.

The author and the Wright Field organization are to be congratulated for the full realization, which is evident from a reading of the paper, of the importance of the casting qualities of a new alloy to be used for cylinder heads. Before a cylinder head may be used it must be cast, and not matter how desirable an alloy may be from other viewpoints, if it cannot be handled in the foundry, it is useless. The author has carried his investigation through the preliminary laboratory stage. The next necessary step of course must be an actual production run. It is not sufficient to make a few cylinder heads, but rather, before the alloy may be accurately evaluated, it must be run in production in comparison with other known alloys on a difficult type of casting.

Again, it is not possible at this time to compare the casting qualities of X alloy with 122 alloy, but it may be pertinent to compare 122 with Y alloy. Within recent years the foundries in this country have had opportunity to obtain considerable experience in casting Y alloy in comparison with 122, and the author believes that all foundrymen who have had this experience feel that in the case of a difficult casting they prefer to use 122 alloy. It is true that a number of foundries have had excellent success with the Y alloy, but this is in spite of its casting characteristics rather than because of them. AER-52-32

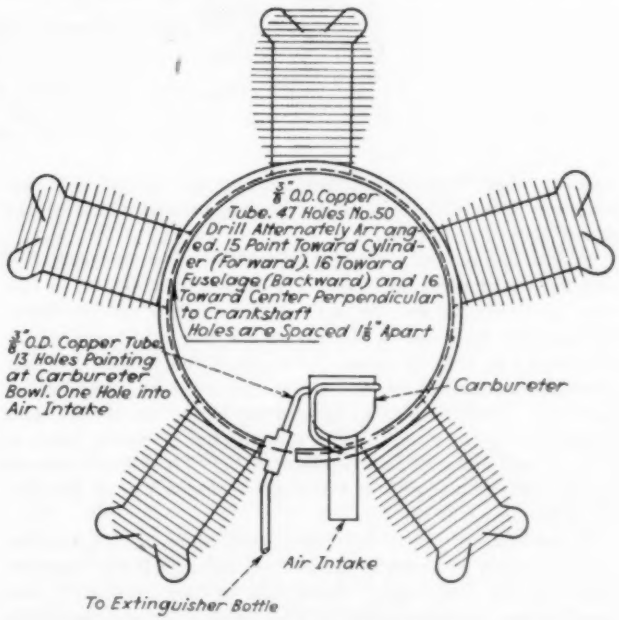
Fire-Prevention Problems

By C. G. McCORD,[1] PHILADELPHIA, PA.

This paper gives a few general principles and points out the trend of investigations that have been made along the lines of fire prevention and the design of fire extinguishers. Prevention in the case of aircraft is a relative term as there are no thoroughly satisfactory fire extinguishers, although the improvements are encouraging as more thought is being given to the subject.

While much work is in progress toward the development of aircraft fire-extinguishing systems in Government departments and by the manufacturers of that type of equipment, and although the need is manifest, there is at present no basis for a hard and fast regulation regarding the nature of equipment to be prescribed for installation in military or commercial airplanes.



MOST FIRES in conventional-type airplanes occur in the engine compartment, and main reliance is placed on apparatus designed to reach that space, portable equipment usually being provided to take care of the other parts of the plane. Protection of multiengined planes, where the engines are mounted in the open or in nacelles, is somewhat more complicated, but the general rules are the same as for engines mounted in the nose of the fuselage. The cause and the cure for fires in aircraft must receive consideration together, and in an effort to cover the ground some grouping or classification of fires is in order.

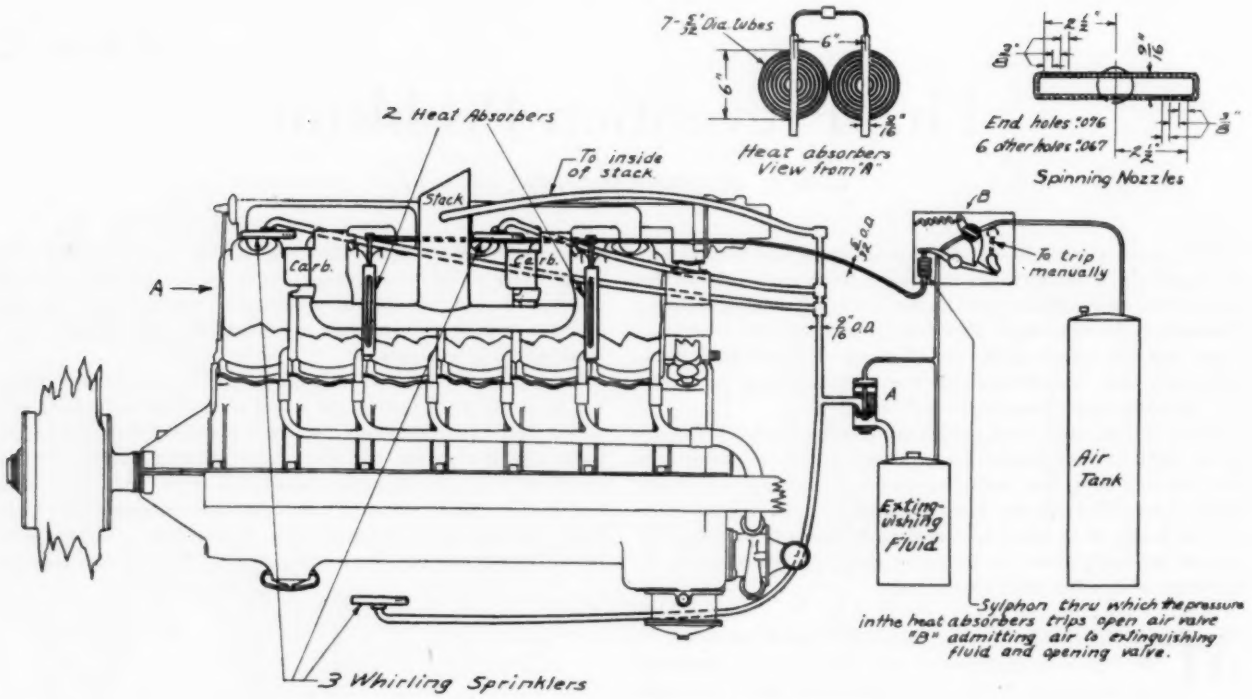
Fires in the air are mainly attributable to broken or leaky fuel systems or oil systems aided by hot engine surfaces including exhaust stacks, electrical discharges, friction or metal impact sparks, open flame from so-called backfires (probably very little from normal exhaust flames, which are usually shrouded in nitrogen, carbon dioxide, and water vapor), or by hot carbon or metal particles from exhaust stacks. In connection with this last-named cause it has been reported that black iron or steel stacks, worked on by erosion and products of combustion of doped fuel containing lead compounds and bromine, will throw off hot scale particles that are a menace where gasoline fumes or even dry doped fabric may be within range.

Some of the causes named are instantaneous and do not continue; others persist and may tend to reignite the fire after the first flames are extinguished. Lightning has been blamed for the destruction of some planes in flight, but as a direct cause of fire it may be disregarded, although bonding of metal parts to avoid possible brush discharges of collected atmospheric electricity has become a standard practice and is probably needed.

Rupture of fuel tanks is a possible cause of fires in the air as well as on the ground. A rupture has occurred in a Navy plane when a partly filled tank was subjected to the hammer of the fuel when the plane was pulled sharply out of a steep dive. In addition to military combat planes many commercial types are now in use, capable of acrobatics imposing high stresses, and the principle being demonstrated, due precautions must be observed in all types.

One cause of reignition of airplane fires on the ground which has been observed during the naval aircraft factory tests and which should be the cause of concern is gasoline released by breaking of fuel lines or tanks and which runs out on the ground. Flames traveling down the dripping stream will often set a puddle of the gasoline afire. Even if the flames are extinguished in the plane the fire will retrace its path up the drip, probably after the extinguishers have been exhausted. There is no means for determining the attitude of the plane after landing, which adds to the difficulty of combating this phase of the danger.

FIRE-EXTINGUISHER MANIFOLD INSTALLATION FOR RADIAL ENGINE



To prevent carburetor back fires causing trouble the air intakes may be screened, with a reduction in brake horsepower as high as 4 per cent, using the Davy safety lamp principle and triple screens properly spaced. However, screened or not, the air intakes should be led well outside the engine cowling. This is not always simple in a seaplane where spray may strike the air horn, but no deviation from the rule should be permitted where it is possible to extend the intakes or air horns and drain the bends and pockets.

Magnetos are usually flame proof to the extent that they could be run safely in an atmosphere of explosive gasoline-air mixture. Broken high-tension lines should be guarded by attention to supporting and location as well as to strength of the materials. When the fire occurs outside the engine compart-

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

INSTALLATION OF AUTOMATIC SAFETY FIRE DEVICE

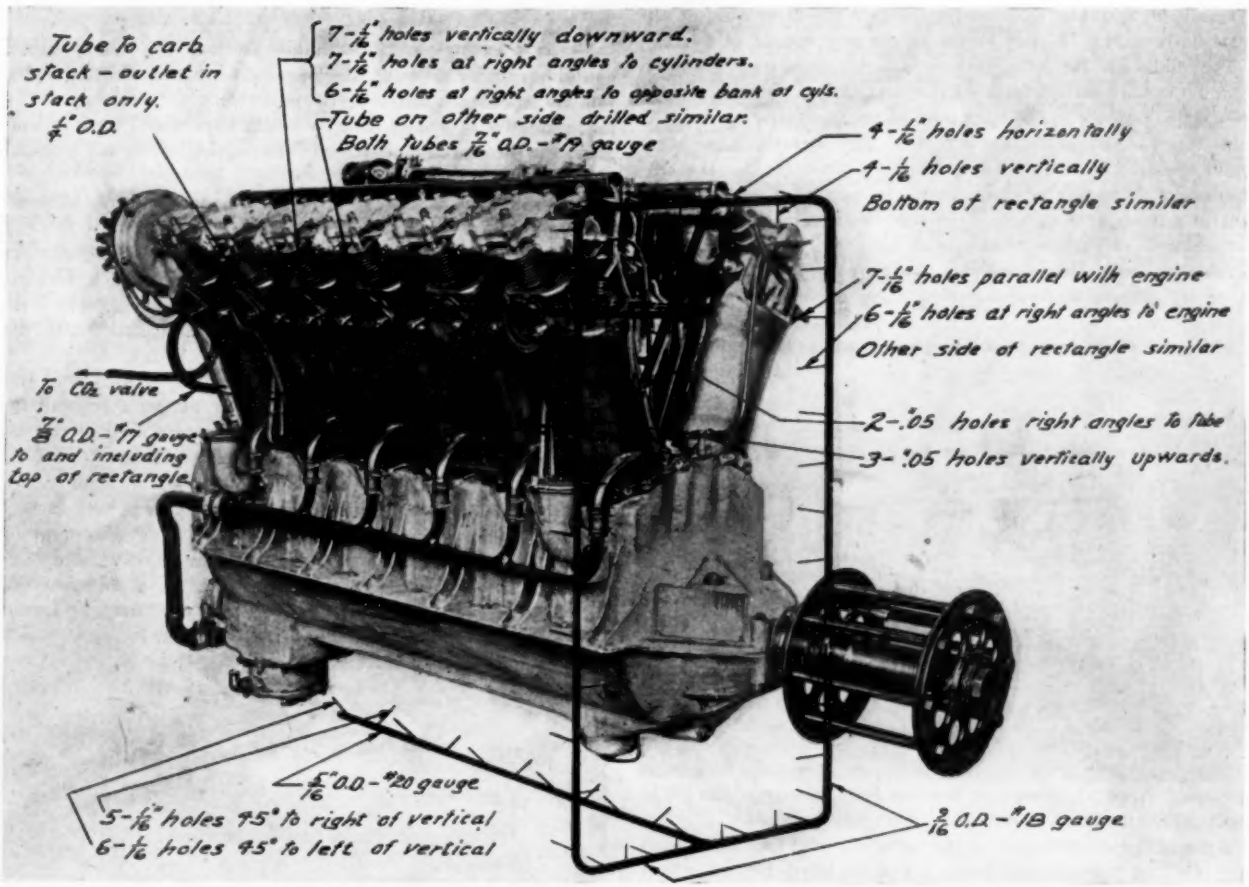
ment or other closed compartment it appears impossible to provide any form of built-in extinguisher apparatus which will be effective.

On the ground consideration should be given to crash fires and hangar or servicing fires. The causes to which crash fires may be attributed are the same as those in the air just listed. Hangar fires and fires in aircraft on the line, when engines are not being run, may be caused by smoking, tool sparks, oily rags or waste accumulations, and are spread by paint, dope, oil, or gasoline. These fires differ from those in the air in that there is less chance for strong drafts, and the use of water, foam, or of powdered material may be resorted to. These fires are more apt to destroy property and less apt to cause loss of life than those occurring in the air.

Fireproofing of fabric by doping with ammonium phosphate or boric acid is no longer in general use, although it was a requirement several years ago. Ventilation of the interior of wing panels where explosive gases may be formed during wing doping is, however, common practice.

Short stacks on the exhaust of an engine, especially if finned for heat dissipation, are better, from the fire-hazard standpoint, than collector rings or long exhaust stacks of the manifold type. A temperature study of a Liberty engine showing that while the manifold type of stack may run as high as 1380 deg. fahr. at its end (full throttle, lean mixture, retarded spark), the short finned stacks on the same engine ran below 475 deg. fahr. The comfort of personnel in the matter of exhaust gases and noise, however, is a factor in the design, and in most modern types of plane the exhaust is collected and led away from the engine, an advantage for night flying, and an aid to comfort, although to some extent a menace in a crash.

Gaseous fuels in lighter-than-air craft seem to be dangerous in proportion to their density as a fire risk. Those heavier than air tend to drop to the lower part of the ship, from a leak, whereas those lighter than air rise to parts where there is no danger. As between liquid and gaseous fuels from the fire-hazard standpoint, the chance of quickly releasing the storage tanks from the ship in emergency would recommend the former.



Placing pipes in jackets containing fire-extinguishing fluid and the introduction of carbon tetrachloride into the gasoline are suggested methods of protection of those vital parts. The former method is open to criticism on account of the danger of the outer jacket being quite as liable to failure as the fuel lines, and probably being drained before the fire occurs. Also, such a system would be heavy. The latter method is of little practical value except in local spots, as it was determined by test in an open container that dilution amounting to 71.5 per cent of CCl_4 in gasoline was required to make a non-inflammable mixture.

In pressure-type gasoline systems it has been suggested that CO_2 pressure be used instead of air pressure. This would add an item of weight, and seems hardly worth the cost as the protection afforded is slight. Whether forcing the gas into the gasoline under pressure as in charging sparkling beverages would have an effect on the detonating characteristics of the fuel is another matter and aside from the discussion.

A general rule in the air is to cut off the fuel supply first, close the shutters and sideslip the plane to keep the flames away from wings and cockpit, and if possible to blow out the fire, meanwhile operating the extinguisher, and then before landing or crashing to cut the ignition. This gives reasonable assurance of the lines and carburetor bowl being empty or at least partly so.

The running engine may serve to blow out the fire or to impact the fire-extinguishing medium against the fire, which chances offset the argument that it fans the fire. Unless wood or some similar substance which burns without definitely volatilizing is present, the strong draft is a cure for rather than an aid to combustion.

Imperfect electrical connections and worn insulation are sources of sparks. The preventive, of course, is rigid inspection and proper closing of connection or fuse boxes. Exposed surfaces on water-cooled engines except exhaust stacks are normally

FIRE-EXTINGUISHER MANIFOLD ON WATER-COOLED ENGINE

below 212 deg. fahr. Cylinder barrels of air-cooled engines may run from 300 deg. to 500 deg. fahr., but these are exposed surfaces and unlikely to be a source of danger as installed.

Lubricating or crude oils are probably more dangerous in contact with a hot surface than gasoline, which evaporates before combustion occurs when in contact with surfaces. Latent heat of vaporization also enters into this. For heated surfaces 720 deg. fahr. seems a safe temperature, the ignition temperature of lubricating oil and doped fabric being around 750 deg. fahr. Although with many liquid fuels an inflammable gas is given off when there is contact with a hot surface at even lower temperatures, this may dissipate too rapidly to ignite.

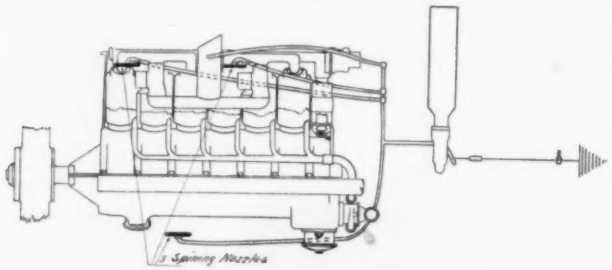
A tight unpainted firewall is necessary to separate the engine compartment from the rest of the plane when engines are mounted in the fuselage. Use of wood, fabric, or paint in an engine compartment adds to fire risk, as all materials of this nature tend to be fanned to a glow by a strong air blast, whereas volatile materials under the same condition have the fire blown out and its spread limited by such a blast.

Battery ignition is probably more hazardous than magneto ignition as the magneto stops when the engine does. The leads are shorter and less liable to breakage from the same cause that would rupture a fuel line, and the magneto itself is easily flameproofed. Static sparks are generated when gasoline is being strained through chamois skin, a very common practice, unless the metal parts such as buckets, tanks, and hose nozzles are grounded. Fuel storage tanks can be protected from fire best by keeping the tanks always full, floating the fuel over water, and having due regard to small leaks in the tanks and connections. This system is employed on seaplane tenders and aircraft carriers in the Navy.

EXTINGUISHING MEDIUMS

Mediums for fire extinguishing may be divided into (*a*) those in a liquid state at ordinary temperatures but forming gases or vapors when heated, (*b*) those which at ordinary temperatures are in a gaseous state, (*c*) solids in a powder form which produce gases when heated, and (*d*) foam.

As applied to aircraft fires in which gasoline or oil may be expected to be liberated, the principle of use of the various classes of extinguishing mediums is the same. Oxygen is excluded from the burning surfaces by the formation of a surrounding blanket or cloud of gas. The change in state or expansion involving a matter of latent heat cools the surrounding surfaces and the fire is extinguished. The problem so far is simple, but the danger of recurrence of the fire is not eliminated. If there is fabric or wood present in the region of the fire, there is danger of recurrence from incandescent sparks remaining in charred material after the flames are out. Wetting the materials is desirable.



WATER

The cheapest and easiest to handle of the liquid mediums, of course, is water. Due to the formation of steam it is useful when applied to a hot fire, but comparatively useless where the fire is less intense. Its use is desirable where there is no gasoline or oil in the fire, a condition seldom found, but it serves to spread gasoline or oil when present. The application of water

is mainly in sprinkler systems for hangars where wetting of all parts surrounding the fire serves to prevent spread of flames.

The materials for extinguishing aircraft fires now in most common use are carbon tetrachloride and carbon dioxide. Both are easy to procure in the open market and are fairly cheap. A substitute for carbon dioxide is methyl bromide, which has been found effective and while not so readily obtainable has the advantage of using lighter equipment. In general it may be said that in aircraft at the present time the choice is limited to carbon tetrachloride or carbon dioxide, and neither of these is entirely satisfactory from all points of view, nor have the experiments been an entire success wherein a combination of the two mediums is employed. The solution is not in sight at present.

The gases which seem most suitable for use as fire extinguishers are constituents of engine exhaust gases. It seems logical to

Water-Cooled Engine Manifold

provide some apparatus for compressing these gases in the plane and storing them as commercial gases are stored for the same purpose. No work along this line has been attempted, and it is mentioned merely as a possible future development.

A few of the shortcomings of the materials tried may be pointed out: Carbon tetrachloride forms a gas, on being heated, which smothers life as well as fire, if highly concentrated. It is reputed to cause an exciting effect on persons subjected to its atmosphere for breathing, and to make the person so affected uncertain in judgment at a time when quick action and use of all faculties may be most needed. Phosgene is also a constituent of this gas, and the Bureau of Mines states that a concentration as low as 25 parts in a million, on 30 to 60 min. exposure, may be fatal. The average phosgene from eight fires on record was 34 parts in a million, only two of the eight fires showing less than 25 parts.

Pure carbon-tetrachloride vapor is lethal in concentrations as low as 2.4 to 4 per cent, and methyl bromide is dangerous within the same range with 30 to 60 min. exposure, and its rapid vaporization has a bad effect if applied to the bare skin, probably due to a combination of drying and latent heat. The products of decomposition under heat of methyl bromide are little known.

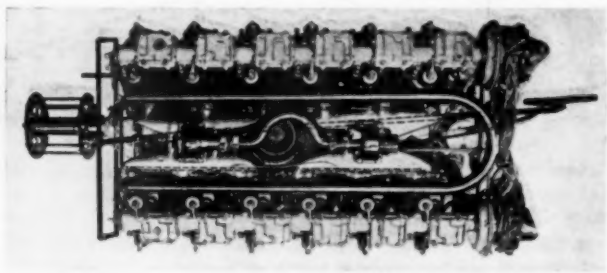
Carbon dioxide in higher concentration shuts off oxygen from the lungs and its effects are too well recognized to merit discussion.

Foam

A foam composed of carbon-dioxide bubbles covering a liquid surface has the advantage of blanketing the surface very well, spreading rapidly, and in still air it will remain on the surface until danger of reignition is past. The bubbles are usually formed in licorice or some similar substance. In a slipstream or strong air blast, foam is of no use as it is blown away as fast as produced, and is not to be considered as acceptable for aircraft use except in hangars.

Foam appears to have the advantage of holding and slowly releasing the carbon dioxide with which it is charged, and for that reason is comparatively safe in a poorly ventilated space.

Methods of Operation



Gaseous extinguishing mediums are held in heavy-walled containers under pressure, and released to the distributing manifold by opening a valve or by puncturing a metal cap. The gas is rapidly expended, and no means is provided for a second charge, when the first charge has been expended, in any apparatus so far submitted.

Carbon dioxide being liquid under storage conditions of pressure must have the outlet of the container at the bottom or it must be provided with a siphon tube extending to the container bottom to secure the best results. The weight of a carbon-dioxide container to hold a 5-lb. charge is about 10 to 11.7 lb. empty. They are made of seamless steel and conform to the I.C.C. regulations for shipping containers.

Liquid mediums are contained within thin-walled shells and ejected by pumps, air or gas pressure, or by pressure built up by explosion of a powder charge. The pressure used in various types of extinguishing apparatus varies considerably.

The volume of carbon tetrachloride in the container varies from one quart to one gallon for each compartment served, and depends on the volume of the compartment. The amount of carbon dioxide varies from 3 to 20 lb. per compartment.

Wide spraying of the extinguishing medium is an essential, and in order to insure this the gas or liquid used must be forced under pressure through manifolds or spray pipes to all parts of the plane in which fire may be expected to break out. Rose nozzles and rotating sprinklers have been tried with a measure of success.

Installation of Manifold on Water-Cooled Engine

Placing of CCl_4 bombs in easily broken glass containers which, shattering on impact, drench the engine compartment is of undoubted value in preventing crash fires, but their fragility makes them hard to handle. One type makes use of a carbon-dioxide cartridge with a cutter which releases the pressure into the fluid container. Another interesting development of foreign origin consists of two pressure systems, being automatic in action.

The starter system made use of a honeycomb container placed in the vee of an engine, which when heated evaporated a contained liquid, creating a vapor pressure which operated through a siphon and bell crank to release compressed air or carbon dioxide from a container communicating with a tank holding the extinguishing fluid, forcing it out to the fire through rotating nozzles. The same pressure served also to shut off the fuel supply, close the shutters, ground the magnetos, and close the throttle. The total dry weight of the system was below 25 lb. Leakage in the pressure system and possibility of premature operation appear to be the drawbacks to this well-thought-out scheme.

Manifolds

Discharge lines must be as short and as free from bends as possible. The container and actuating apparatus are not large

and may be located at any convenient point, provided the release operating gear is within reach of the operator and is distinctively marked.

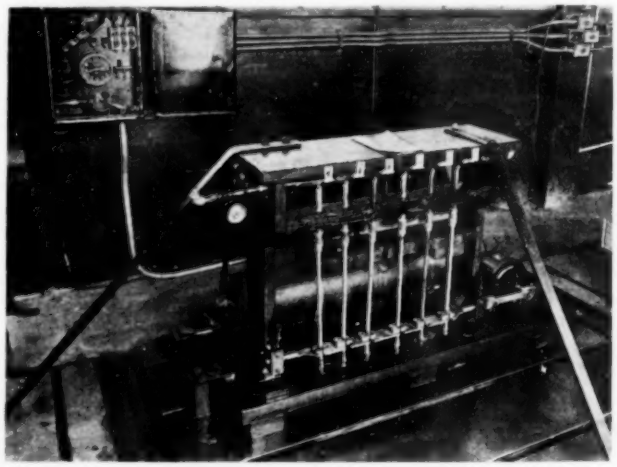
As to material for the manifolds in the immediate vicinity of the fire, duralumin or similar alloys do not stand heat as copper or ferrous alloys will. The piping, in case the apparatus is not operated immediately upon starting the fire, will burn under the blow-torch effect of the fire in the strong air stream. Bronze or copper, which are easily formed, are recommended for this part of the equipment.

The remainder of the piping may be of light material, duralumin tubing having been found reliable in thin-wall form. The minimum allowable inside diameter of tubing is $^3/_8$ in. for carbon tetrachloride or CO_2. Annealed copper, aluminum, or duralumin tubing designed to bursting at 4000 lb. is required for carbon dioxide.

The location and size of outlet holes vary for each type of installation. For an open radial-engine installation, where carbon tetrachloride is used, it is usually sufficient to pipe the manifolding around the carburetor, and some form of enclosure is built to surround the installation and hold in the smothering gases. In general this is an easier matter to handle than where a vee or in-line engine is mounted in a closed cowling, as in the

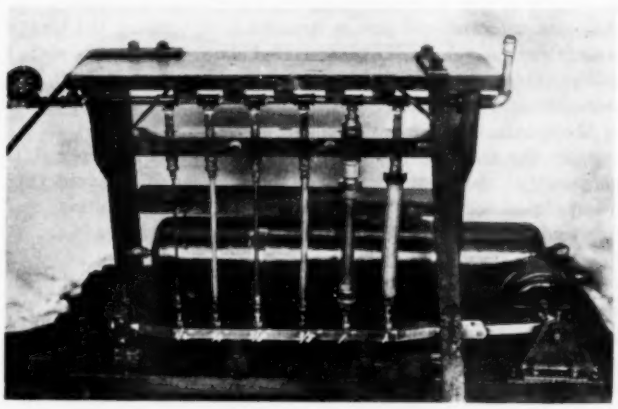
Fire-Extinguisher Test Rig Showing Carbon-Dioxide Snow Extinguishing Fire in an Uncowled Air-Cooled Engine

latter case not only must the distributing manifold be led around the engine and interior of the compartment with a larger number of outlets, but the ventilation of the compartment must be arranged so as to give enough air flow to carry off oil and gasoline fumes without sweeping away the extinguishing gas too rapidly.



The direction of the outlet of the jets, when using a gas, is important, even to include jets directed against the fire wall behind the engine. The holes must be at least $^1/_{16}$ in. in diameter.

Prevention of the main cause of fires may be insured by selection of proper materials, design and shop practice regarding fuel and oil tanks and plumbing, with due regard to inspection at intervals to insure against loosening of joints by the ever-present vibrations, partial breaks in piping and tanks, and imperfect closing of carburetor-float joints or engine parting faces which would cause leakage of fuel or lubricating oil in flight, especially when the plane is to be placed in unusual attitudes.

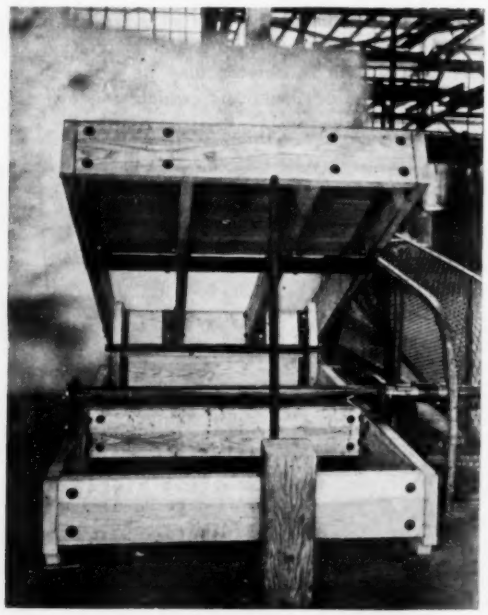


The importance of strength of fuel lines, tanks, and connections cannot be too strongly stressed, and material to be used must be capable of standing up under both vibration and shock tests. Here, as in some other regards to be mentioned later, the designer must allow safety to come before considerations of weight.

Strength, in this regard involves the factor of corrosion and protection against it, also the element of design for proper support of fuel lines to avoid a whip which may cause loosening of joints or embrittlement of the metal. Copper tubing requires torch annealing at the time of general overhaul of a plane to take care of this embrittlement.

The effect of broken fuel lines is twofold: The flow of gasoline to the carburetor is reduced, and the fuel is exposed and usually fed under pressure to the potential source of ignition. The reduced fuel flow to the carburetor may be sufficient to cause lean-mixture popping or backfiring, which under certain conditions is an ignition source.

Vibration Tester for Solid Fuel Lines Showing Automatic Shut-Off Gear



Vibration Tester as Used on Flexible Fuel Lines

Choice of material for fuel lines for Navy aircraft is determined by tests. The threading and belling qualities of solid tubing material are obtained by shop tests, and the tensile strength and elongation are determined in the usual way; then specimens of the tubing are placed in a vibrator rigidly secured at the upper end, with the lower ends attached to a solid bar which is shuttled back and forth by a motor-driven eccentric. The tubing is filled with gasoline under pressure, and the apparatus is designed to stop operation when a rupture occurs anywhere in the pressure system.

This method of tests provides for a severe reversal of stresses of a vibratory nature, and introduces compression and tension. The tubing and attached fittings are, by means of this vibrating jig, subjected to a punishment probably exceeding the maxi-

mum stresses encountered in aircraft, but which forms a basis for comparison between different types of tubing and fittings.

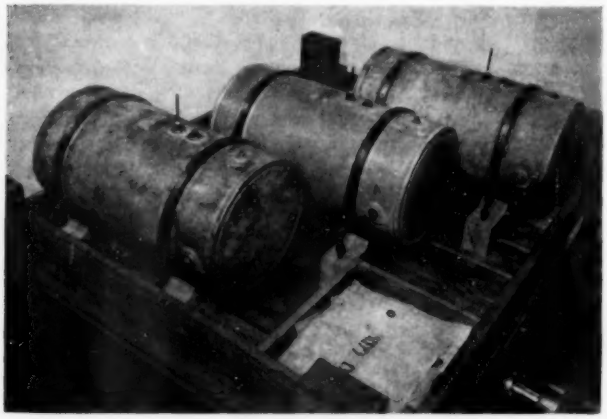
Recently nickel, copper after various treatments, aluminum, and duralumin samples have been subjected to comparative tests to determine their relative value for fuel lines, and in addition a thorough investigation of the properties of several brands of flexible tubing is being conducted for the same purpose. In this case an additional test is imposed to determine the tensile strength of the tubing when assembled, as the fittings are seated to the tubing ends. Loads in tension are applied in 50-lb. increments at 5-min. intervals to take up any cold flow of solder in the joints.

Vibration Tank Tester Showing Construction

After the material for the fuel lines has been selected it is necessary to design the layout of the lines so as to avoid long unsupported sections which tend to whip under vibration, and to avoid nips or possibility of wearing where bulkheads are to be passed.

On complete overhaul of a plane it is recognized as good practice to anneal the fuel lines, if of copper, usually by torch. It is questionable whether duralumin tubing should be replaced or similarly annealed. The condition of bends and belled joints is the index in this case.

Tanks



Fuel tanks are also subjected to vibration testing by securing them to a heavy table under mounting conditions similar to those encountered in a plane, the table being vibrated at a high rate of speed with the tanks partly filled with water. The means for vibrating the table are of considerable variety, the simplest way of securing an uncushioned shock being to rotate a large hex bar of steel upon which the table rests. Wear of the bar is the main trouble with this method. The punishment is very severe in this case, as in the tubing tests, and 25 hours appears to be enough to settle the question of suitability.

A shock test by allowing a partly filled tank, swinging on a long line from overhead suspension, to strike a cushioned wall seems desirable for fuel tanks designed for combat or stunting planes. A typical test of a fire-extinguishing system is conducted as follows:

A fire is lighted by torch in the gasoline around a small radial engine with flooded carburetor, and a fuel-supply line sawed partly through at two points near the carburetor, mounted in the slipstream of a pusher propeller driven by an engine placed in front of the test rig.

Gasoline is fed to the fuel system at the rate of 50 to 60 gal. per hr. After the fire has burned for a period of not over 20 sec. the fire extinguisher is operated, the variables in the test being slipstream velocity, amount of extinguisher charge, internal diameter, and length of tubing in the manifold. Installing or removing engine cowling is an additional variable.

Time for the fluid to reach the discharge jets and time to extinguish the flames are recorded if possible, as well as time to empty the system. Usually, 20 to 30 trials are attempted with each combination of variables in order to secure fair averages. For further testing a vee-type engine completely cowled, a pan of gasoline in the vee is used, and in some cases oily waste or charred wood is placed in the engine compartment. For a particularly hot fire the addition of naphthalene flakes in the open pan of gasoline will aid.

Vibration Tank Tester With Tanks in Place

The results of these tests are reported to the Navy Department, and where proprietary apparatus or materials are involved the results are not available for general publication except in the form of specifications for the supply of material and the construction of aircraft which are written around the test results.

Discussion

H. E. Newell.[2] Commander McCord's paper is an able statement of the fire-prevention and protection problem introduced by the airplane. It is unquestionably true that when applied to the airplane the shortcomings of the various types of fire-extinguishing devices and systems are emphasized; nevertheless, it is the writer's opinion that there are available today systems and devices that will afford a very substantial degree of protection if properly installed.

Available extinguishing agents are capable of successfully coping with the types of fire likely to be encountered on the airplane. Adequate means of application, however, stands out as a feature of pronounced importance and concerning which greater knowledge is essential.

The solution of the fire hazard attendant to crashes is indeed a difficult problem. By its very nature it tends to prevent mitigation through installation, no matter how rugged, and thus

[2] Engineer, National Board of Fire Underwriters, New York, N. Y.

largely offsets the extinguishing value of the fire-extinguishing agent provided. In the writer's opinion this hazard will be reduced only by the development of safer fuels, coupled with improved features of design and construction.

With reference to reignition of airplane fires originally due to broken fuel lines, this can possibly be mainly overcome by providing extinguishers of larger capacity on the plane. This condition frequently develops at or near hangars, and experience otherwise has also demonstrated the need there for extinguishers of capacity greater than the usual first-aid appliances, such as a 50-lb. or 100-lb. CO_2 extinguisher on wheels or others of type suited to gasoline fires in the form of generators or so-called engines.

In connection with carburetor backfires, screens are very important. It is suggested that there be provided a separate compartment or baffled space for a screened carburetor intake.

The statement concerning fires that occur outside the engine or other closed compartment is very true and should be borne in mind. Extinguishers to protect such spaces could be designed and would be successful, but the probability hazard is low, and, further, the weight of such systems would be prohibitive.

With reference to fires on the ground and in hangars no mention is made of carbon dioxide or carbon tetrachloride as fire-extinguishing agents in Commander McCord's paper. For first-aid purposes both of these extinguishing agents have proved effective, and extinguishing devices using these agents have been examined and listed by Underwriters' Laboratories.

In connection with fires of this type, however, it is of pronounced importance that there be at hand extinguishers of greater capacity than those commonly used for first-aid purposes.

With reference to exhaust stacks, it is the writer's impression that crash tests indicated that long exhaust stacks were the main cause of fire. Commander McCord has shown rather conclusively that, so far as temperature is concerned, short stacks are preferable. In comparing the manifold type of stack and the short-finned stack he states that the temperatures in the latter run below 475 deg. fahr., which is merely another way of saying that the temperatures were below the point of self-ignition. The suggestion has been made that stacks be air-cooled in order to reduce temperatures.

In connection with pressure-type gasoline systems, the writer heartily concurs that substituting CO_2 for air pressure would accomplish nothing regarding fire prevention in connection with the crash hazard and might effect combustion of gasoline due to the CO_2 dissolved, as stated in the paper.

Contrary to common belief, fires are much harder to extinguish and are considerably more voluminous with low or zero slipstream than with high-velocity slipstream. Actual tests have shown that under certain conditions fires could be blown out by wind velocities, where gasoline leak or drip was not excessive and slipstream high. Wood in the engine section should be prohibited, if possible.

Much wider use should be made of carbon dioxide as an extinguishing agent for airplane fires. It is realized that the question of weight is involved, but it is felt that the importance of this factor has been somewhat overstressed. Certainly, so far as commercial aviation is concerned, if the question of weight is the principal factor standing in the way of the development of a more successful type of extinguishing system, it should not be lightly discarded. Mention has also been made of methyl bromide; objection to this agent has been made on the ground that it is toxic. The writer questions whether the toxic properties of this material are such as to rule it out of consideration. Methyl bromide as a fire-extinguishing agent has been used in Europe for many years. So far as its use on airplanes is concerned, the writer is inclined to think that the possibility of the formation of dangerous concentrations would be rather remote, for the reason that the infiltration of air would in all probability be such as to prevent the building up of such dangerous concentrations.

In this general connection the writer is inclined to believe that the possible dangers of carbon tetrachloride, so far as toxicity is concerned, have been considerably overstressed. A recently issued bulletin of the United States Public Health Service contains a table which compares the toxic properties of various refrigerants. This rather definitely indicates that methyl bromide is more dangerous to life than carbon tetrachloride. However, as indicated before, the writer is of the opinion that neither of these extinguishing agents involves dangers worthy of serious consideration in connection with their use on airplanes.

So far as the life hazard of CO_2 is concerned, it should be borne in mind that systems employing this material discharge in a few seconds and that the possibility of producing harmful results in so short a time is remote. The CO_2 systems of the total room-flooding type are in fairly general use throughout the country, and as such systems are installed where persons are continuously at work it is apparent that the possible danger to life involved is not considered material.

In connection with the train of operations mentioned in the paragraph immediately preceding the subject "Manifolds," the complication of the system described in this paragraph suggests the desirability of advising a word of caution with regard to giving encouragement to automatic systems involving a chain of operations, the failure of one of which might interfere with the primary object of the equipment.

In the last paragraph immediately preceding the subject "Tanks," the author states that the annealing of copper fuel lines is a recognized good practice. The writer wonders if any means of control of the extent and uniformity of annealing may be obtained. It appears to him that over-annealing may be dangerous and that failure to properly anneal may not be easily detected. In this connection it may be similarly important to look into the condition of the distributing tubing of carbon-tetrachloride and carbon-dioxide systems. An extinguisher system is of course not subject to the constant test of performing essential service as is a fuel line, and for this reason it might be well to give a word of advice as to the need for inspecting and testing the distributor lines at frequent intervals. If such inspection and test is not made, the writer anticipates that such lines may become cracked on account of embrittlement or worn through at points of contact with surfaces on which the lines are mounted. With systems of such limited capacity as those which must be provided for airplanes a relatively small crack might seriously rob the supply of extinguishing medium to critical points in the system of orifices.

DR. S. A. REED.[3] The writer, in his earlier engineering career, was for some years on work for the Fire Underwriters Boards, and finally for several years was one of three consulting engineers acting for a committee of the National Board of Fire Underwriters to investigate the conflagration hazard in all the large cities of the United States.

It seems to me that Commander McCord has made real progress toward the establishment of correct standards for fire prevention and extinction in aircraft. The writer's acquaintance with the subject has given him a great appreciation of the large share taken by automatic extinguishing means in restricting successfully the aggregate annual fire loss of the country, which it is believed Mr. Newell will substantiate. The writer therefore hopes that Commander McCord will give a favorable presumption to automatic appliances which may come up for his investigation.

[3] Aeronautical Engineer, New York, N. Y.

Commander McCord referred to the caution with which one should accept tradition and cited the effect of a blast of air, which may be favorable if strong and unfavorable if weak. The writer is encouraged to give a similar word of caution with reference to the use of water on an oil fire. It is generally said that water is wrong, and that only some extinguishing fluid or gas, or something like sand, should be used. The writer thinks that this is also a question of degree. If there are pools or ponds or reservoirs of oil or combustible fluid, then water may aggravate the situation. But the writer can say from experience that oil-smeared surfaces or conditions, even with minor leaks of oil or gasoline, are quite amenable to prompt extinction by a good souse of water, and it is believed that the universal taboo should be qualified, so that many small fires may not fail of extinction because no other means but water is present.

Author's Closure

With reference to Dr. Reed's discussion of the use of water, it should be pointed out that gases or vapors are the most convenient extinguishing agents and that in most cases, where the operator cannot reasonably expect to have ready access to the fire or be able to direct a stream of water, except for steam formed by contact with hot surfaces, water in comparison with other materials mentioned must rank low. In order to insure reaching all vital points with a liquid extinguishing medium a large quantity must be carried and the distribution manifold is necessarily complicated and heavy.

The remoteness of danger due to the use of the gases of varying degrees of toxicity, as pointed out by Mr. Newell, is probably a matter of fact, and it is impossible to establish the degree to which this danger may exist, from any figures that the author has seen regarding fire statistics.

While this is largely a point for academic discussion, it is believed that there are plenty of nonpoisonous gases, as yet untried, which would prove useful and that research along new lines is warranted.

Regarding the annealing of copper fuel lines, it is of course advisable to use furnace annealing where possible, for uniformity. This requires special apparatus and is not ordinarily possible for the private owner or the small-scale operator of aircraft who must resort to torch methods.

Proper supporting of lines and protection against the effects of vibration may save many an embrittled or overannealed pipe line.

AER-52-33

The Problem of the Propeller With Minimum Loss of Energy

By ENRICO PISTOLESI,[1] PISA, ITALY

In previous papers the author has indicated the necessity of a thorough study of propeller problems, and has indicated the basis upon which such a study should be established. In his present contribution he undertakes to determine the distribution of velocity in an infinitely distant section of the slipstream which, for a given thrust, will result in a minimum loss of energy.

IN A PAPER by the author in 1928,[2] he indicated the necessity of a thorough study of propeller problems, keeping in mind the partial vacuum which is formed within the slipstream because of the effect of the tangential velocity of the fluid particles. Before that, in another paper[3] he indicated the basis upon which such a study would have to be established. Recently, M. Roy has published a discussion of the subject.[4] In this he considers what happens in the section which is at an infinite distance in the slipstream of the propeller. Among the problems to which he refers, but does not solve, there is that of the minimum loss of energy, a problem which has already been studied by Betz,[5] although he does not take into consideration the partial vacuum of the slipstream.

In the present paper it is assumed that the slipstream is entirely influenced by the propeller. This avoids the case, although an interesting one, considered by Roy, in which the active part of the disk area of the propeller is limited to an annulus at the rim. The present research will consist of determining the distribution of velocity in an infinitely distant section of the slipstream which, for a given thrust, results in the minimum loss of energy.

1 Let r indicate generally the radius of a point in the slipstream in the aforementioned section, V_0 the original velocity of the current, v the axial increment, ωr the tangential or circumferential velocity, Ω the rotational velocity of the propeller, p the pressure at a point of the section, p_0 the pressure of the undisturbed fluid, and R the radius of the section It is assumed that the propeller has infinite blades so that v, ω, and p will be only functions of r.

Since in the section under consideration the radial velocity is zero, the following relation[6] obtains:

$$p - p_0 = \rho r^2\omega\left(\Omega - \frac{\omega}{2}\right) - \rho v\left(V_0 + \frac{v}{2}\right) \quad [1]$$

Also,[7] for the pressure, we have the differential relation:

$$\frac{dp}{dr} = \rho\omega^2 r \quad [2]$$

Differentiating Equation [1], we have:

$$\frac{dp}{dr} = \rho\,\frac{d(r^2\omega)}{dr}\left(\Omega - \frac{\omega}{2}\right) - \frac{1}{2}\rho r^2\omega\,\frac{d\omega}{dr} - \rho(V_0 + v)dv$$

Eliminating dp/dr by means of Equation [2], we obtain:

$$(\Omega - \omega)d(r^2\omega) = (V_0 + v)dv \quad [3]$$

This is the fundamental differential relation which binds the increments to one another and with the radius r. It is easy to prove that this equation is identical with the one given by Roy in the aforementioned work, in which if we consider $\omega r = u$, we have:

$$(\Omega r - u)\left(\frac{u}{r} + \frac{du}{dr}\right) = (V_0 + v)\,\frac{dv}{dr}$$

The equation of thrust T is derived from the application of the theorem of momentum, taking into account the underpressure in the slipstream:

$$T = \int_0^R 2\pi r\rho(V_0 + v)v\,dr + \int_0^R 2\pi r(p - p_0)dr \quad [4]$$

Analogously, the total energy communicated to the fluid flowing into the slipstream in a unit of time is given by

$$E = \int_0^R 2\pi r(V_0 + v)(p - p_0 + \frac{1}{2}\rho(V_0 + v)^2 + \frac{1}{2}\rho r^2\omega^2 - \frac{1}{2}\rho V_0^2)dr \quad [5]$$

Eliminating $p - p_0$ from Equations [4] and [5] by means of Equation [1], we obtain:

$$T = \rho\int_0^R 2\pi r\left[r^2\omega\left(\Omega - \frac{\omega}{2}\right) + \frac{v^2}{2}\right]dr \quad [6]$$

$$E = \rho\int_0^R 2\pi r(V_0 + v)r^2\Omega\omega\,dr \quad [7]$$

To this last formula, moreover, we can arrive by the calculation of the couple Q to be applied to the shaft of the propeller, taking as a basis the theorem of the moment of momentum:

$$Q = \int_0^R 2\pi r\rho(V_0 + v)r^2\omega\,dr \quad [7a]$$

since manifestly $E = Q\Omega$.

Equations [6] and [7] are also found in Roy's contribution.

2 It is now necessary to determine the minimum of E, or of Q, given T, which is a problem in the calculus of variations. We can consider the function under the integral signs to be functions of v or of ω, v and ω being connected by the differential relation [3]. It is necessary, however, to make an exchange of variables, placing

$$r^2\omega = y \quad [8]$$

Equation [3] then becomes

$$\left(\Omega - \frac{y}{r^2}\right) dy = (V_0 + v)dv \quad [9]$$

Equation [6],

$$T = \rho \int_0^R 2\pi r \left[y\left(\Omega - \frac{y}{2r^2}\right) + \frac{v^2}{2} \right] dr \quad [10]$$

and Equation [7a],

$$Q = \rho \int_0^R 2\pi r(V_0 + v)y dr \quad [11]$$

Indicating by $-K$ Lagrange's factor, we have:

$$\frac{d}{dy}\left\{ V_0 + v)y - K\left[y\left(\Omega - \frac{y}{2r^2}\right) + \frac{v^2}{2}\right]\right\} = 0$$

or

$$\frac{d\,[(V_0 + v)y]}{dy} - K\left(\Omega - \frac{y}{r^2} + v\frac{dv}{dy}\right) = 0$$

and from [9],

$$\frac{d}{dy}\,[(V_0 + v)y] = K(V_0 + 2v)\frac{dv}{dy}$$

Integrating:

$$(V_0 + v)y = C + {}^1/_4K(V_0 + 2v)^2$$

an expression that, including the term ${}^1/_4KV^2$ in the constant C, can be easily transformed into:

$$(V_0 + v)y = C + K(V_0 + v)v \quad [12]$$

a very simple relation that connects the two increments.

Equation [12] may also be written:

$$y = Kv + \frac{C}{V_0 + v} \quad [13]$$

Differentiating [13] and comparing the value of dy/dv deduced from it with that given by [9], we obtain

$$\frac{V_0 + v}{\Omega - \omega} = K - \frac{C}{(V_0 + v)^2} \quad [14]$$

Equations [12] and [14] permit us to determine v and ω in functions of r.

Because of this we put $r^2\omega$ in place of y in [12] and keep the auxiliary unknown $V = V_0 + v$. With this, [12] and [14] become respectively:

$$Vr^2\omega = C + KV^2 - KV_0V \quad [12a]$$

$$\frac{V}{\Omega - \omega} = K - \frac{C}{V^2} \quad [14a]$$

We deduce now for V an equation of the fourth power,

$$V^4(K^2 + r^2) - KV^3(KV_0 + r^2\Omega) + CV(KV_0 + r^2\Omega) - C^2 = 0 \quad [15]$$

The constants K and C are determined on the basis of conditions at the boundary of the slipstream, through Equation [1], in which we get $p - p_0 = 0$, and assign either the value v_1 or ω_1 of one of the two increments for $r = R$, or the value of T, from which v_1 and ω_1 may be later derived.

3 The solution and discussion of Equation [15] is a rather difficult and complicated matter.

For brevity, we shall limit ourselves to two cases. The first is one in which $V_0 = 0$ *for a fixed propeller*. Then $V = v$, and Equation [15] becomes:

$$v^4(K^2 + r^2) - Kv^3r^2\Omega + Cvr^2\Omega - C^2 = 0 \quad [16]$$

which cannot be materially simplified. If we put

$$\xi = \frac{2}{K}, \qquad \nu = \frac{v}{K\Omega} = \xi\frac{v}{r\Omega}, \qquad \alpha = \frac{C}{K^3\Omega^2} \quad [17]$$

ξ, ν, and α are dimensionless ratios and we shall have:

$$\nu^4(1 + \xi^2) - \nu^3\xi^2 + \alpha\nu \mp \alpha^2 = 0 \quad [18]$$

This equation contains only one arbitrary constant α in the variation of which there are quite possible infinite types of distribution of ν in the function of ξ. These possible types have an extreme case corresponding to $\alpha = 0$, for which following equation holds:

$$\nu^4(1 + \xi^2) = \nu^3\xi^2$$

from which, eliminating the triple solution $\nu = 0$, as lacking significance:

$$\nu = \frac{\xi^2}{1 + \xi^2} \quad [19]$$

Further, from the second one of Equation [15] we have:

$$\frac{\omega}{\Omega} = 1 - \frac{\nu^3}{\nu^2 - \alpha} \quad [20]$$

which in the case where $\alpha = 0$ gives

$$\frac{\omega}{\Omega} = 1 - \nu = \frac{1}{1 + \xi^2} \quad [21]$$

The formulas [19] and [20] can be interpreted geometrically, placing $\xi = r/K = \tan\varphi$. From this it follows that

$$\nu = \sin^2\varphi; \frac{\omega}{\Omega} = \cos^2\varphi$$

In the other cases the curve of ν may be traced in functions of α for each value of ξ, solving Equation [18] with respect to ξ[3]

$$\xi^2 = \frac{\nu^3 + \alpha\nu - \alpha^2}{\nu^3(1 - \nu)} \quad [18a]$$

From Equation [20] we then obtain the value of ω/Ω.

4 The other limiting case is when v is very small in relation to V_0. Equation [12] may then be simplified as follows:

$$V_0r^2\omega = C + KV_0 \quad [22]$$

from which

$$r^2\omega = \frac{C}{V_0} + Kv$$

Differentiating and substituting in [3],

$$K(\Omega - \omega) = V_0 + v$$

$$r^2K\Omega - K\frac{C}{v_0} - K^2v = r^2V_0 + r^2v$$

[3] This may also be done with [15].

and finally:

$$v = \frac{r^2(K\Omega - V_0) - KC/V_0}{r^2 + K^2} \quad \ldots\ldots [22]$$

$$\omega = \frac{K(K\Omega - V_0) + C/V_0}{r^2 + K^2} \quad \ldots\ldots [23]$$

If we put:

$$\xi = \frac{r}{R},\ c^2 = \frac{K^2}{R^2},\ a = \frac{K\Omega}{V_0} - 1,\ b = -\frac{C}{KV_0^2},$$

$$\nu = \frac{v}{V_0},\ \text{and}\ \mu = \frac{K\omega}{V_0}$$

we have:

$$\nu = \frac{a\xi^2 + bc^2}{\xi^2 + c^2} \quad \ldots\ldots [22a]$$

$$\mu = \frac{c^2(a - b)}{\xi^2 + c} \quad \ldots\ldots [23a]$$

Bearing in mind Equation [1], where r is put equal to R (whence $\xi = 1$), $p - p_0 = 0$, and where v and ω may be disregarded in the presence of V_0 and Ω, we then obtain easily between a, b, c, and $v = V/R\Omega$ the relation:

$$\gamma(a + bc^2) = c(a - b) \quad \ldots\ldots [24]$$

Moreover it is easy to verify between a, b, and c the relation

$$c = \gamma(1 + a) \quad \ldots\ldots [25]$$

which permits us to substitute to [24] the following formula:

$$b = \frac{a^2}{c^2 + a} \quad \ldots\ldots [26]$$

The following relation, moreover, is true:

$$\nu + \mu = a$$

and Equation [22a] may accordingly be written:

$$\nu(\xi^2 + c^2) = a\xi^2 + bc^2 \quad \ldots\ldots [22b]$$

It is not without interest to compare the preceding relation with one which is derived upon the basis of the same hypothesis that v is negligible compared with V_0, whenever the underpressure in the slipstream is not considered.[9]

$$\nu(\xi^2 + r^2) = K\xi^2$$

The two expressions differ because of the substitution of c to γ in the first member and because of the addition of the constant bc^2 in the second. Putting, as in the aforementioned reference,

$$\frac{\xi^2}{\xi^2 + c^2} = \cos^2\varphi, \text{ whence } \frac{c^2}{\xi^2 + c^2} = \sin^2\varphi$$

Equation [22a] becomes:

$$\left.\begin{aligned} \nu &= a\cos^2\varphi + b\sin^2\varphi \\ \mu &= (a - b)\sin^2\varphi \end{aligned}\right\} \quad \ldots\ldots [26]$$

For $\xi = 1$, we have:

$$\tan\varphi_1 = c$$

If we place $\tan\varphi_2 = cb/a$ and $\gamma = \tan\mu$, it follows from [24] that

$$\mu = \varphi_1 - \varphi_2$$

[9] See E. Pistolesi, "I Propulsori Elicoidali e i Recenti Progressi dell'Aerodinamica" (The Screw Propeller and Recent Progress in Aerodynamics). Report of Ist. Sperim. Aeronaut., vol. 8, p. 235.

which expresses in a more suggestive manner the relation between the values which rule in the problem.[10]

5 Let us now calculate T and E by means of Equations [6] and [7] upon the basis of the formulas in the preceding paragraph, neglecting, in accordance with the hypothesis which has been assumed, the square of the incremental velocity; or

$$T = 2\pi\rho\int_0^R r^3\Omega\omega dr \quad \ldots\ldots [6a]$$

$$E = 2\pi\rho\int_0^R r^3\Omega\omega V_0 dr \quad \ldots\ldots [7a]$$

We find that $E = TV_0$ (whence $\eta = 1$, as a natural consequence of the procedure) and moreover:

$$\tau = \frac{T}{\rho R^4\Omega^2} = \pi\gamma c(a - b)\left[1 + c^2\log\frac{c^2}{1 + c^2}\right] \quad \ldots\ldots [27]$$

or, from [24]:

$$\tau = \pi\gamma^2(a + bc^2)\left[1 + c^2\log\frac{c^2}{1 + c^2}\right] \quad \ldots\ldots [27a]$$

or also, taking note of the fact that a, b and c are connected by Equation [26]

$$\tau = \pi\gamma^2 a\left(1 + \frac{ac^2}{a + c^2}\right)\left[1 + c^2\log\frac{c^2}{1 + c^2}\right] \quad \ldots\ldots [27b]$$

The calculation of τ, in case that the underpressure is not taken into account, assuming that the law of the distribution of the increment v is unchanged, is effected upon the basis of the formula:

$$T = \int_0^R 2\pi\rho r V_0 v dr$$

and leads to the following results:

$$\tau' = \pi\gamma^2 a\left[1 + c^2\log\frac{c^2}{1 + c^2}\right] - \pi\gamma^2 bc^2\log\frac{c^2}{1 + c^2}$$

The difference between the two results should be noted.

Equation [27b] may be transformed by dividing both members by $\pi\gamma^2$, and as a matter of fact $\frac{\tau}{\pi\gamma^2} = \frac{T}{\rho\pi R^2 V_0^2}$ is the coefficient of thrust, referred to the area of the section (which, in the given hypothesis, is equal to the disk area) and to the square of the velocity. We then have:

$$\frac{\tau}{\pi\gamma^2} = a\left(1 + \frac{ac^2}{a + c^2}\right)\left[1 + c^2\log\frac{c^2}{1 + c^2}\right] \quad \ldots\ldots [27c]$$

Note that in the hypothesis ν = a constant, and always neglecting the underpressure, we simply find that

$$\nu = \frac{\tau}{\pi\gamma^2}$$

This is to be noted for the comparison.

It is scarcely necessary to state that the expression [27], combined with [25] and [26], permits the determination of the values a, b, and c, τ and γ being known.

For brevity's sake the many conclusions which might be drawn from the results obtained are omitted.

[10] Instead of the ratio μ, one can make use of u/V_0, where $u = r\omega$, giving

$$\frac{u}{V_0} = \frac{c(a - b)\xi}{\xi^2 + c^2} = (a - b)\sin\varphi\cos\varphi$$

AER-52-34

Flying Boat Design

By ADOLF K. ROHRBACH, BERLIN, GERMANY

This paper tells of some of the problems encountered in designing flying boats, and compares their characteristics with those of landplanes. Five outstanding considerations include: the size of boat, aerodynamic qualities, floating system, structural principles, and general arrangement. The best shape for a flying-boat hull must be determined by experiment.

PROBLEMS encountered in the design of flying boats are in some respects rather different from those pertaining to the design of land machines. Whereas land machines operate from solid fields, flying boats have to contend with a water surface, the condition of which depends very much on the weather and on the place. The reaction between boat and water in turn depends very much on the shape of the boat.

In analyzing the design of a flying boat, there are five main problems: the size of the boat, the aerodynamic qualities, the floating system, the structural principles, and the general arrangement, which combines the best solutions for the first four problems.

Size of Boat. As far as the ground operation of landplanes is concerned there is practically no advantage in a bigger machine over a smaller one, whereas bigger flying boats, like bigger surface vessels, are much more stable in rough seas. In flight a big commercial flying boat of 20,000 lb. and over is considerably more economical than a landplane of equal weight. It is an established fact that the weight of the flying structure of large machines is a greater portion of the gross weight than of small ones. This is particularly so if heavy planes are built with relatively large wings and small wing loadings, because much weight or aerodynamical resistance is required for these widely stretched wings and corresponding fuselage and tail-plane structures.

On account of the restricted size of landing fields and the high ceiling needed to fly over mountains, big landplanes must have relatively small wing loadings and landing speeds. The result is that for commercial landplanes the greatest efficiency seems to be reached with a size of about 10 to 12 tons. Beyond this size the increased weight of the structure becomes more and more pronounced, and counteracts the payload carrying capacity. In the case of the flying boat, the effect of increased size is less pronounced. It is admitted today by many authorities that the landing speed of large flying boats within reason can be increased over that which is good practice in small seaplanes. The reason is that a certain wave representing a certain weight of water means less to a large heavy boat than to a small light seaplane.

This increase of the landing speed is about 20 to 25 per cent in a big flying boat, and means a relatively smaller span, smaller length of tail, and smaller area of tail planes. This more concentrated flying structure is so much lighter than that of a landplane of the same gross weight would have to be, that the most economical sizes for commercial flying boats today have a gross weight of about 20 to 25 tons, which is more than twice that of the most economical landplane. The *Inflexible*, a giant bomber which was designed for the British Air Ministry, has about the same wing area as the *Romar* flying boat, although the weight of the former is 15 tons against a weight of 19.5 tons for the latter. The span of the *Inflexible* is 150 ft. and of the *Romar* but 120 ft. In accordance with these mechanical laws and weight proportions, the heaviest landplanes in existence have a gross weight of about 15 tons, whereas the heaviest flying boat, the Dornier Do-X, has flown with a weight of 48 tons, which was taken off after a run of 160 sec. Though the Do-X has not yet passed its development period, its weight empty of about 35 tons with equipment is 73 per cent of the 48 tons, whereas the *Romar*, with a gross weight of 19.5 tons including equipment, has a weight empty of 11.2 tons, or 57.5 per cent of the gross weight. These figures prove that the Do-X has already passed the most economical size from a weight standpoint.

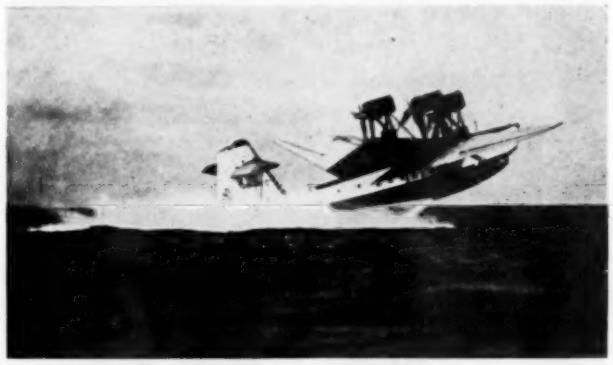

Fig. 1 The Flying Boat Romar

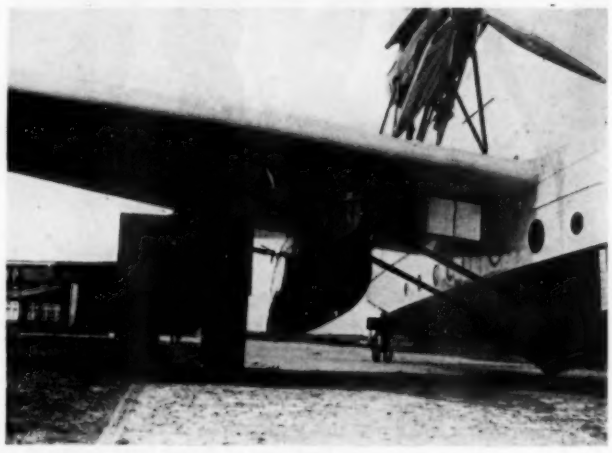

Fig. 2 Method of Attaching Floats

As far as the cost of construction is concerned it is hard to say how it will influence the most economical size. The greater number of machines that can be sold in smaller sizes reduces their cost, whereas the building cost of a big machine compared to its carrying capacity is relatively smaller for the same reasons which in other fields reduce the cost of one big unit against that of a combination of small units of equal total power. The heavier

Presented at the Great Lakes Aeronautical Meeting, Cleveland, Ohio, August 31, 1929, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

wing loading of a big flying boat reduces somewhat its speed of climb, but a high ceiling is not needed and even a heavily loaded four-motored flying boat has enough margin of power to fly for any length of time with one motor dead.

In regard to the emergencies of forced landings, a big landplane is usually much worse off than a smaller one, which can make forced landings relatively easy, and if it should not be able to take off again without much trouble can be transported to some flying field. The opposite is true of flying boats which cannot count on outside help as quickly as landplanes. For this reason it is very important that the flying boat be self-contained, and it is obvious that the larger machine, with its greater seaworthiness, with its spacious rooms, and more numerous crew, certainly offers a great

FIG. 3 METHOD OF MOUNTING ENGINES

advantage over a small machine with a crew of two. It is understood that if the technically best size of flying boat today is 22 to 25 tons, it will steadily be increased by every improvement that is contributed to the art.

The *Romar*, with the experience of today, powered by four Hornet motors, will with a weight of 19.5 tons carry up to 45 passengers over a distance of a few hundred miles and several thousand pounds of payload over a distance of 2000 miles, allowing a 25 per cent distance reserve for the longest leg of the Europe-South America route. Within two or three years it will be possible to carry a payload of several thousand pounds over a distance of 3000 miles allowing the necessary 50 per cent distance reserve for the flight between the Azores to Bermuda, where strong headwinds are encountered over the greater part of the way.

Aerodynamics. The monoplane type of flying boat, especially in large sizes, is preferable because of greater speed and greater simplicity. The aspect ratio of monoplane flying-boat wings varies in different types from 1:5 to 1:10. The wings of some types of flying boats are rectangular. Tapered wings, though more costly to build, have the advantage of lighter weight and smaller rolling moments in a side wind while the machine is floating on the water. The double tapered wing has a greater ratio of thickness to chord at the root than at the tip, and has least weight and sometimes smaller air resistance through the thinning out of the wing profiles near the tip. It is important that the wing profiles be designed so that there is a minimum variation of aerodynamic moment or, as some put it, a minimum movement of center of pressure for various angles of incidence. Obviously the smaller this variation of aerodynamic moment the smaller are the counter moments that are to be provided by the tail planes. This in turn means smaller tail surfaces and a shorter tail for a certain controllability at a certain speed.

Flying boats, in order to be safe at stalled landings in heavy seas, should have a very good controllability at lowest speeds. The moments that can be exercised with full elevator or full rudder must be considerably greater than those needed to counteract the aerodynamic moments of the wing and than those needed for land machines. Therefore the smaller the aerodynamic moment of the wing, the greater the controllability that can be obtained with a certain area of tail planes and length of tail, and correspondingly with a certain weight expended to build these parts.

It has been found necessary to balance all control surfaces of big boats. The most satisfactory method up to now has been to place the axle about 15 to 22 per cent of the chord length behind the leading edge. Rather large vertical fins are necessary in order to provide longitudinal stability in spite of the great portion of the boat that is in front of the wing. A dihedral angle of from 4 to 8 deg. is important in order to have good lateral stability at stalling speed. If all the before-mentioned aerodynamic conditions are fulfilled, the flying qualities of a big flying boat are as perfect as those of the best training planes. The *Romar*, for instance, is stable in all three directions. Curves up to a bank of 70 deg. can be flown with the rudder alone. The machine recovers from a sideslip if controls are not touched, and it has been reported that during the last flights of 12 and 17 hours' duration the controls remained practically untouched during the entire time.

Floating System. The floating system has to fulfil the following conditions: Flotation at rest must be longitudinally and laterally stable under all possible conditions of wind and load. At moderate speeds on the water the flying boat must be as perfect a surface vessel as possible; there must be good controllability, and not too much spray must be thrown up in a rough sea with a strong side wind. At high speeds close to take-off speed, the running must be free from pounding, and at all speeds the resistance should be the minimum possibly attainable.

A flying boat with a hull sufficiently long to support the tail planes has automatically enough longitudinal floating stability. In order to obtain lateral stability it has been found best to have two side floats of substantial size, not too far away from the hull and well immerged at rest. The lateral stability of this arrangement is so that a side wind of 30 m.p.h. will not force the leeward wing into the water. Flying boats of this type have been on the water for many hours in gales up to 55 m.p.h. without any special precaution. It is believed that the boats always will be able to ride out gales of similar force floating behind a drift anchor. The high bow, which cannot cut under waves, is of extreme importance in these conditions.

At taxiing speeds of about 15 m.p.h. the side floats give the greatest hydrodynamical lift, aiding the boat to plane at about 25 m.p.h., and during planing the side floats are entirely clear of the water. In order to avoid shocks during planing, the bottom

has a pronounced V of about 27 deg. medium angle. The outer part of the bottom V is curved so that the water is thrown downward with a corresponding increase in lift. In front of the main step the keel is widened to a narrow gliding surface with hollow sections which firmly support the planing boat shortly before take-off. The V shape is so steep that, in spite of the curves of the outer part of the bottom, the boat does not pound in rough seas. The bottom aft of the main step has straight V sections until near the second step where it is shaped somewhat similar to the main step, though less pronounced, in accordance with the smaller hydrodynamic forces acting on the second step. Aft of the second step, the bottom has a straight V rising sharply in order to be free from the water at all speeds.

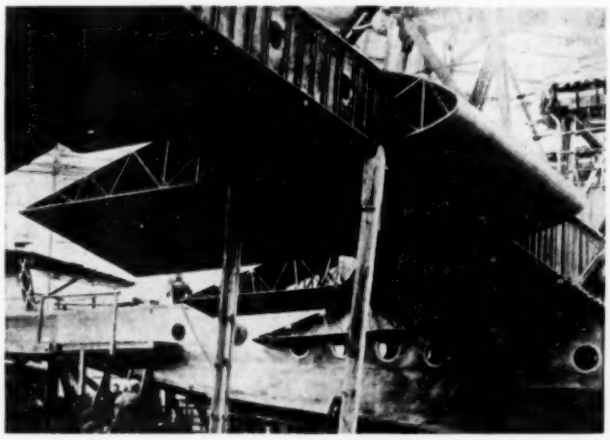

FIG. 4 BOX-SPAR WING GIRDER AND NOSE

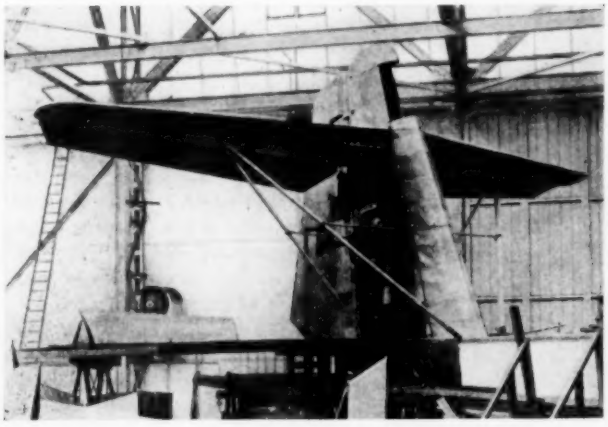

FIG. 5 CONSTRUCTION OF TAIL UNIT

The hydrodynamical problems to be solved in order to produce a flying-boat bottom that will plane with the smallest resistance and greatest lift are very similar to those of water turbines where a maximum torque obtained from the flowing water is the object. Therefore no genius can design the best shape of a flying boat hull, but this will be found by experiments alone. The company with which the author is connected has carried out more than 2000 towing tests in a model basin, running several hundred models over a total distance of more than 1000 miles. The results obtained by these model tests have been checked by hundreds of actual take-off tests with several types of flying boats. The take-off conditions of a new type can, on this experience, be predicted with an accuracy of 5 to 8 per cent, regarding weight. Though some progress has been made there is still much to perfect.

The very deep sharp V and the narrow gliding surface in front of the main step have the advantage that the boat is planing in a very high position; that means about 4 ft. higher than the floating position at rest. It is obvious that this high planing position offers excellent protection for wings and all other parts of the structure when taking off in a rough sea. So far take-offs have been made in waves of 12 to 15 ft. On the other hand, the small water resistance of this shape of hull has resulted in a good take-off from a calm sea with maximum load, which is not astonishing considering that all the towing tests have been made on smooth water.

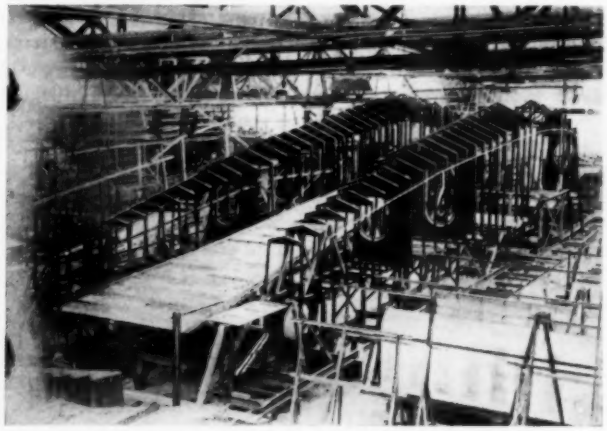

FIG. 6 SKELETON HULL SHOWING SHIPBUILDING METHOD OF CONSTRUCTION

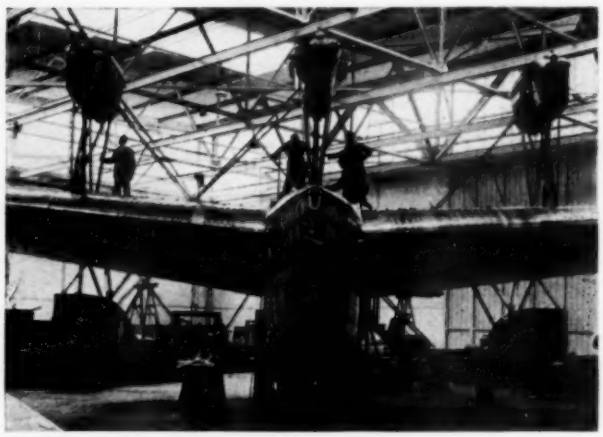

FIG. 7 THICKNESS OF CHORD OF WING AT ROOT AND V-BOTTOM

Structural Principles. Materials for flying boats, aside from workability, must have a good ratio of strength to weight, and unlike the materials of land machines their qualities must not be changed by the influence of seawater. Therefore in the course of further development wooden structures and canvas covering of wings should be replaced by duralumin sheet construction. Great care must be taken to avoid corrosion by use of suitable materials, working methods, and protective means, such as coats of other metals, paint, grease, etc. All structural details should be of so simple design and built of so many separate parts that everything can be easily inspected and maintained from all sides.

Watertightness forms the best anticorrosive protection for the

inside of many parts, since it is the only means to exclude all corroding moisture. It is mostly for this reason that the duralumin wing-box girders of later flying boats are watertight over the greater part of the span. As a secondary result it may be of interest that the buoyancy of this wing-box girder alone could keep the machine afloat indefinitely.

In big duralumin flying boats, the flat skin plates of wing and hull, by means of stiffening profiles, should take a substantial part of the stress. Very much weight and labor would be needed, however, to provide stiffening profiles so close together that considerable compression or bending forces could be transmitted by the skin. Therefore the structural members of all parts are arranged so that profile girders take the compression stress, whereas the skin plates transmit the shearing forces by means of rather widely spaced stiffeners. The shearing stress of a flat skin is much greater than that of a curved one of equal weight. Therefore, and because of cheaper construction, flying boats have flat sides and decks, and it is believed that this type of construction will be universally adopted. The mechanical qualities of skin plates under shearing stress have been systematically studied by numerous experiments.

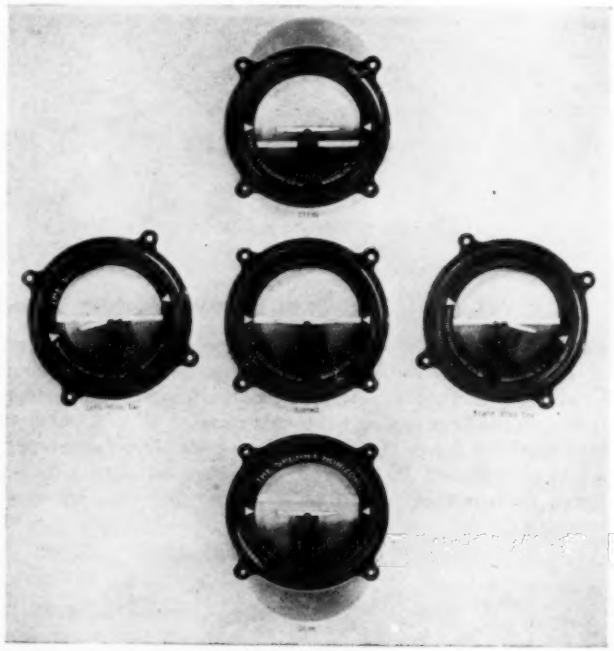
The weight prediction for a new type is correct today within 5 per cent. The whole development of the flying-boat design in about one year has reached the stage where for a given design one can predict with great accuracy not only its flying performance but also what it will do on the water. This means that flying boats can now be designed with certain predetermined and commercially desirable qualities and performances. This has brought us only to the beginning of the real development in flying-boat design which will be based on their transportation utility.

AER-52-35

The Artificial Horizon

By ELMER A. SPERRY, JR.,[1] BROOKLYN, N. Y.

This paper describes the "artificial horizon," an instrument developed recently to aid blind flying. Through the use of a gyroscope a gravity device is constructed with a very slow rate of motion that will maintain a horizontal position in an airplane with sufficient accuracy to make a most useful instrument. Test data for the instrument are given.



THERE has been a long-felt need for an improved instrument to aid blind flying, an instrument to show at a glance the true horizontality of the airplane at all times. Flying blind on a straight course for any length of time by instruments is a difficult and very tedious job. Making quick turns while flying blind and immediately resuming normal straight flight is practically impossible with the instruments of today.

Up to the present no instrument shows the true horizontality of the airplane at all times, but merely gives an indication of something else from which the horizontality must be determined by the pilot. The altimeter shows when the plane gains or loses altitude. The rate of climb shows when the plane climbs or descends. The air-speed and tachometer indications decrease when the plane climbs and increase when it dives. But these instruments do not immediately indicate a nosing up or down of the plane. Their inherent lag makes it difficult for a pilot to fly blind by them without oscillating or pitching.

The turn indicator and bank indicator are used for determining lateral horizontality while flying blind as well as indicating yaw and proper bank. However, the pilot must translate the indications of these instruments in order to determine his lateral position, and it takes a great proficiency to interpret the "language" of these instruments before a pilot feels at ease while flying blind by them.

Gravity devices such as a pendulum or bubble level behave quite well in an airplane when flying a steady, straight course through smooth, clear air. In bumpy air an undamped gravity device will oscillate badly, and during maneuvers of the airplane will respond to acceleration or centrifugal forces. Gravity devices damped by being connected directly to the airplane as by a dashpot or a viscous, restricted-flow liquid will not oscillate as much. To some extent, ship's movements will be imparted to the device through the damping means. Gravity devices that are damped in a different manner, such as two pendulums of different periods or a pendulum and a balanced mass, connected together in some manner which dissipates energy, or a continuous-circuit viscous-liquid bubble, will not be energized as much by ship's motion but will respond to acceleration and centrifugal forces quite readily.

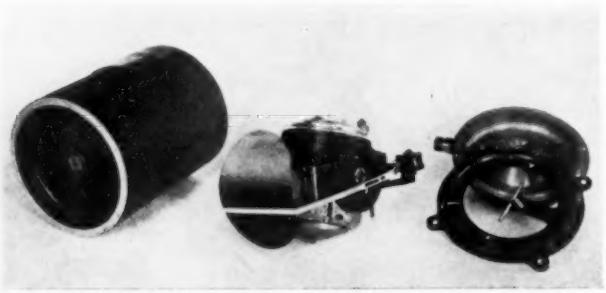
These pendulous devices for aircraft can be divided roughly into three classes: Those having quite a rate or period of motion, those having a relatively slower rate of motion by reason of being well damped, and those designed to have a very slow rate of motion of only a few degrees per minute which are aperiodic. Instruments in the first class respond to every movement of the plane and oscillate badly. These might be called bump indicators and are not satisfactory for aircraft use. Those in the second class do not oscillate as much, though they still respond to centrifugal forces readily. Accelerometers, banking indicators, and bubble inclinometers are in this class and serve useful purposes. Those in the third class do not oscillate, and respond to centrifugal forces only according to their rate and the duration of the forces. There are only a few instruments of this class in use today.

THE HORIZON INDICATOR FOR VARIOUS POSITIONS OF THE FLIGHT OF THE PLANE

Instruments of the third class can be made to maintain the vertical on the airplane with a surprisingly high degree of accuracy due to the fact that centrifugal or acceleration forces are of comparatively short duration when undirectional as, for instance, when the airplane increases or decreases air speed. When centrifugal forces exist for any considerable length of time, such as when an airplane continues to turn in circles, they are in the same direction with respect to the airplane, that is, athwartship, but are not in the same direction with respect to the earth. Therefore, the mean effective centrifugal force with respect to any particular direction in azimuth equals zero for a complete turn. The greatest mean-effective centrifugal force with respect to any direction, therefore, is for a turn of 180 deg. If the turn is less than 180 deg. the mean-effective centrifugal force will

[1] Sperry Gyroscope Company.

Presented at the Fourth National Aeronautic Meeting, Dayton, Ohio, May 19 to 22, 1930, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.



NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

be less, and if the turn is greater, that part which is over 180 deg. will cancel an equal amount diametrically opposite, making the total effect again smaller.

The mean centrifugal force acts for the entire time of the turn. For instance, an airplane flying at 100 m.p.h. makes a 180 deg. turn in 30 sec., banking 25½ deg. The centrifugal force at every moment during the turn is 0.43 lb. on every pound in the airplane, exerted athwartship or radially to the turn. The mean centrifugal force for the entire turn acting in one direction is 0.265 lb. acting for 30 sec.

If a pendulous device of class 3 had a rate of response of 1 deg. in 30 sec., it would only depart 1 deg. from the true vertical during the above turn, whereas a pendulous device of class 2 would depart 25½ deg. during the turn, as the banking indicator does. If the airplane made a complete circle instead of only a 180 deg. turn, the slow-responding pendulous device (of class 3) would go off only a small amount during the turn, but would be left correct again at the end of the turn.

It has been found possible by using a gyroscope to construct a class 3 gravity device of slow rate that will maintain a horizontal position in an airplane with sufficient accuracy to make a

THE INTERNAL PARTS OF THE ARTIFICIAL HORIZON

most useful and perfect blind-flying instrument. An instrument of this kind was constructed in such a manner that its rate could be adjusted to meet normal operating conditions. This was installed on the Guggenheim Fund Consolidated N. Y. 2 and flown by Lieutenant James H. Doolittle during his blind flying experiments at Mitchell Field. Test data from an instrument adjusted for a rate of approximately 4 deg. per min. are given herewith.

TEST RESULTS OF INSTRUMENT

90 m.p.h. air speed average Turn	Bank	Time for 180 deg. turn	Center of pointer	Right end of pointer	Recovery
180 deg. left	40 deg.	15 sec.	Held	Up 1/32	Immediate
180 deg. left	25 deg.	28 sec.	Down 1/32	On O. K.	Immediate
180 deg. left	17 deg.	43 sec.	Down 1/32	Up 1/32	Immediate
180 deg. left	7 deg.	1 min. 45 sec.	Down 1/16	Up 1/16	Immediate
180 deg. right	36 deg.	18 sec.	Held	Up 1/32	Immediate
180 deg. right	29 deg.	26 sec.	Held	Up 1/32	Immediate
180 deg. right	14 deg.	50 sec.	Down 1/32	Up 1/32	Immediate
180 deg. right	6½ deg.	1 min. 54 sec.	Down 1/16	Down 1/32	Immediate

2 min. straight course held between turns to allow instrument to settle.
Climb at 10 deg. for 5 min. after leveling off, pointer of indicator O. K.
Dive at 15 deg. for 4 min. after leveling off, pointer of indicator O. K.
Vibration, pointer, none.
Vibration, instrument board, slight.

This new horizon has a small circular face of about 4 in. diameter constructed for flush mounting in the instrument board. The face of the instrument consists of a smooth background, blue on the upper half to denote sky, shading to a dark grey on the lower half to represent ground. Horizontally across the middle of this field is a straight bar, both ends of which extend beyond the mask which surrounds the instrument face. This bar simulates the horizon. In front of the bar and the field is a small tail view of an airplane held at the center of the instrument face as part of the mask which tilts with the plane. If the plane climbs or noses down, the horizon-bar falls or rises respectively in just the same manner as the actual horizon appears to fall or rise as the pilot looks over the nose of his ship. As the plane banks, the bar remains horizontal, whereas the dial and the airplane silhouette tilt with the plane. The horizon bar is thus free to rise, fall, and tilt, and can assume any possible combination of these positions. The bar is held in the horizontal position by a small air-spun gyroscope mounted in a gimbal ring, and having its spinning axis vertical.

For a gyroscope spinning in this manner to maintain a true vertical axis, it is necessary to have gravity act on it in some manner, and this very fact has been the stumbling block of many early artificial horizon designs, because when gravity acts directly on a gyroscope (for example, by making it decidedly pendulous in its gimbal mounting) the gyroscope precesses at right angles to the tilt, and therefore starts an oscillation of slow period which has to be damped out before the axis can recover the vertical. In such a case, any maneuvering of the airplane or change of its course causes an acceleration pressure on the pendulous gyro which throws it off of the true vertical and starts an oscillation. In this horizon instrument the effect and the resulting oscillation has been entirely avoided by making gravity act indirectly on the gyroscope so that the gyroscope precesses in the correct direction from any tilted position directly to the vertical without passing through any period of oscillation. This is accomplished by utilizing the same air which drives the gyroscope to create an erecting or damping torque on the gyroscope, and cause it to seek and hold the axis vertical.

The air flow through the instrument is obtained by means of a venturi tube mounted in the air stream. The venturi is designed to give sufficient pressure at the normal flying speed of the ship to spin the rotor at about 10,000 r.p.m.

The gyro casing consists of two chambers. The gyroscope mounted in the upper element is spun by the air from three nozzles in the casing striking the peripheral blades of the rotor tangentially. This air then passes into the lower chamber which is of a hemispherical shape. Hanging from the center point of this chamber is a small universally mounted pendulum of such length and shape that it swings freely inside the hemisphere with a small clearance between itself and the shell.

At three equally spaced points on the hemisphere there are orifices through which the air exhausts. Each orifice carries a tube with an elbow in it so that the air exhausts tangentially to that portion of the hemisphere. The exhausting air causes a reaction on the gyro casing which is at right angles to the reaction from an open port at the same location. The pendulum bob inside the shell is designed so that it covers an equal portion of each of the three ports when the gyro and its casing are in the vertical position. The air reactions, therefore, from the three ports are equal and neutralize each other. If the position of the gyro is tilted, the pendulum closes the low port and opens the high ports. The air reaction creates a torque about the gimbal axis of the gyro mounting so that the gyro precesses directly back to the vertical position. The gyro, its casing, and the pendulum are all balanced as a unit so that the unit is only slightly pendulous, and therefore, it is impossible to throw it into a periodic oscillation due to acceleration forces.

The rate of precession which is caused by the air reaction is adjusted to such an amount that it is negligible during the time that an airplane can make the maximum change of course, that is, 180 deg. Since all other maneuvers give less acceleration force than the 180 deg. turn, the artificial horizon therefore holds its position through any amount of maneuvering or tossing about of the ship.

The gyro casing is mounted in pivot bearings in the gimbal ring. The gimbal ring is pivoted to the instrument casing about

the longitudinal axis of the instrument, freedom 90 deg. bank, 80 deg. climb, and dive. The sky-earth background of the instrument face is attached to this gimbal ring and therefore tilts with the gyro and horizon. Hence, the blue sky always remains above the horizon bar no matter how much the instrument or ship is tilted. The horizon bar is carried by a link from the rear part of the gyro casing through a pivot on the gimbal ring and thence out in front of the field as a light horizontal bar. The reason for this reversing linkage is that this corrects the horizon motion to the normal apparent motion of the real horizon as observed by the pilot when he climbs or dives. It is the correction of the behavior of this bar to the normal appearance of the real horizon for any position or maneuver that makes this instrument easy to fly by a new pilot, and entirely non-fatiguing for a pilot who has to fly long periods of time blind.

Acknowledgment is made for the valuable aid in the development of the artificial horizon to the following: Curtiss Aeroplane and Motor Company, Guggenheim Fund, National Air Transport, Transcontinental Air Transport, and Eastern Air Transport.

Air-Transport Management

By D. W. TOMLINSON,[1] GLENDALE, CAL.

Problems which must be solved by a manager of air-transport lines are discussed in this paper. The operating department of the T.A.T.-Maddux Air Lines is divided into two groups: (1) flight and (2) engineering. The first corresponds to the operating department of a railroad, and the second takes care of inspection, maintenance, and general overhauling of equipment. There are many essentials to a well-organized air-transport company. Weather conditions must be studied and reported, radio is a necessity, and the flying force must be chosen for its keen sense of observation as well as for skill in flying. The author describes the duties of each class into which the force is divided and tells how the work is carried on with greatest success and reliability.

THERE are three general divisions of air-transport management: executive, operations, and traffic. This paper deals exclusively with certain problems confronting a manager of air-transport operations. One of the first duties of a manager of operations of an air line is to form his organization. From the head of the operations department down to the very ship cleaners, it is of vital importance that there be a clear-cut and thoroughly understood chain of authority and succession of responsibility. The duties of every man must be clearly defined. The limits of his authority and responsibility must be established and clearly set forth in written instructions promulgated to all personnel. It is not enough that the individual himself shall know the limits of his authority and responsibility; it is also important that every man in the organization be instructed regarding the duties and authority of those with whom he works.

The choice of leading personnel is the most important problem of the manager of operations. Having planned his organization and prescribed the duties of the key men, he must fill these positions, and the selection of such men must be based on merit and proven ability alone. A mistake here can upset the entire machinery. Friendship and outside influence must be completely ignored. Too much depends upon the choice of the men in these positions, not only from a business standpoint, but from the standpoint of human lives.

To be a successful leader, a man must be of unimpeachable character himself and must possess the outstanding qualities of judgment, initiative, thoroughness, reliability, knowledge of his work in all its phases, complete loyalty to his superiors, and an ability to maintain discipline once it is established. His personality must be such that the men will labor for him out of sheer respect for the man himself, not merely because of the authority vested in him.

The operations department of an air line should be divided for administration purposes into two groups: flight and engineering. The flight superintendent is the senior of the two subdepartments, and in addition he acts as assistant to the manager of operations. The chief engineer is responsible (through the flight superintendent) to the manager of operations for the efficient maintenance of all airplanes, engines, base machinery and automotive equipment.

Under the flight superintendent are the flying superintendents of divisions and all pilots. Pilots are permanently assigned to divisions. One pilot on each division is designated as division or section superintendent. He is held responsible for the efficient performance of duty and the observance of company orders and policies by the personnel under his jurisdiction. The flight superintendent is also the chief pilot, and is in charge of all personnel. In the flight office, over which he has supervision, are kept all operating, engineering, and personnel records. To assist in handling this work he has a chief clerk, a timekeeper, and a secretary. All pilots' schedules are made up monthly by the flight superintendent in collaboration with the division and section superintendents.

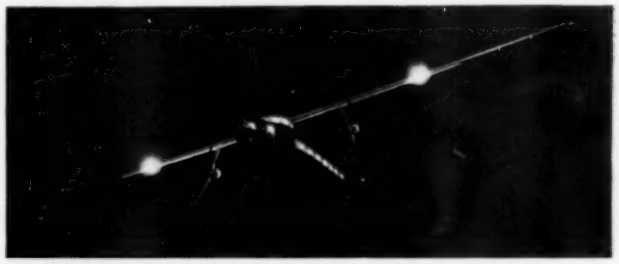

FIG. 1 FORD PLANE APPROACHING FIELD FOR NIGHT LANDING

FIG. 2 EMBARKING PASSENGERS AT GRAND CENTRAL AIR TERMINAL, GLENDALE, CALIFORNIA

As assistant to the flight superintendent, a senior pilot is designated. This pilot is picked on the basis of sound judgment and executive ability. In the event of the absence of both the manager of operations and the flight superintendent, this pilot succeeds to the full authority of the head of the operations department.

At irregular intervals the flight superintendent flies over the line in place of the senior pilot, for the purpose of keeping himself familiar with conditions on the route, and during his absence the senior pilot takes training for the position of flight superintendent, familiarizing himself with the administration work of that office.

Field managers are in charge of intermediate landing fields along the air-line route. Field crews vary, according to whether the field is merely a service stop or an overnight base. At fields where planes stop only to be serviced, the personnel consists of a weather man and a mechanic in addition to the field manager.

---

[1] Vice-President in Charge of Operations, T.A.T.-Maddux Air Lines.

Presented at the Seattle Aeronautic Meeting of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS, Seattle, Wash., May 28 and 29, 1930.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

At overnight bases the complement is augmented by an office clerk, an additional mechanic, and a helper. The latter also acts as janitor and caretaker of the field.

A triple responsibility rests upon field managers. They are accountable to the traffic department for the handling of passengers, to the head of the operations department for general administration, and to the chief engineer for the mechanical condition of equipment under their charge.

Weather Service

The senior meteorologist and an assistant prepare the weather data at the base field. For the purpose of coordinating and standardizing the routine of weather reports, the senior meteorologist is in charge of the weather service. All weather data and meteorological reports are submitted by the weather men at intermediate fields to the senior meteorologist at the base field. While the individual weather men at intermediate fields are a part of the field complement, the weather service as a unit comes under the senior meteorologist, who in turn is responsible to the flight superintendent.

Radio

A radio engineer at the base field is in charge of all radio development work, installation of equipment in planes, and routine maintenance. Radio operators live at each radio station on the transcontinental division. The radio operators are a part of each field complement, and they are responsible to the radio engineer for the performance of their duties.

Control of Operations

An experienced pilot with a keen sense of responsibility is the only logical person to control air operations. No man without years of flying experience should be entrusted with authority over flying personnel. In addition there must be a sense of complete understanding and personal harmony between whoever is in charge and the flying crews themselves. In other words, the pilots must feel free to bring to the head of operations any problems with which they are confronted, knowing that he would not ask them to do anything he could not do himself.

At base fields there must always be one of the following on duty while planes are in the air: Manager of operations, flight superintendent, and senior pilot. Whenever the slightest doubt arises regarding any plane movement the chief despatcher is required to obtain the written approval of the head of the operations department on duty. No pilot is ever ordered to take off the ground against his personal wishes.

Fig. 3 Ford Planes Circling Aguascalientes, Mexico

After a pilot has received his instructions and has been released he alone is responsible for the safety of his plane. He may be advised regarding weather conditions, and suggestions may be made to him, but in the last analysis the pilot's judgment must be unquestioned. He alone, once he is in the air, is fully cognizant of the conditions immediately confronting him. Only under the following conditions may a pilot in the air be given direct orders:

Having landed at any field he may be ordered to remain on the ground. If in the air in sight of an established field, he may be ordered by radio to land at that field; if clear weather is known to prevail between a plane and an established field and if the plane has ample fuel, the pilot may be ordered by radio to proceed to that field.

In our own case the control of operations is delegated at distant terminals to duty pilots. For instance, the weather conditions at and adjacent to San Francisco present problems peculiar to that locality. They cannot be judged accurately from the weather reports which are received at present. Certainly, then, operations out of this area cannot be intelligently controlled by any one in Los Angeles. To overcome this, three pilots, picked because of their thorough knowledge of San Francisco weather conditions, are permanently based at Alameda. These men have proved themselves leaders and are respected as such by the other pilots. Each day one of the three is on duty at the Alameda base, under the title of "acting division superintendent." He has full control of operations out of Alameda, he makes recommendations to the head of the operations department on duty at Los Angeles, and he keeps the latter advised at all times of unfavorable or unusual flying conditions. These three pilots have the following schedule: Each of them in turn makes a round trip to Los Angeles one day, is off duty the next day, and on the third day is in charge of operations at Alameda.

The transcontinental division is another example of this system. The stretch of country between Clovis, New Mexico (the end of the run), and Los Angeles is too long for any one man to watch. Weather conditions over this route vary widely. It is therefore divided into two sections: Section A, from Los Angeles to Winslow, Arizona; section B, from Winslow to Clovis, New Mexico.

Air operations on section A are controlled by the head of the operations department on duty at Los Angeles. Operations over section B are controlled by a duty pilot at Clovis. Four pilots are assigned to this section. A pilot flies from Clovis to Winslow one day, he returns the next, is off duty the third day, and on the fourth day he is on duty in charge of operations over the section. Thus there is a pilot thoroughly acquainted with the terrain and the weather in charge of plane movements. This pilot, while on duty, is required to collaborate closely with the weather man at Clovis, and his decisions regarding plane movements over his section are final. He releases the westbound plane from Clovis. It proceeds to Albuquerque, and at that point is again released by him by wire. It proceeds to Winslow, and at this point responsibility for its movements passes from the hands of the duty pilot at Clovis and into the hands of the head of the operations department at Los Angeles. The same scheme of things prevails with the eastbound plane, which, after reaching Winslow, passes from the jurisdiction of the Los Angeles office into that of the duty pilot at Clovis, who is thereafter responsible for its movements.

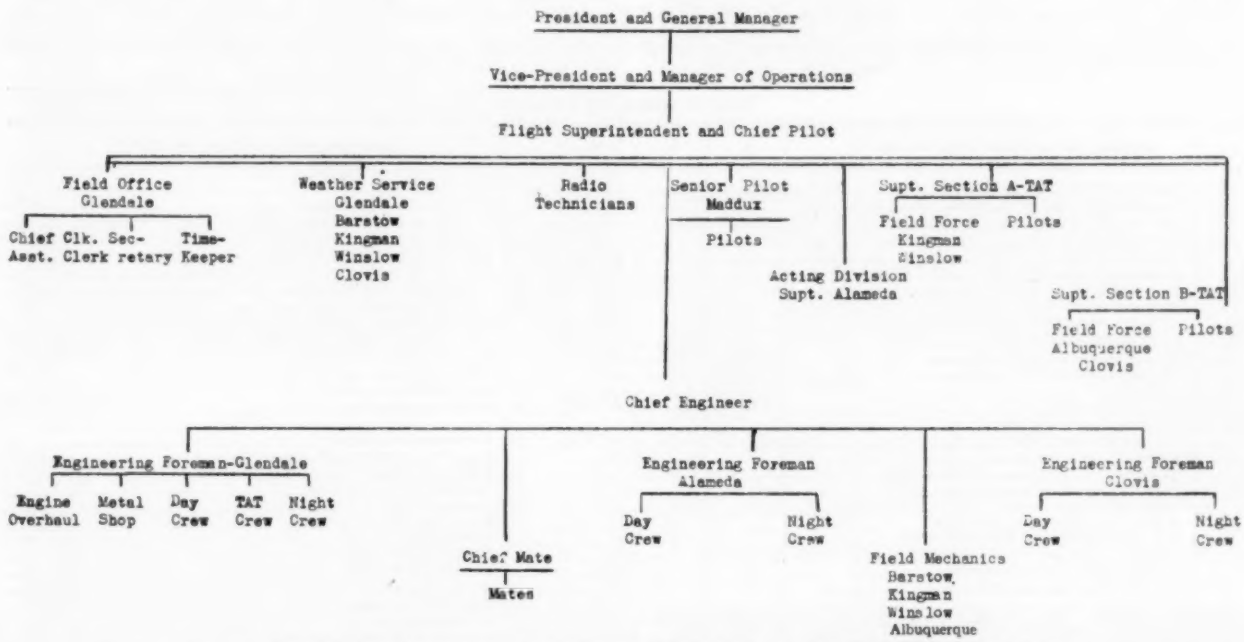

FIG. 4 ORGANIZATION CHART FOR OPERATIONS DEPARTMENT OF T.A.T.-MADDUX AIR LINES

This is based on the principle that two heads are better than one. It is believed that the pilot who is actually flying the plane has all he can do to take care of the immediate situation. He should not be asked while in flight to spend mental energy in analyzing weather conditions beyond his next stop. This job can be done by the duty pilot who, working in close cooperation with the weather service, can study carefully the reports and, together with his own knowledge of conditions gained by routine flying over the same route, arrive at a sound decision. Some may object to this arrangement on the ground that one irresponsible pilot may do untold damage. It is presumed, however, that every pilot has been selected as much for his sense of responsibility and judgment as for his flying ability.

It should be a cardinal principle in directing and managing air operations that a pilot need violate orders but once, or display poor judgment, or take unnecessary risks but once, to lose his job.

FIG. 5 MAINTENANCE REPORT FOR T.A.T.-MADDUX AIR LINES

The locomotive engineer who passes a stop signal is through. The pilot who in any way shows the least indication of lack of judgment, lack of respect for his company's policies, bad airmanship, or disloyalty to his superiors must be discharged immediately. Such action may occasionally entail some injustice to the individual, but the majority must be considered and also the fact that today human lives are at stake in this pilot's care, to say nothing of the thousands of dollars which are bound up in equipment under his control. The success of an aviation enterprise must not be jeopardized out of sentiment for some one individual.

Engineering Force

The mechanical force and the flying mates are under the chief engineer. At the base field and at outside fields where planes

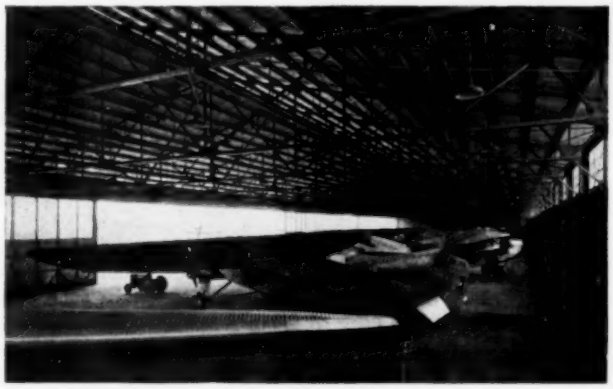

Fig. 6 Interior of Hangars at Grand Central Air Terminal, Glendale, California

Fig. 7 Despatcher's Office at Western Division Headquarters, T.A.T.-Maddux Air Lines

are regularly based overnight and maintenance work is done, there is an engineering foreman. He is responsible to the chief engineer for maintenance of equipment and for efficient workmanship by his men. In accordance with established routine, he assigns planes to routes. He is in charge of the operating line where engines are warmed up. The base-field force is further divided under the engineering foreman, as follows: (*a*) An engine-overhaul foreman is in complete charge of the engine-overhaul shops; (*b*) a metal-shop foreman is in complete charge of the metal shop and all metal work on planes or equipment; (*c*) a night foreman is in complete charge of the night crew.

The latter is a most important assignment, as the major portion of routine maintenance of planes and motors is done at night. All engines are changed at night. In order properly to fill the position of night foreman a man must be exceptionally competent. Although the chief engineer is available on call,

Fig. 8 Metal-Work Shops at Western Division Headquarters, Glendale, California

Fig. 9 Engine Overhauling Shop at Western Division Headquarters

Fig. 10 Motor Dismantling and Cleaning Department at Western Division Headquarters

the night foreman has frequently to cope with situations requiring knowledge of ship movements the following day. It is no small task to detail a night crew in such a manner as to complete the varying work necessary on as many as twelve trimotored Fords. This demands not only executive ability, but a thorough understanding of the capabilities of each man in the crew.

Inspection Forms

An inspection form is made out for each flight. This printed form shows the total plane hours, hours since overhaul of each motor, hours since etching, and check of each propeller, plane, and motor numbers, and (in column form) a list of all routine maintenance work which may be required. Before a plane leaves the operating line the chief mate inspects the plane, and if it is all right he signs the form in the proper place. The pilot then signs as accepting the plane for flight. Upon completion of the trip the mate enters the flying time for the trip. This brings the plane, engine, and propeller hours up to date.

Under the heading "Remarks" are noted any special comments regarding behavior of motors or work to be done thereon. Routine servicing required is checked in the proper place on the form. The mate then signs the form as engineer of the plane.

On arrival at the base field this form is taken up by the engineering foreman. He is responsible that the work indicated on the inspection form be performed. In event that major repairs or something unusual is required, he may consult with the chief engineer.

All foremen and mechanics are assigned numbers. Mechanics are detailed by the engineering or night foreman (as the case may be) to perform the required work. As each operation is performed and checked off, the man doing that work places his number against the check mark on the inspection form. If work is done in addition to that required by the mate of the plane, an entry is made on the last inspection form, and the number of the mechanic performing this work also appears thereon.

Thus it is possible to check on the quality of every mechanic's work. Faulty or careless workmanship can be traced directly to the man responsible. Errors by mechanics are severely dealt with.

Engine Operation

A considerable departure from the present standards of engine operations is employed. Pratt & Whitney Wasp engines are run between 400 and 500 hr. without overhaul. It is the author's belief that a smooth-running engine should not be removed from a plane and given a major overhaul merely because its log shows that it has run, say, 250 hr. An aircraft engine, such as the Wasp, will give definite indications that an overhaul is due well in advance of actual failure or even serious wear. Such engine operation presupposes painstaking and careful routine service. The periods between routine greasing, checking, and changing of oil are set very conservatively and are rigidly observed. Most satisfactory results have been obtained.

As an experiment twelve Wasp engines were allowed to go between 850 and 900 hr. before being removed from the planes for major overhaul. All these motors were top-overhauled at approximately 450 hr. At this time valves were ground and new rings installed. When torn down for major overhaul the maximum cylinder wear was 0.003 in. No cylinders were over 0.001 in. out of round. The master rod bearings showed a wear of 0.0015 in. beyond normal. A few knuckle pins were too loose and required replacing. Aside from the foregoing and new rings and exhaust valve guides, these engines were in splendid condition.

Further operating experience proved top overhauls to be uneconomical. For this reason, and because top overhauls entailed keeping a plane out of commision during a flying day, all engines are now removed for major overhaul after between 400 and 500 hr. of service. A special night crew changes all engines. Wasp engines are changed by a crew of three mechanics, this operation requiring 8 hr. to perform.

Flying Mates

The chief mate is directly responsible to the chief engineer for the assignment of mates to planes and for the manner in which they discharge their duties. The chief mate is also chief inspector of planes and is required to inspect every plane before it leaves the operating lines. The mates are flying mechanics. About half the mates are transport pilots. The other half hold limited commercial licenses. They must be expert mechanics.

A mate is assigned to each plane. He remains with this plane on all trips, except on his day off, when a relief mate is assigned. A mate is held rigidly accountable for the condition of his plane and its motors. It has been found that men of the right caliber take great personal pride in their particular planes.

With the present excess supply of pilots it is possible to find many well-trained and experienced transport pilots of first-pilot timber who are glad to avail themselves of the chance to train as mates with a view to being selected as pilots on the line as vacancies occur. A board composed of the flight superintendent, senior pilot, and division superintendents selects such pilot material from among the mates employed on the line.

As a mate is selected for the pilot availability list, he is given one hour's solo in tri-motored Fords, at the end of which time he is required to make turns and approaches to landings on one- and two-motor combinations. He is also checked for night flying and given ten solo night landings. In this manner there are always available mates who can be moved up to pilot's rating whenever they are needed.

Discipline

The day of the haphazard barnstormer or fixed-base operator is past. Discipline in the air is as essential today as in any other line of commercial endeavor. Perhaps it is more vital in aviation than in any other line, both on the ground and in the air, because of the human lives directly involved. Many fatal accidents and much avoidable inefficiency may be laid directly to lack of ordinary discipline; and hand in hand with discipline go the morale of the organization—that unspoken, intangible *esprit de corps* which exists in the rank and file—the pride of every man in his job, the knowledge that an order issued is an order to be obeyed, and the determination to work for "happy landings" which extends from the pilot in the cockpit to the humblest ship-cleaner on the field.

APM-52-1

Natural Frequency of Gears

By R. E. PETERSON,[1] EAST PITTSBURGH, PA.

The natural frequency of machine parts as related to the noise problem in machine operation is discussed in a general manner. Vibration phenomena in disks and rings are described in detail, following which the author discusses the manner in which a gear vibrates at its natural frequency. An empirical formula is given for the natural frequency of a gear in terms of its dimensions and material.

ONE of the tendencies in engineering design at the present time is to increase the speed of rotating machinery. In many cases noise and vibration become the limiting condition as the speed is increased, such being frequently the case in gear operation. This has stimulated considerable research in sound and vibration phenomena, which will eventually make it possible to deal with problems of this type in a more fundamental manner. This paper deals with a type of vibration which under certain conditions becomes important in rotating machinery.

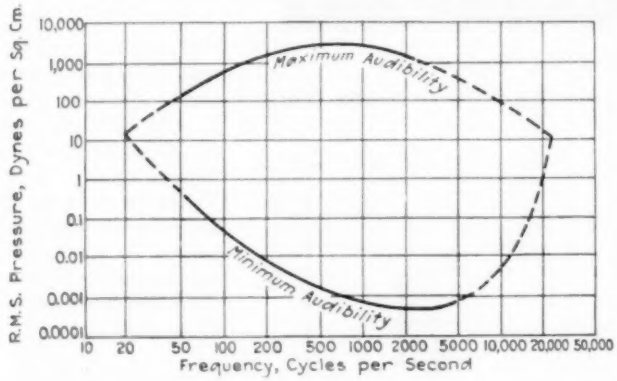

FIG. 1 RANGE OF AUDITION

If a machine part is suspended by a wire and struck with a hammer, a number of sound frequencies can be elicited by striking in various places. The lowest of these sound frequencies corresponds to the "fundamental" mode of vibration of the part, and the higher sounds are "overtones." Although all of the component sounds are "natural frequencies," it will be convenient to refer to the "fundamental" as the "natural frequency" of the machine part in question.

A study of "natural frequency" of machine parts is important for two reasons. First, if the part in question is subject to impacts it will vibrate at its natural frequency and thereby generate sound, provided the frequency is within the range of audition shown in Fig. 1.[2] Each impact will instigate a train of damped waves, as shown in Fig. 2, while the frequency is always the same, being the natural frequency of the machine part.

In gear operation it is common experience that an idling condition is apt to result in quite pronounced ringing. Particular examples of this occur in street cars during coasting and in punch presses when idling. This ringing sound has been shown experimentally to be of a frequency corresponding to the natural frequency of the drive gear. Light loads seem to be particularly conducive to the impact type of excitation referred to above. The second reason for the importance of "natural frequency" is the possibility of resonance. If the machine is operated at such a speed that a vibration occurs which is of the same frequency as the "natural frequency" of a machine part, a resonant condition occurs which may result in a tremendous increase in the amplitude of vibration. Fortunately resonance does not occur very often in gear operation according to present practice. In railway gearing, for instance, the number of tooth contacts per second is of the order of 100–300, while the natural frequency of the gear is 800–1200 cycles per second. However, with increased speeds and teeth of finer pitch, resonant conditions will occur more frequently than at present.

It will be noticed from Fig. 1 that the natural-frequency values of railway gears (800–1200 cycles per sec.) are such as to be quite close to maximum aural sensitivity. It is also apparent from Fig. 1 that to produce audibility of a sound of 1000 cycles per second requires only about one-hundredth of the pressure necessary to produce audibility at 100 cycles per second. The high sensitivity of the ear to frequencies of the order mentioned tends further to increase the importance of natural-frequency phenomena of gears.

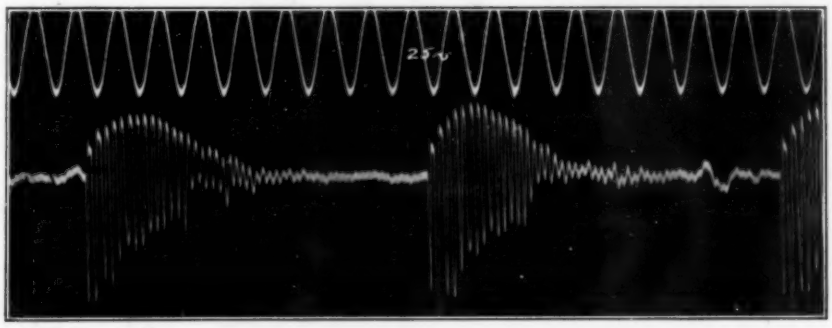

FIG. 2 TRAIN OF DAMPED WAVES DUE TO IMPACTS

Various methods of determining the frequencies of sounds are available, the following of which were tried in connection with this investigation:

1 Variable resonator
2 Microphone, amplifier, and oscillograph
3 Microphone, amplifier, and tuning-circuit analyzer.

The latter method, making use of an analyzer developed by Messrs. Spooner and Foltz,[3] proved to be the most expedient

[1] Research Engineer, Westinghouse Elec. & Mfg. Co. Assoc. Mem. A.S.M.E.

Contributed by the Applied Mechanics Division and presented at the Annual Meeting, New York, December 2 to 6, 1929, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

[2] H. Fletcher, "Useful Numerical Constants of Speech and Hearing." *Bell System Tech. Jl*, vol. 4, no. 3, p. 2.

[3] T. Spooner and J. P. Foltz, "Study of Noises in Electrical Apparatus." *Jl. A.I.E.E.*, Mar., 1929, p. 199.

and was used in obtaining the data given in this paper. Oscillograms taken according to the second method mentioned are shown in Figs. 2 and 3.

This investigation was made with particular reference to railway gearing of a rolled forged-steel type. The results, however, if judiciously used, may be applied to other types of

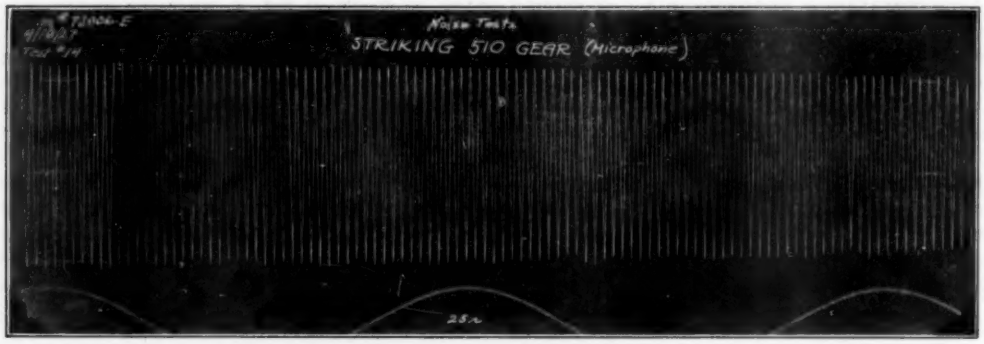

FIG. 3 OSCILLOGRAM TAKEN WITH MICROPHONE, AMPLIFIER, AND OSCILLOGRAPH

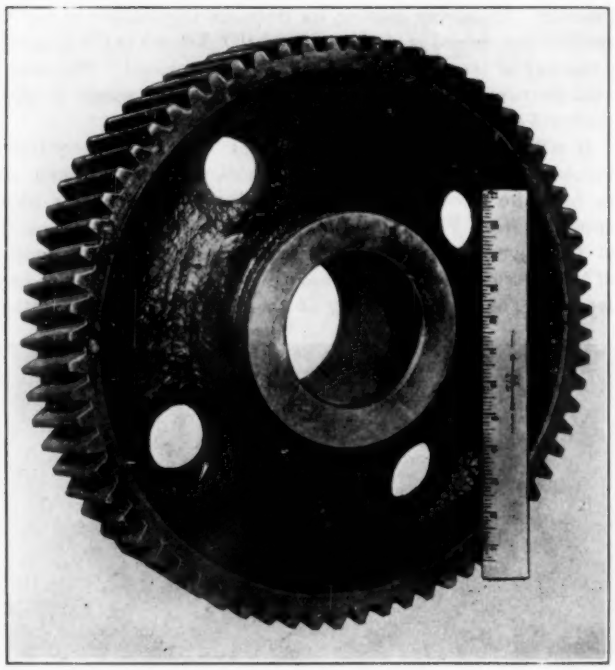

FIG. 4 TYPICAL RAILWAY GEAR

gearing, as well as to wheels, disks, rotors, and other circular machine elements. A typical railway gear is shown in Fig. 4, and a cross-section of such a gear with the notation used is shown in Fig. 5.

The first step in our analysis is to determine the upper and lower limits of frequencies which are possible in such a design, keeping the same face width and diameter. Considering first the unbored blank (before cutting teeth), when $w = a$, the result is a disk having a width a and an outside diameter d_o; and when $w = 0$, the result is a ring of width a and thickness t_b. The disk will have the highest frequency possible for a given width and diameter of gear space, while the ring will have the lowest frequency for the same space. An actual gear will have a frequency intermediate between the disk and the ring, depending on the web dimensions. It is clear, then, that a fundamental study of the vibration of disks and rings forms a logical basis for this work.

DISK VIBRATION

The natural frequency of a thin disk was solved analytically by Kirchoff[4] in 1850.

$$p^2 = \mu \frac{Eh^2}{\rho a^4} \quad \ldots [1]$$

where p = frequency $\times 2\pi$
E = Young's modulus
h = half-thickness
a = radius
μ = numerical coefficient depending on mode of vibration and on Poisson's ratio.

The mode of vibration having the lowest frequency has two nodal diameters (Fig. 6), for which $\mu = 10.61$ when a value of 0.3 is used for Poisson's ratio. Using a value of 30×10^6 lb. per sq. in. for E and a density of 490 lb. per cu. ft., the following formula will give the lowest frequency of a thin steel disk:

$$f = 208{,}400 \frac{w}{d^2} \quad \ldots [2]$$

where f = frequency of vibration in cycles per second
w = thickness of disk in inches
d = diameter of disk in inches.

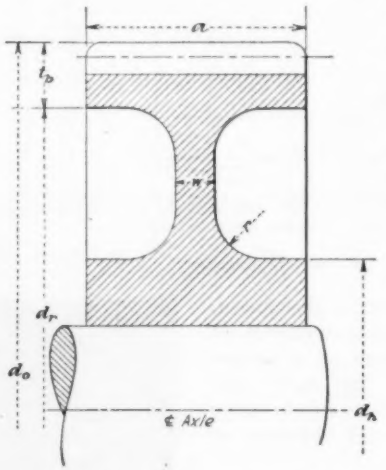

FIG. 5 CROSS-SECTION OF A GEAR, SHOWING NOTATION USED

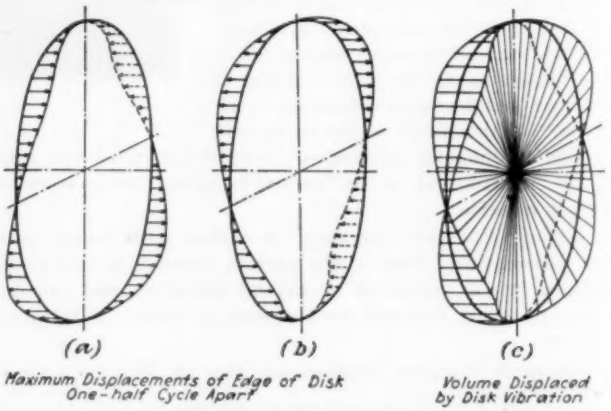

FIG. 6 VIBRATION OF A DISK (FUNDAMENTAL MODE)

[4] "Über die Schwingungen einer elastischen Scheibe," *Crelles Jl.*, vol. 40, 1850; *Pogg. Ann.*, vol. 81, 1850. See also "The Vibrations of a Spinning Disk," H. Lamb and R. V. Southwell, *Proc. Royal Soc., A.* vol. 99, p. 272.

Inasmuch as the foregoing formula applies only to thin disks it was necessary to determine frequency values experimentally for relatively thick disks. Three different diameters were used, and the results are given in Table 3 and shown graphically in Fig. 7. It will be noticed that for thin disks the agreement between theory and experiment is close, but that for thicker disks the slopes of the experimental curves decrease with increasing thickness.

Ring Vibration

The natural frequency of a ring was solved analytically by Hoppe in 1871 for radial vibrations such as are shown in Fig. 8.[5]

$$p^2 = \frac{EI}{\gamma r^4} \times \frac{s^2(s^2-1)^2}{1+s^2} \quad \ldots\ldots\ldots\ldots\ldots [3]$$

where p = frequency $\times 2\pi$
I = moment of inertia of cross-section

TABLE 1 DATA ON FREQUENCIES OF RINGS

(Thickness in radial direction = 1 1/16 in.)

Type of vibration	Mode of vibration	Outside diameter, d_o (inches)	Width in inches (in axial direction) 3 1/2	2 1/2	1 1/2	5/8
Radial	4 loops	10 3/8	1230	1230	1220	1225
		12 7/8	760	..	720	740
		18 3/4	320[a]	300[a]	310[a]	300[a]
	6 loops	10 3/8	3300	3400	3350	3350
		12 7/8	2080	..	2050	2000
		18 3/4	920	920	930	905

TABLE 2 RATIO OF FREQUENCY OF SIX-LOOP VIBRATION TO FOUR-LOOP VIBRATION

Type of vibration	Outside diameter, d_o (inches)	Width in inches (in axial direction) 3 1/2	2 1/2	1 1/2	5/8
Radial	10 3/8	2.68	2.77	2.75	2.74
	12 7/8	2.74	..	2.85	2.71
	18 3/4	..	..	..	..
Axial	10 3/8	..	..	2.76	2.78
	12 7/8	..	..	3.10	2.88
	18 3/4	2.78	3.05	2.93	..

Avg. ratio = 2.83.

r = mean radius of ring
s = number of complete wave lengths in circumference
E = modulus of elasticity
γ = mass per unit length of ring (on arc).

The fundamental type of vibration of a ring is similar to that of a disk (Fig. 6) in that there are two nodal diameters, mutually perpendicular. Therefore, in the Hoppe formula [3] $s = 2$ for the fundamental mode. The first "overtone" will be a type of vibration having three nodal diameters ($s = 3$) as shown in Fig. 8 (*b*).

Using values of $E = 30 \times 10^6$ lb. per sq. in., $\sigma = 0.3$, and a density of 490 lb. per cu. ft., the following formula results, giving the lowest frequency for radial vibrations of steel rings of rectangular cross-section:

$$f = 25{,}000\ \frac{t}{r^2} \quad \ldots\ldots\ldots\ldots\ldots [4]$$

where f = frequency in cycles per second
t = thickness in radial direction (inches)
r = mean radius (inches).

It will be noticed that according to formula [4] the frequency

[5] Rayleigh, "Theory of Sound," p. 417. Lord Rayleigh gives a solution for the radial vibrations of a long, thin tube. This differs from Equation [3] by the "plate modulus" $1/(1-\sigma^2)$, where σ = Poisson's ratio, the difference in frequencies being of the order of about 4 per cent. Equation [3] is the one which is applicable in this case, since in gears the axial dimension is less than the radius.

of radial vibrations is independent of the width (in the axial direction) of the ring. This is verified experimentally by the data of Table 1. The close agreement between theoretical and experimental values is shown by Fig. 9.

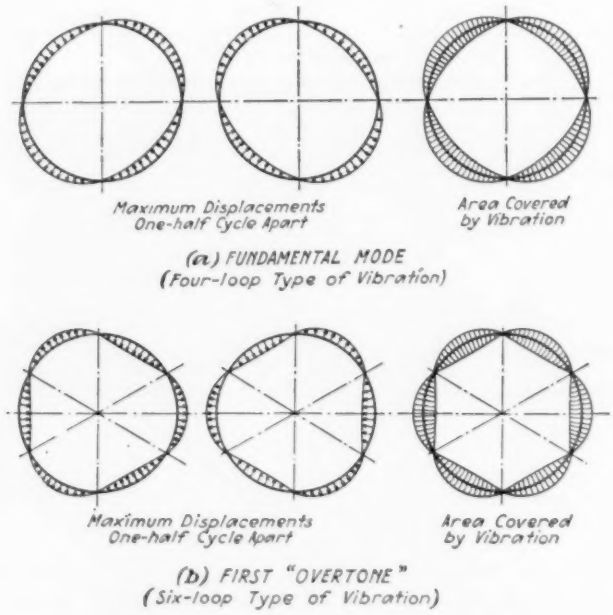

FIG. 8 RADIAL VIBRATIONS OF A RING

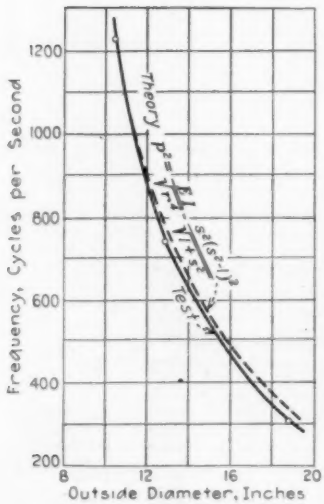

FIG. 9 NATURAL FREQUENCY OF RINGS (FOUR-LOOP RADIAL VIBRATIONS)

(Steel rings $1^1/_{16}$ in. thick; widths, $^5/_8$ in., $1^1/_2$ in., $2^1/_2$ in., and $3^1/_2$ in. See Table 1.)

Frequencies corresponding to both four-loop and six-loop types of vibration are given in Table 1. According to the Hoppe formula [3], the ratio of the frequency of a six-loop vibration to the frequency of a corresponding four-loop vibration should be 2.82. An average of the ratios of the experimental values as given in Table 2 (omitting approximate values) is 2.83. This furnishes an excellent check on the data, and also indicates a method of obtaining the value of a fundamental frequency of a ring which is too low for the apparatus (below 200–300 cycles per sec.) by obtaining the first overtone and dividing by the above ratio.

The frequencies of rings when vibrating in an axial direction (similar to Fig. 7) were also determined experimentally and are given in Table 1 and shown graphically in Fig. 10. The axial type of vibration of a ring is of particular interest because it furnishes the lower frequency limit referred to previously. This is due to the fact that the web of the gear prevents the rim from vibrating in a strictly radial manner such as in Fig. 8. In an axial direction, however, the web has much less stiffening effect, so that such vibrations are easily elicited. Therefore only the axial-frequency data are used in building up the frequency formula for gears.

VIBRATIONS OF A GEAR

Although the web of the gear prevents the rim from vibrating in a strictly radial manner, there is a radial vibration of the rim due to the axial vibration discussed above. This is clear from the cross-section (*a*) in Fig. 11, which shows that an axial displacement s is accompanied also by a rotation θ of the rim section. A similar cross-section (*c*) taken 90 deg. from (*a*) would show, at any particular instant of vibration, displacement and rotation in a direction opposite from (*a*). A nodal cross-section (*b*) would have no motion in an axial plane, remaining always as shown in (*b*). From these remarks it can be concluded that the rim of the gear vibrates in the form of a warped surface, and not as a cylindrical surface as shown in Fig. 8.

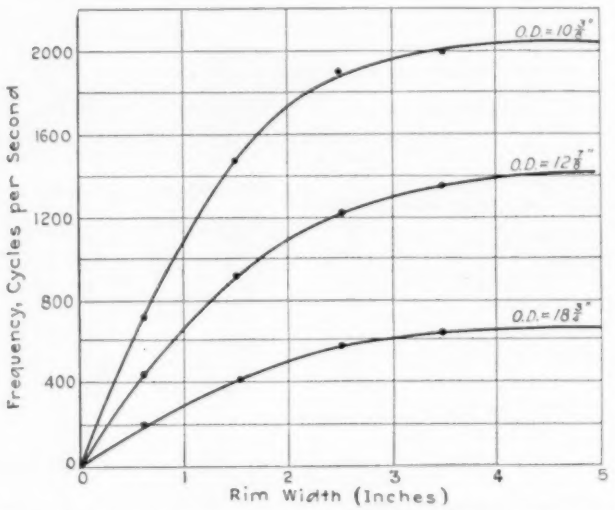

FIG. 10 NATURAL FREQUENCY OF RINGS (FOUR-LOOP AXIAL, FOR RIM THICKNESS = $1^1/_{16}$ IN.)

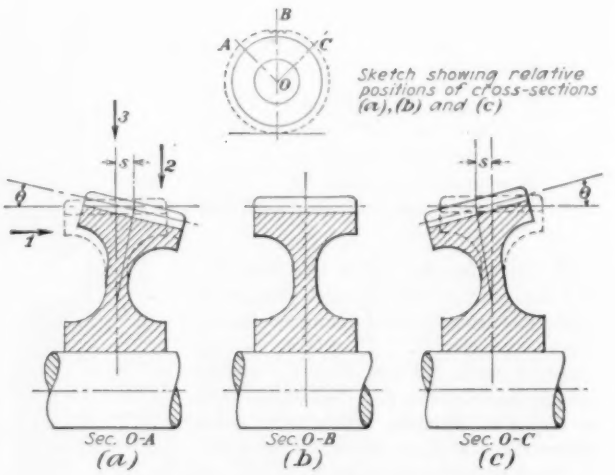

FIG. 11 VIBRATION OF A GEAR RIM

This can be verified experimentally, in that the "natural-frequency" sound can be elicited not only by striking the rim axially [direction 1 of Fig. 11 (*a*)], but also by striking an edge of the rim radially (direction 2). The "natural frequency" cannot be elicited by striking directly over the web [direction 3 as applying to the dotted outline of Fig. 11(*a*)], which should be obvious from the foregoing remarks. It follows that meshing gears in which the mating-tooth elements are not parallel ("riding on

an edge") will be more prone to ring than gearing properly aligned.

The nodal positions of a gear rim can be demonstrated by the set-up shown in Fig. 12. The gear standing on the table will have a node at *a* where the gear makes contact with the table. The remaining nodes are then at *b*, *c*, and *d*. A point *e* midway between *a* and *b* (45 deg. from the vertical diameter) will correspond to a position of maximum amplitude of a loop. In performing the demonstration, the gear is struck a series of successive blows with a babbitt hammer at *e*. The sound is received by the microphone *P* and its frequency determined by the analyzer *A*. The sensitivity of the apparatus is adjusted so that practically a full-scale reading results on the meter *M*. If the hammering is continued with the same vigor, but the point of contact is slowly shifted along the rim from *e* to *b*, the meter reading will drop correspondingly from a maximum to practically zero. Continuing the hammering from *b* to *c* along the rim will cause the meter reading to rise and fall again. Proceeding all around the rim shows practically zero readings at *a*, *b*, *c*, and *d* (nodes) and maximum readings at points midway between the nodes. Although this phenomenon is best demonstrated by means of the apparatus as described, it is distinctly noticeable by listening with the unaided ear; the effect, however, is somewhat masked due to contact noise of the hammer.

FIG. 12 SET-UP FOR DEMONSTRATING NODES

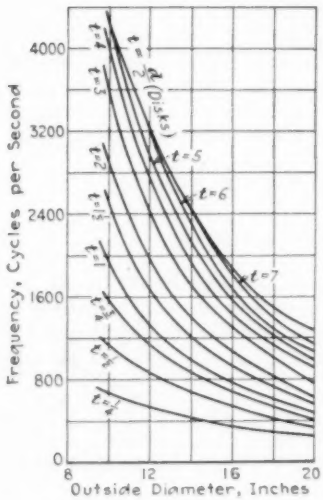

FIG. 13 NATURAL FREQUENCY OF RINGS (FOUR-LOOP AXIAL, FOR WIDTH = 2½ IN.)

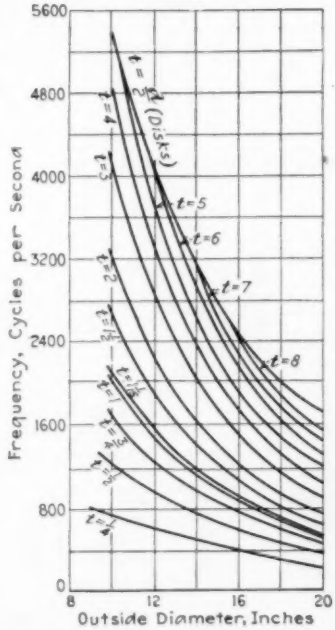

FIG. 14 NATURAL FREQUENCY OF RINGS (FOUR-LOOP AXIAL, FOR WIDTH = 3½ IN.)

NATURAL-FREQUENCY FORMULA

As previously explained, the frequency of a gear will be intermediate between that of a ring represented by the rim and a disk represented by the gear space. From Figs. 7 and 10, a series of ring-frequency charts were made for ring widths of 2½ in., 3½ in., 4 in., and 5 in. (Figs. 13, 14, 15, and 16). These widths were chosen to correspond to the face widths of railway gears. From the data given, other similar charts can readily be made for other widths. The upper curve in each chart represents disk frequencies (the ring thickness then being equal to half the outside diameter). The upper and lower frequency limits can be determined by use of one of the charts shown. Thus for a gear having an outside diameter d_o = 16 in., a face $f = 3\frac{1}{2}$ in., and a rim thickness t_b = 1 in., the frequency range becomes 860–2560 cycles per sec., corresponding to the ring and disk frequencies of Fig. 14. The actual frequency of the gear will be somewhere between the limits determined above, depending on the stiffening effect of the web.

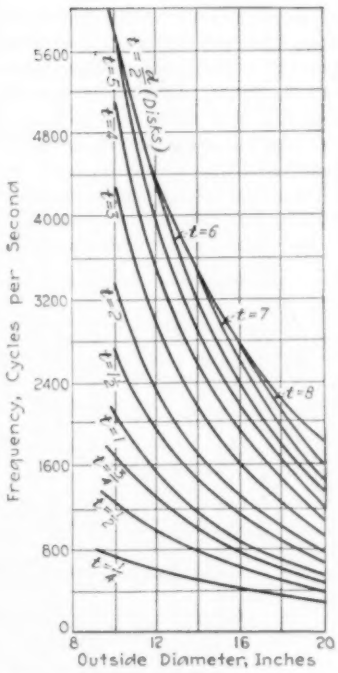

FIG. 15 NATURAL FREQUENCY OF RINGS (FOUR-LOOP AXIAL, FOR WIDTH = 4 IN.)

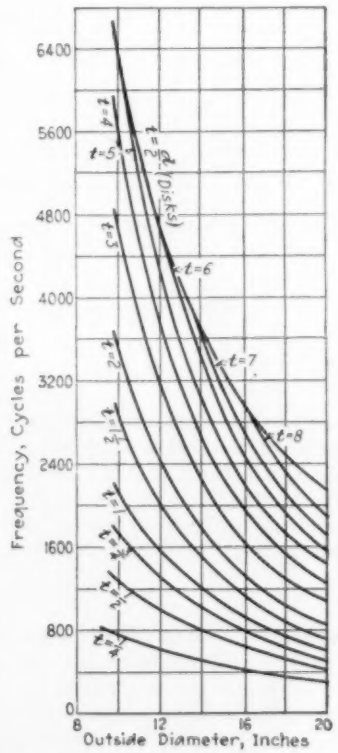

FIG. 16 NATURAL FREQUENCY OF RINGS (FOUR-LOOP AXIAL, FOR WIDTH = 5 IN.)

If the stiffening effect of the web be denoted by K_w, the

actual effect may be formulated as applying to the frequency range discussed above in the following manner: $K_w(f_d - f_r)$, where f_d = frequency of disk and f_r = frequency of ring. The web factor K_w depends on the ratio w/a, and must be such that $K_w = 0$ when $w/a = 0$, and $K_w = 1$ when $w/a = 1$. The web factor also depends on the ratio of d_h/d_r, and must be such that $K_w = 1$ when $d_h/d_r = 1$.

From the data of Table 3, a chart (Fig. 17) was made giving K_w as a function of d_h/d_r, with w/a as a parametric relation.

The data for web effect were taken on blanks having a fillet

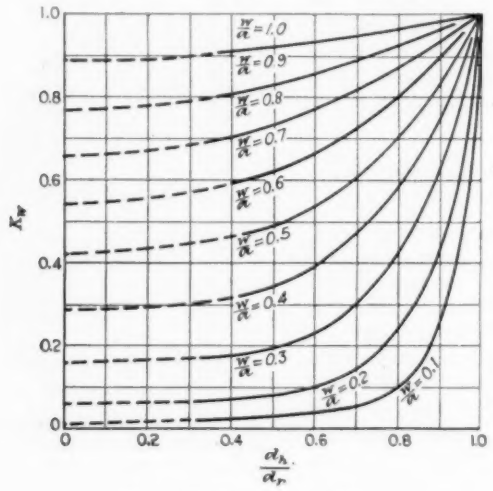

FIG. 17 WEB EFFECT K_w

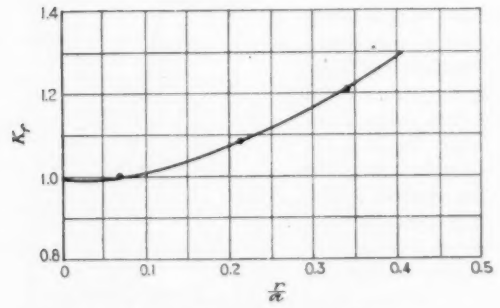

FIG. 18 FILLET EFFECT K_f

radius $r = 1/4$ in. To determine the effect of fillet radius, a series of tests were made wherein only the fillet radius was changed. The results of these tests are shown in Fig. 18, where the abscissas are given as a function of r/a, the fillet factor K_f applying to the entire blank. Thus the frequency of the steel blank (before cutting the teeth) becomes

$$f_b = K_f[f_r + K_w(f_d - f_r)] \quad [5]$$

where f_b = frequency of steel blank, cycles per sec.
K_f = fillet factor (Fig. 18)
K_w = web factor (Fig. 17)
f_r = frequency of ring (Figs. 13–16)
f_d = frequency of disk (Figs. 13–16).

The effect of cutting teeth on the frequency of the blank was determined for four gears (Table 4). On the basis of these rather incomplete data, Fig. 19 was drawn. For the types of gearing investigated, the effect of cutting teeth may be approximated by $K_t = 0.9$. Thus the formula for the complete steel gear becomes

$$f_g = 0.9\ K_f[f_r + K_w(f_d - f_r)] \quad [6]$$

where the notation is as given above for the frequency of the blank.

The effect of heat treatment on natural frequency was shown to be negligible (Table 5). The four holes usually bored through the web also have practically no effect on frequency. The same is true of bore size, the hub diameter being taken account of in the web factor K_w.

Formulas [5] and [6] are applicable only when the material is steel. A formula will now be given for use in connection with materials other than steel.

In Equation [1] the material is represented as a function of $\sqrt{E/\rho}$ which is the velocity of sound in the material.[6] This is also true in Equation [3], and is quite generally the case for solids other than disks and rings.

For steel having $E = 30 \times 10^6$ lb. per sq. in. and a density

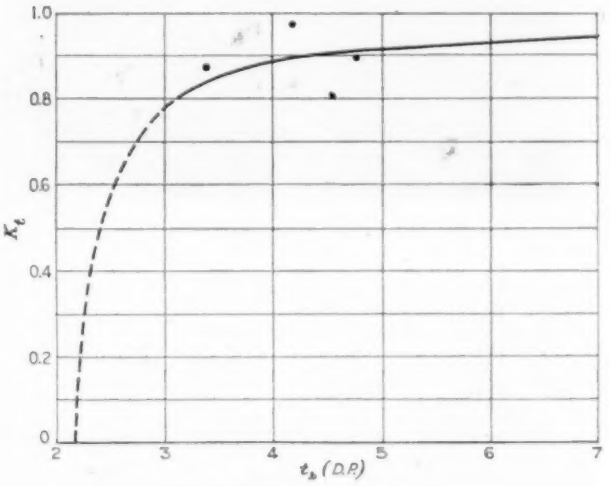

FIG. 19 EFFECT OF TEETH K_t

of 490 lb. per cu. ft., the velocity becomes 16,800 ft. per sec. The comparative effect of materials may therefore be entered as $V/16{,}800$ or $V \times 5.95 \times 10^{-5}$ where V = velocity of sound in the material in ft. per sec. (See Table 6.) Formula [6] then becomes

$$f_g = 5.35 \times 10^{-5}\ V\ K_f[f_r + K_w\ (f_d - f_r)] \quad [7]$$

TABLE 4 EFFECT OF CUTTING TEETH ON FREQUENCY

No. of teeth	D.P.	t_b	Frequency — Blank	Frequency — Gear	K_t

75	3	444	455	+11	+2.5
69	4	900	895	− 5	−0.6
53	4¼	1360	1360	0	0

After completing the work just described, it was thought desirable to check the frequencies obtained by formulas [5] and [6] for a number of gears picked at random against the actual frequencies as determined by the analyzer. This was done for twelve gears, and the results are given in Table 7. The average numerical error (departure from test value) is

[6] Barton, "Text Book of Sound," vol. 1, p. 183.

5 per cent. The errors are plus and minus, so that the average algebraic error is less than 1 per cent. It may therefore be concluded that the above formulas give good results for gears having a rim thickness between 3/4 in. and 1 1/2 in. and an outside diameter between 12 in. and 36 in. It may be possible to extrapolate the data to sizes out of the range specified, but the accuracy of such a procedure has not as yet been checked.

In order to determine the natural frequency of a gear, the following measurements should be made with an ordinary scale:

(1) d_o = outside diameter
(2) d_r = rim diameter (inside)
(3) d_h = hub diameter
(4) a = face
(5) w = minimum web thickness
(6) r = fillet radius (estimate).

$$t_b = \frac{d_o - d_r}{2}$$

The frequency is then obtained by substituting in formula [6] values obtained from one of the ring charts (Figs. 13–16, depending on face width), and other values obtained from Figs. 17 and 18.

It is hoped that the data given in this paper may also prove useful in connection with applications other than gearing.

ACKNOWLEDGMENT

Acknowledgment is due Messrs. T. Spooner and J. P. Foltz for the use of the sound analyzer and for assistance in obtaining the data, to Mr. J. P. Den Hartog for suggestions in regard to presentation of the ring frequency equations, and to Messrs. C. Bethel and J. M. Lessells for instigation and encouragement of gear-noise research.

Discussion

A. A. Ross.[7] 'It may be of interest to know how we attempt to change this natural frequency in railway gears. Everybody will agree that the average street car is noisy. The gear is blamed for the larger part of the noise, although in reality it is responsible for a very small part of it.

[7] Engineer, Gear Department, General Electric Company, West Lynn, Mass.

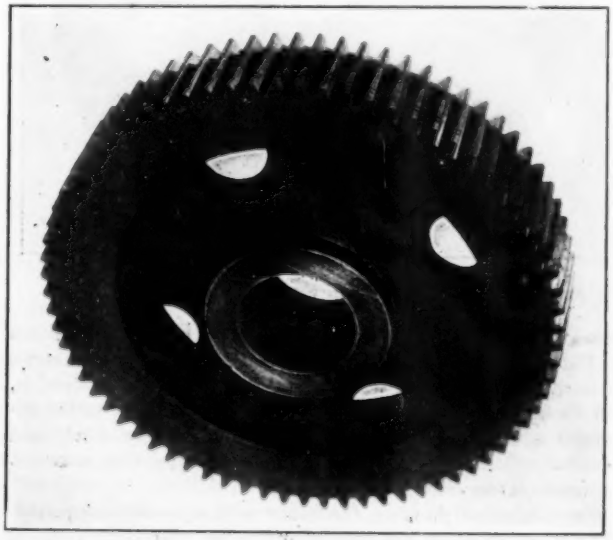

FIG. 22 CAST-STEEL GEAR SHOWN IN PLAN IN FIG. 21

In 1922 and 1923 we began a study of some commercial method of deadening railway gears or to change the natural frequency in order to overcome the very objectionable high-pitch ringing it stick. This led to the type of gear shown in Figs. 21 and 22, which are cast-steel gears with circumferential webs on each side of the rim which collected the grease in the gear pan. This acted as a satisfactory deadener, and in order to produce this same effect on the forged gear, grooves were cut on the under side of the rim and sheet-metal rings were snapped into the grooves, as shown by Figs. 23 and 24. These sheet-iron rings were snapped in place in much the same way as the retaining rings that hold an automobile tire, and after the rings were snapped in, the ends were spot-welded.

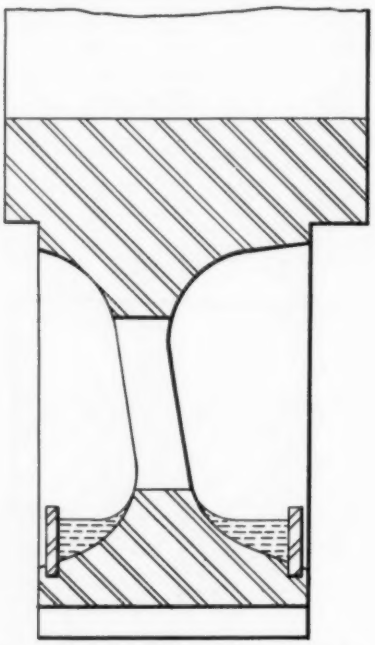

FIG. 23 FORGED OR CAST NON-RESONANT GREASE-TYPE GEAR

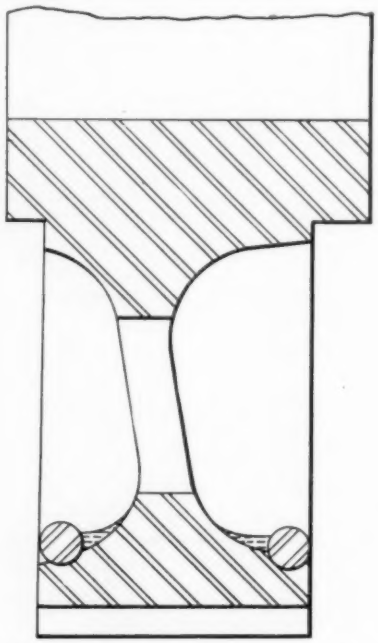

FIG. 25 FORGED OR CAST NON-RESONANT RING-TYPE GEAR

Both the cast and forged grease-type gears were effective from a deadening point of view, but the customers objected to the additional amount of grease which it was necessary to put into the pan, their objection being that much grease was thrown out on the street. Several thousands of this type of gear have been placed in service.

To overcome the objections to the added amount of grease it was discovered that sheet-steel rings, shown in the forging in Figs. 23, 24, 25, and 26, had a considerable deadening effect without the grease, and this led to what we call our standard non-resonant type of railway gears, as shown in Figs. 25 and 26. By this plan a groove was cut on the under side of the rim, both in the casting and the forging, and $^3/_{16}$-in. cold-rolled rods were wound into rings and snapped into the grooves, and the ends were spot-welded. It is surprising to notice the deadening effect between this type of gear and one without rings.

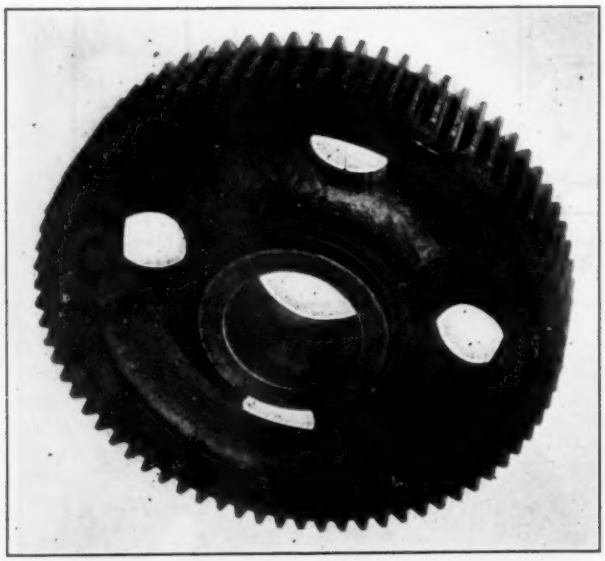

FIG. 24 CAST-STEEL GEAR SHOWN IN PLAN IN FIG. 23

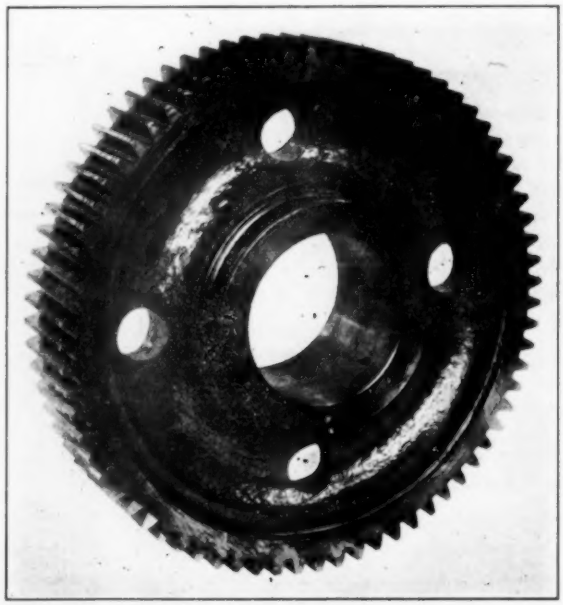

FIG. 26 FORGED OR CAST GEAR SHOWN IN PLAN IN FIG. 25

sound when the car is coasting. This brought out a gear as shown by Fig. 20. This is a double-web, cast-steel gear with a space between the webs filled with ground cork. This was effective, and about 500 were placed in service, but they were rather expensive to make and could be furnished only in cast steel; and since the rolled forged gear was the popular type, they were not a commercial success.

We then tried painting the gears with a heavy compound, which when dried on was very effective, but vibrations loosened the compound, and we could find no satisfactory way of making

GEORGE B. PEGRAM.[3] It is stated in the paper that the number of tooth contacts per second in railway gearing is 100 to 300,

[3] Dean, School of Mines, Engineering, and Chemistry, Columbia University, New York, N. Y. Mem. A.S.M.E.

while the natural frequency of the gear is 800 to 1200 cycles per second. Likening the system to a pendulum which receives timed impulses at definite intervals of a few swings, it might be expected that with the natural frequency of the gear 1200 cycles per second, for example, distinct resonance of this type might appear when the number of tooth contacts is, say, 300 per second, giving an impulse every fourth vibration. Does this actually occur?

The curves in Fig. 7, representing a comparison of frequencies of circular plates as obtained empirically with those obtained from Kirchoff's formula, are very interesting. They show that the theoretical formula is very satisfactory if the thickness is small in comparison with the radius of the plate. For thicker plate, the discrepancy obtained can be explained by taking into account the effect of shearing forces. Due to these forces, the flexibility of the plate increases, hence the lowering of the frequency with increase in the thickness of the plate.

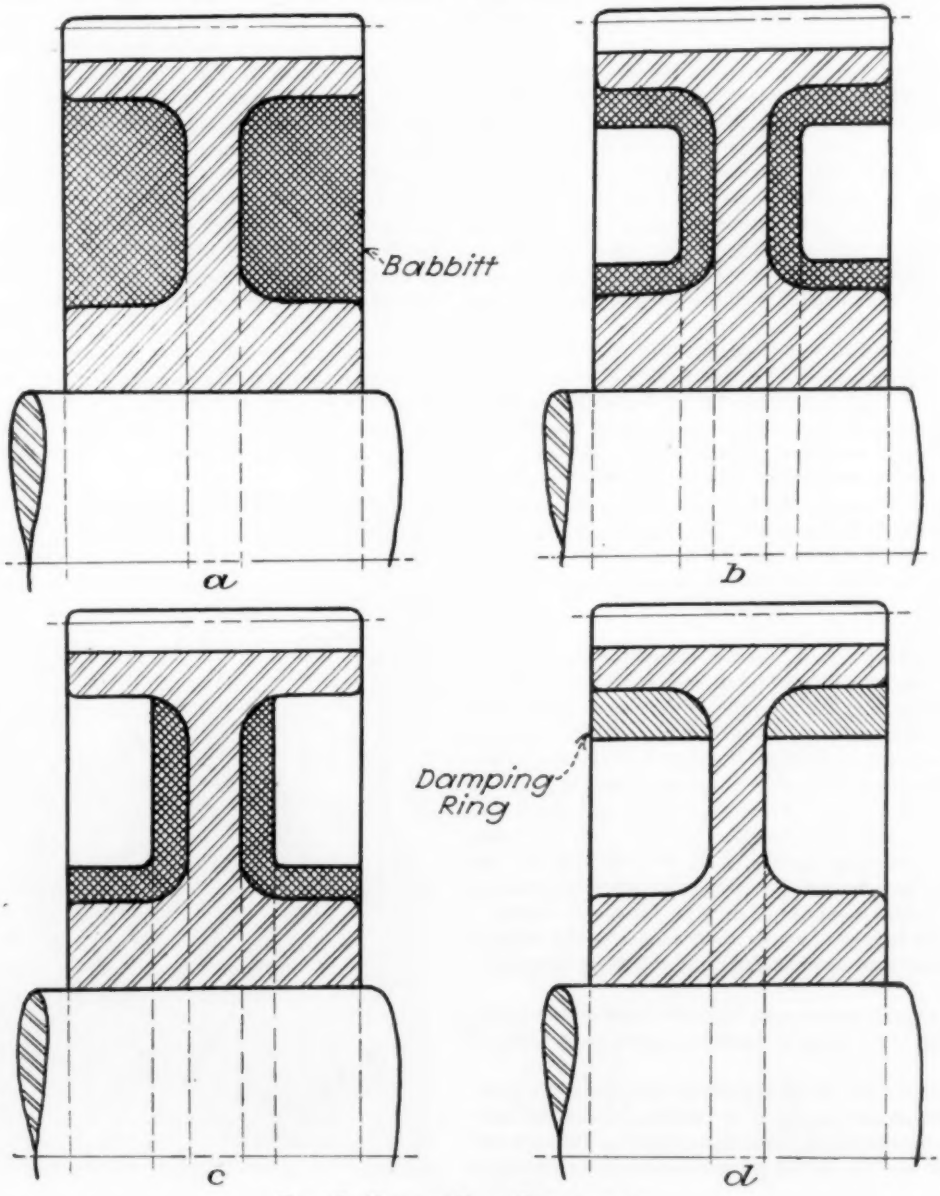

FIG. 27 DAMPING-RING DEVELOPMENT

S. TIMOSHENKO.[9] The author must be congratulated on his very interesting paper. By using empirical method, a table of frequencies of gears of various proportion was established which enables a designer to predict with sufficient accuracy the frequency of vibration of a gear, knowing the dimensions and physical properties of the material.

SANFORD A. MOSS.[10] The author has given a remarkable treatment of a subject which, so far as the writer has been able to find out, has never before been discussed. The method of vibration of a thin disk has long been known. Spreading sand on a horizontal disk, which is then set into vibration, results in the collection of

[9] Professor of Mechanical Engineering, University of Michigan, Ann Arbor, Mich. Mem. A.S.M.E.

[10] Engineer, Thomson Research Laboratory, General Electric Company, Lynn, Mass. Mem. A.S.M.E.

the sand along two diameters, which are thereby shown to be at rest, with spaces of maximum oscillation between.

As the writer understands it, the author shows that the well-known ringing sound of a noisy gear is exactly the same sort of thing. His demonstration of this and his method of computing the period are novel and remarkable. Of course, it is well understood that poorly cut teeth and other items contribute to gear noise. Nevertheless, the author's treatment of actual frequency of the gears is a fundamental item.

However, the mere scientific analysis of the fundamental principles of noisy gears leaves the subject very much in the condition of the successful operation where the patient died. Not only must we have the scientific analysis which the paper presents but also means of eliminating the noise. There are a number of methods of doing this which wholly depend upon the stopping of the natural vibration which the author discusses, and some mention of these should be included in the paper. All of these methods accomplish the same thing that is accomplished by the soft pedal of a piano when it touches a vibrating string and so serves to damp the vibration.

A. A. Ross, of the Metal Gear Department of the General Electric Company, has accomplished much in this direction. The device which he now has in commercial use, consisting of metal rings fitting in grooves at each edge of the gear rim, makes a remarkable difference in the noise. A gear without the ring, when tapped with a hammer, makes the ringing sound which the author so ably treats. If, then, Mr. Ross's rings be snapped in place, the ringing sound entirely disappears, leaving only a low thud. The exact reason for all of this is completely given by the author. The writer is informed that the noise of a gear in service is similarly affected.

J. P. Den Hartog.[11] A. A. Ross mentions the fact that the ringing of a gear can be prevented by slipping in two rings, having initially a larger diameter than the slot in the gear in which they fit. The action of these rings, in the writer's opinion, is due to the small relative motions between the rings and the gear while vibrating. This causes dissipation of energy, which is in a way proportional to the product of the relative displacements and the friction. It is clear that when the pressure between the ring and the gear is very small or zero, there is no friction and the scheme does not operate. On the other hand, when the pressure between ring and gear is very great or when the ring is welded to the gear in a large number of points, there cannot be any relative motion, consequently no energy dissipation, and again the scheme will not work.

Between these two extreme cases, however, there must be some pressure at which the ringing is deadened in the most effective manner.

I would like to ask Mr. Ross whether he ever has noticed any differences in the deadening action of various rings in the same gear, and if so, whether he has found any correlation between this deadening action and the initial pressure between the rings and the gear.

Author's Closure

The discussion has been unusually profitable, and the author wishes to express his appreciation to all who have participated. A particularly interesting feature was the discussion of the methods of damping natural frequency ringing of gears. The manuscript for this paper was prepared over two years ago, and although damping rings were in use at that time, not enough was known concerning their behavior to enable the author to include an accurate scientific treatment of the damping phase of the subject. Our initial experience with damping means was rather interesting. We realized from the manner in which a gear vibrates (Fig. 11) that practically all of the vibration was in the rim. To check this an experiment was made, using babbitt as a damping medium. A gear was filled with babbitt as shown in Fig. 27*a* and was very dead when struck with a hammer. Then the babbitt was cut out until a $^3/_8$-in. shell remained, as shown in Fig. 27*b*, which arrangement was also dead. The next step was to cut the babbitt away from the rim portion as shown in Fig. 27*c*, resulting in a gear which had a lively ring when struck with a hammer. This confirmed the theory as to the source of vibration and made it clear that the place to apply damping means was to the rim. A large number of damping rings have been applied since that time, but it is only recently that the fundamental action involved has been realized. The damping takes place in the manner described by Dr. Den Hartog in his discussion—i.e., a sliding friction due to relative motion between the ring and the rim. That a relative motion will ensue is clear from a consideration of Fig. 11. Dr. Den Hartog points out that at very loose or very tight pressures the ring should be ineffective. This has been known for some time to be the case, but only recently has the author been able to obtain experimental verification, making use of the sound analyzer and a source of constant energy excitation in the form of the hammer-blow apparatus shown in Fig. 28.

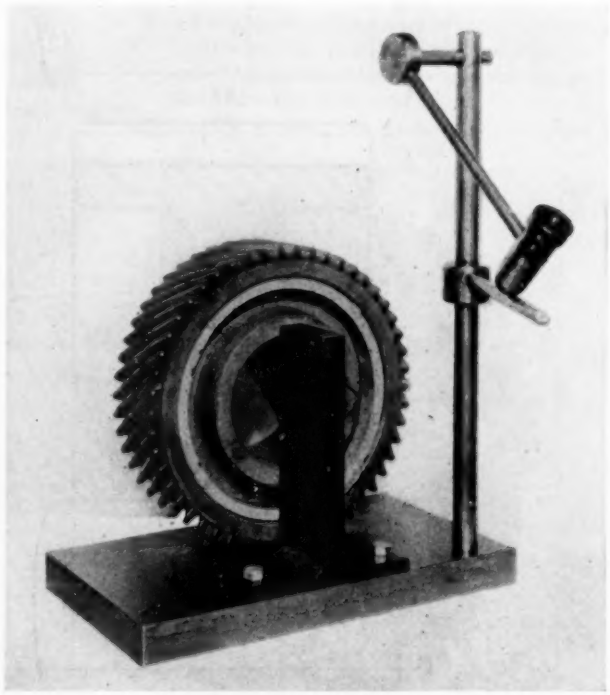

Fig. 28 Hammer-Blow Apparatus

The author feels that Mr. Ross is to be congratulated on producing an inexpensive damping device. The fundamental action in all devices of this kind seems to be the same, and it is interesting to note that results of quite similar nature were evolved from developments which proceeded independently along radically different lines.

Dean Pegram raised the question of resonance due to excitation which is a sub-multiple of the natural frequency of the gear. Such resonance does not occur,[12] as can be shown from

[11] Engineer, Research Department, Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa. Assoc-Mem. A.S.M.E.

[12] Frith and Buckingham, "Vibration in Engineering," p. 36.

general vibration properties.[13] The ratio of periods mentioned by Dean Pegram is 0.25 and by reference to Fig. 255 of "Applied Elasticity,"[13] it is seen that the resonant effect is about 1.05. This means an increase in amplitude of about 5 per cent, which is small compared to resonant effects of several hundred per cent.

[13] Timoshenko and Lessells, "Applied Elasticity," p. 331.

The remarks of Dr. Timoshenko concerning plate theory are interesting. The effect of the shearing forces is capable of analytical solution, and it may prove interesting for some one to work this out and compare the results with the actual frequency measurements on thick plates as given in this paper.

In conclusion, the author wishes particularly to express his gratitude for the discussion by Dr. Moss and for his comments before and after the presentation of the paper.

APM-52-2

Factor of Safety and Working Stress[1]

By C. RICHARD SODERBERG,[2] VESTERAS, SWEDEN

This paper contains a general discussion of the fundamentals on which working stresses in machine parts should be based. The terms "failure" and "factor of safety" are also discussed. Rules for the determination of working stress as established by the East Pittsburgh Works of the Westinghouse Co. are given. It is stated as the author's opinion that the engineering profession is in need of a general code on the subject of working stress. The beginning of such a code has been made in the "Code for Design of Transmission Shafting" approved by the American Standards Association in 1927. In an appendix, this code is also discussed. It is hoped that this paper may lead to some action on the part of the A.S.M.E. toward the establishment of a general standard or code on the subject.

Introduction

CALCULATION of the strength of a mechanical structure is properly subdivided into two problems:

(1) Determination of the stresses actually existing in the various parts of the structure.

(2) Determination of the danger of failure of the various parts of the structure under these stresses, or, as it is usually expressed, determination of the working stresses corresponding to a certain factor of safety.

Both are problems in the theory of elasticity, and both have been the subject of much theoretical and experimental study. In practical engineering work, however, the former problem has been given far more attention than the latter.

One of the reasons for this is the difference in the nature of the two problems. The results in the former appear as solutions of certain mathematical problems, and have a satisfactory degree of preciseness and accuracy. The final conclusions in the second problem, on the other hand, are based upon experiments both difficult in execution and interpretation and extending into several branches of engineering science. In addition, our knowledge of the mechanism of strength and failure of engineering materials is discouragingly incomplete, and it is only in recent years that definite and reliable principles have started to emerge out of the controversy between different theories.[3]

It seems safe to state, at the present time, that there are very few engineering problems where it is not possible by theoretical reasoning or experiments to arrive at a practical solution of the existing stresses, provided that the nature of the problem warrants the expenditure of the necessary effort. When the consequences of these stresses are to be predicted, however, the solution, if at all possible, is very uncertain, and it is only in certain simple problems that the results of independent engineers will agree. This condition will remain even if we eliminate the element of variability in our materials; it exists partly because of the lack of knowledge on the subject and partly because of the lack of clear definitions.

From a practical point of view it is obvious that a stress calculation, however complete and correct, is utterly useless unless it is associated with an evaluation of the stresses in terms of failure.

The "technical worth" of engineering materials was discussed by A. B. Kinzel[4] in an interesting paper before the A.S.M.E. in 1928, and the subsequent discussion indicated that this general subject is one of great interest to mechanical engineers. It appears desirable to the author to give this subject further attention, and the present paper has been written in the hope that it might lead to some action, on the part of the A.S.M.E., toward the establishment of a certain standard or code on the subject.

The beginning of such a code has already been made in the "Code for Design of Transmission Shafting" approved by the American Standards Association in 1927. This represents a nucleus of valuable material which deserves to be enlarged.

It is the opinion of the author that the engineering profession is in need of a general code on the subject. It is freely admitted that our knowledge on the subject of failure of materials is insufficient for a definite standard in the ordinary sense of the word, but as long as it is sufficient to design machinery successfully it deserves to be classified in a system where the terms have a significance as definite as that of any other engineering science. This is, unfortunately, not the case at the present time.

It is not the object to give definite recommendations for the subject matter of this code. The paper contains a general discussion of the terms "failure" and "factor of safety." Appendix No. 1 gives an example of rules on working stresses established by the East Pittsburgh Works of the Westinghouse Electric & Mfg. Co., and Appendix No. 2 gives a discussion of the above-mentioned "Code on Design of Transmission Shafting." The latter gives an example of deductive reasoning which shows that in many instances the knowledge available at the present time may be systematized into rules no more complicated than purely empirical short cuts.

Failure

Popularly, the word "failure," when applied to the qualities of strength in an engineering structure, signifies a disastrous event: a boiler exploding or a bridge falling down. Technically the word "failure" signifies a cessation of the proper functioning of the structure; whether the consequences are disastrous or not depends on the manner in which the potential energy stored in the structure is dissipated.

This cessation of the proper functioning of the structure may correspond to stresses near the ultimate strength, the yield point, or the elastic limit, or to stresses far below any of these values. In brittle materials it may be accompanied by an actual crack in the structure, in ductile materials by a certain yielding. The term "failure," therefore, involves the nature of operating conditions, the nature of the stress conditions, and the behavior of the materials under these conditions.

A very important part of the work toward a code on working

stresses must therefore be the classification of operating conditions, stress conditions, and materials. This is probably one of the most difficult points, and one that is most likely to create controversy. It is obvious, however, that this classification must conform to the coordinated knowledge of the behavior of the materials. For example, the common method of classifying stresses into static stresses and dynamic stresses is dangerously vague. The dynamic stresses in a rotating hoop and the static stresses in a cylindrical vessel under pressure obviously belong to the same group of steady stresses. It is entirely possible that the designer may find it prudent to employ different working stresses for the two applications, but there is no reason why the working stress—or the factor of safety—should not be defined in the same manner in the two cases. The same state of stress may also require different treatment for two materials. For example, the case of combined torsion and bending in a rod requires one treatment for mild steel and an entirely different treatment for cast iron.

Fig. 1 gives an example of a scheme of classification, which is given here merely as a possible plan.

It goes without saying that the object of a classification such as the one given in Fig. 1 is to systematize the available knowledge of the subject. Several points and combinations, such as the general subject of impact stresses, or the behavior of materials under elevated temperatures and variable stresses, are practically unknown at the present time, because the need for the solution of these problems has not become sufficiently acute. These must be left open until the incentive for the knowledge appears, when a more or less complete solution will also be forthcoming. Many combinations may be justifiable as approximations only. For example, the distinction between brittle and ductile materials is one which is associated with the state of stress as well as with the material itself. Under certain conditions of stress even very brittle materials, such as marble and cast iron under compression, behave as ductile materials. Whether or not this would invalidate a classification of engineering materials into ductile and brittle materials is a point which must be settled by considering the importance of exceptional cases of this kind. It does not appear to the author that this would be the case.

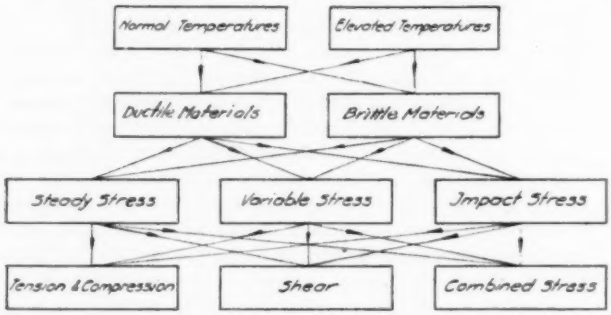

FIG. 1 CLASSIFICATION OF CONDITIONS OF FAILURE

FACTOR OF SAFETY

Having classified the conditions contributing to failure, we arrive at the central part of the problem, the specification of working stresses. Here we may also expect considerable controversy. A considerable number of engineers would probably insist upon having the stresses specified in pounds per square inch for the various subtitles of the classification and for different standard materials. While a certain amount of conventional information of this kind may be of value, it is feared that such a code would miss the point altogether. There is only one agency that can specify working stresses with finality, and that is the engineer, or the firm, responsible for the operation of the device. This is the only agency which has access to the experience from previous undertakings of the same kind, and apart from the question of public safety, it is the agency which carries the chief consequences of failures.

Past experience may be interpreted more or less intelligently, however, and it is here that a code, representing a synopsis of the knowledge on the subject, will be of value. The chief function of the code, therefore, should be to aid the designer in interpreting his experience. We may express this by stating that the code should *define* the factor of safety and the designer should *decide* on its actual value.

Unfortunately, the term "factor of safety" is one of the most abused terms in our engineering vocabulary. Fundamentally, it should represent the margin of the possibilities of the material, which is not taken into account in the functioning of the structure in question. Actually, it is used as a symbol for the designer's relative ignorance of the factors contributing to failure. This ignorance is not always unavoidable, and uncertainty of the existing stresses or conditions of operation must necessarily influence the degree to which the possibilities of the materials are brought into use, but it is not necessary that it should influence the definition of the factor of safety.

As usually expressed, the factor of safety is the ratio of the stress which will cause failure to the actual stress. If we denote the former by S_i and the latter by S, the factor of safety,[5] n, is

$$n = S_i/S \quad \ldots\ldots [1]$$

According to this definition a factor of safety of unity corresponds to failure. It is obvious that this definition is somewhat unsatisfactory in that the factor of safety itself does not express directly the fundamental idea of the margin of safety. This objection could be removed by expressing the factor of safety as the ratio of the difference between the limiting stress and the actual stress, but in practice this method appears unnecessarily complicated.

Another and a far more attractive possibility is to drop the expression factor of safety altogether, and introduce in its place its inverted value. This might be named the *factor of utilization* or the *stress factor*. Denoting it by u, we shall have

$$u = S/S_i \quad \ldots\ldots [2]$$

It could be expressed as a fraction, or as a percentage. It expresses something tangible: *the degree to which the possibilities of the material have been brought into use.*

Naturally, no fundamental advantage other than clarity of expression can be obtained by the introduction of a new term of this kind. This appears of sufficient importance to warrant its introduction, however.

The selection of constants of this nature should, of course, be made with a view toward simplicity of application. In electrical engineering one uses impedance or admittance according to whether one or the other gives simpler expressions, the simplicity usually being synonymous with the possibility of combining elements by direct addition. In the present problem this argument is in favor of the factor of utilization, as shown by the following example.

Consider a mechanical structure subjected to a system of generalized forces P_1, P_2, etc. The stress in a certain member

[5] It should be noted that the factor of safety defined in this manner has a definite meaning only when there is a single stress which contributes to failure. The meaning is still definite for combinations of tension and shear, when a combined stress can be defined. For combinations of constant and variable stresses further qualifications are necessary.

determines the safety of the structure. If all forces produce stresses of the same kind, and if there is proportionality between loads and stresses, we see directly that the factor of utilization of the material in the member in question is

$$u = u_1 + u_2 + \ldots \quad [3]$$

where u_1, u_2, etc. are the factors of utilization corresponding to the forces P_1, P_2, etc. Obviously, the factor of safety can also be evaluated from the expression

$$1/n = 1/n_1 + 1/n_2 + \ldots \quad [4]$$

but it is certainly more convenient to use the former expression.

In many cases the law of superposition given by Equation [3] or [4] will hold even if the stresses produced by the generalized forces are not all of the same kind. Such a case is given in Appendix No. 2, where it is shown that, with a certain modification of the experimental results, the effects of variable and constant stresses may be superimposed.

The principal object of a code on working stresses would thus be a definition of the factor of utilization (or the factor of safety) for each combination of practical interest in the causes of failure. It is a matter of coordinating the available knowledge in the theory of elasticity, strength of materials, and metallurgy in such a form that the factor of utilization is a definite quantity for each case. It cannot be achieved without considerable labor, and many points must be established empirically until more knowledge is available, but it is believed that the results would be of great value to industry.

Appendix No. 1

THE FOLLOWING rules for determining working stresses were proposed at the East Pittsburgh Works of the Westinghouse Electric & Mfg. Co. in 1928. They are given here to show an example of the type of rules which the author has in mind, but should not necessarily be regarded as a definite recommendation for general application.

The term "factor of safety" has been retained in these rules because it was considered unwise to establish a new term for practical purposes until it had received the official sanction of the profession. It is obvious, however, that the general form of the rules need not be changed if the factor of safety were replaced by the factor of utilization.

RULES FOR WORKING STRESSES AT NORMAL TEMPERATURES

I—Introduction

The following general rules establish the fundamental principles upon which the determination of all working stresses is to be based.

All materials are divided into two groups: ductile materials, having an elongation of more than 5 per cent, and brittle materials, having an elongation of less than 5 per cent. The principles for determination of working stresses are fundamentally different for these groups.[6]

[6] Under certain conditions all materials can be deformed permanently to a large amount without visible signs of failure. This is true even of our most brittle materials such as cast iron or marble, when they are subjected to sufficiently large *pressures* and when at least one of the principal stresses differs from the others. Ductility and brittleness, therefore, are not strictly properties of the materials, but depend on the type of stress application as well.

It has been found, however, that a classification of ductile and brittle materials, based on their properties in straight tension, is satisfactory from a practical point of view. The limit of 5 per cent permanent elongation is arbitrary, but has been found to give a safe boundary between the two groups.

All conditions of stress application are divided into two groups: steady stresses and variable stresses. The principles for determining the working stresses are different for these two types of stress application.

Only three of the material constants usually available are used for the quantitative determination of the working stress. These are yield point and endurance limit for ductile materials, and ultimate strength for brittle materials. The remaining constants are often of importance in selecting materials for specific applications, but these are taken into account in a qualitative manner only.

One of the most important objects of these rules is to give the term factor of safety a uniform significance, so that the same factor of safety in all cases designates a certain definite ratio of the stress which will cause failure to the actual stress.

While the following rules define the working stresses from the point of view of failure, there are numerous other factors involved in a design which determine material dimensions, such as rigidity, corrosion, wear, the use of standard parts, etc. For these reasons it is impossible and impractical to specify inflexible rules for the determination of the factor of safety. Furthermore, this element always involves experience from past practice, commercial considerations, and the individual problems of each type of apparatus. In cases of steady stresses in ductile materials, the factor of safety may be as low as 1.25 when the stresses and the properties of the materials are fully known. Cases involving uncertainty of any one of these elements demand higher factors of safety, but very few applications of ductile materials under static stress should require higher factors of safety than 2.0. Ductile materials in applications of variable stress and all applications of brittle materials require factors of safety above 2.0 because of the uncertain element of stress concentration.

II—Nomenclature

Items	Symbols	Units
General symbol for stress	S	lb. per sq. in.
Tensile or bending stress	S_t	lb. per sq. in.
Shearing stress	S_s	lb. per sq. in.
Principal stresses, $S_1 > S_2 > S_3$	S_1, S_2, S_3	lb. per sq. in.
General symbol for constant component of stress in cases of variable stresses	S_c	lb. per sq. in.
General symbol for variable component of stress in cases of variable stresses	S_v	lb. per sq. in.
Ultimate strength—general symbol	S_u	lb. per sq. in.
Yield point in tension or compression	S_y	lb. per sq. in.
Endurance limit for complete reversal	S_e	lb. per. sq in.
Torsion moment	M_T	inch-pounds
Bending moment	M_B	inch-pounds
Factor of safety—general symbol	n	
Factor of stress concentration—general symbol	k	
Diameter of round section	d	inches
Ratio of variable component of stress to constant component—general symbol	α	
Constants for combining variable stresses	K_1, K_2	

III—Ductile Materials
(Elongation more than 5 per cent)

1 Static Stresses. **The yield point in tension or compression**

is to be taken as the basis for the determination of the working stress.

For materials which do not have a well-defined yield point, the stress at which the permanent deformation is 0.2 per cent is to be taken as the defined yield point.[7]

(*a*) *Simple Tension or Compression.* The working stress is determined by

$$S_t = S_y/n \quad \ldots\ldots [5]$$

(*b*) *Pure Shear.* The yield point in shear for ductile materials is one-half the yield point in tension. This has been verified by experiments and furnishes proof of the validity of the maximum-shear theory. The working stress in shear is determined by

$$S_s = S_y/2n \quad \ldots\ldots [6]$$

Torsion of a bar with round section is the most common example of pure shear. The working stress is determined by

$$S_s = \frac{\frac{M_T}{\pi d^3}}{16} = \frac{S_y}{2n} \quad \ldots\ldots [7]$$

[7] The stress-strain curves, which are obtained from annealed ductile materials, can be classified into three groups.

(*a*) *The first iron type* (Fig. 2a). The deformation is elastic up to a certain point, continuing into a peak, after which it drops to the yield point S_y.

(*b*) *The second iron type* (Fig. 2b). The transition between the elastic and the plastic state is rounded, but the yield point is well defined.

(*c*) *The copper type* (Fig. 2c). The permanent part of the deformation increases gradually with increasing stress. A definite and sudden yielding cannot be observed.

This type of material is particularly susceptible to cold working (permanent plastic deformation at normal temperature), and the yield point is raised by this process (Fig. 2d). When the stress is reversed, however, after the cold working, the yield point for the reversed condition of stress is not raised materially.

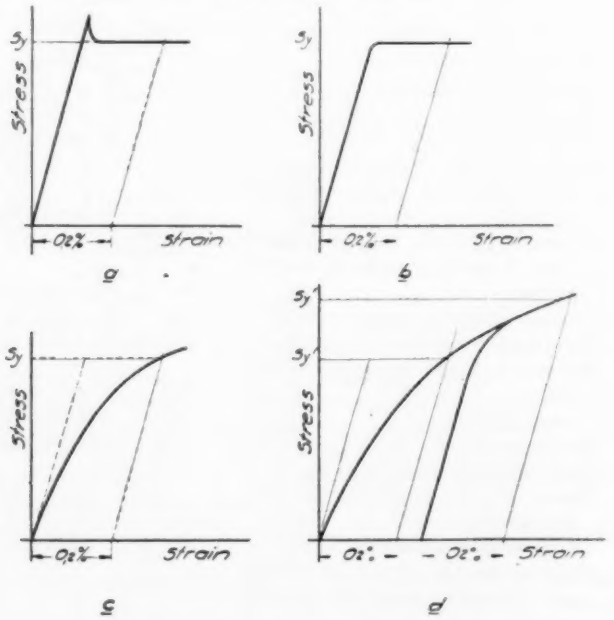

FIG. 2 TYPES OF STRESS-STRAIN CURVES

The selection of 0.2 per cent permanent deformation as the basis for a definite yield point in materials of this type is arbitrary, but in general it will give a stress at which the deformation begins to be objectionable.

See A. Nadai, "Der bildsame Zustand der Werkstoffe," Julius Springer, 1927. J. M. Lessells, "Concerning the Yield Point in Tension," Am. Soc. for Test. Matls, vol. 28, part 2, p. 387.

(*c*) *Combined Stresses.* The determination of the stress which causes failure is based upon the maximum-shear theory, which has been verified by experiments on ductile materials.

In the general case of three principal stresses (Fig. 3), failure occurs when the maximum difference between two of the principal stresses equals the yield point. If $S_1 > S_2 > S_3$ the working stresses are determined by

$$S_1 - S_3 = S_y/n \quad \ldots\ldots [8]$$

In this formula, the stresses must be taken with their proper signs (+ for tension, — for compression).

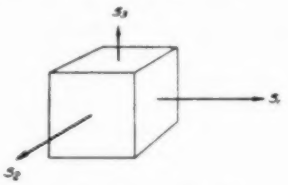

FIG. 3 THREE PRINCIPAL STRESSES

In the case of tension and shear (Fig. 4), the principal stresses are, in the order of magnitude,

$$\left.\begin{aligned} S_1 &= \frac{1}{2}\left[S_t + \sqrt{S_t^2 + 4S_s^2}\right] \\ S_2 &= 0 \\ S_3 &= \frac{1}{2}\left[S_t - \sqrt{S_t^2 + 4S_s^2}\right] \end{aligned}\right\} \quad \ldots\ldots [9]$$

The direction of S_1 is given by the angle θ, determined by

$$\tan 2\theta = \frac{2S_s}{S_t} \quad \ldots\ldots [10]$$

The working stresses are determined by the equation

$$S_1 - S_3 = \sqrt{S_t^2 + 4S_s^2} = S_y/n \quad \ldots\ldots [11]$$

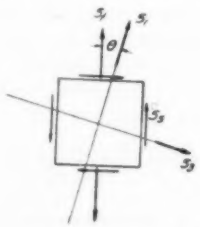

FIG. 4 TENSION AND SHEAR

Note that the combined stress $\sqrt{S_t^2 + 4S_s^2}$ is twice the maximum shearing stress, occurring in a plane at 45 deg. to the direction of S_1. This combined stress produces failure in the same manner as if it acted in pure tension or compression.

Torsion and bending of a bar with circular section is the most common example of combined tension and shear. The maximum tension and shear stresses are

$$S_t = \frac{\frac{M_B}{\pi d^3}}{32} \quad \text{and} \quad S_s = \frac{\frac{M_T}{\pi d^3}}{16} \quad \ldots\ldots [12]$$

The working stresses are governed by the relation

$$\sqrt{S_t^2 + 4S_s^2} = \frac{\sqrt{M_B^2 + M_T^2}}{\frac{\pi d^3}{32}} = \frac{S_y}{n} \quad \ldots\ldots [13]$$

2 Variable Stresses.[8] The general case of variable stress involves a cycle of stress which consists of a static component S_0, and a variable component S_v. (See Fig. 5.) The frequency of variation does not have a perceptible influence upon the behavior of the material, and need not be taken into account in the determination of the working stress.

The working stresses for ductile materials under variable stress are based upon yield point in tension or compression, and the endurance limit for complete reversals of stress. With a few exceptions for non-ferrous metals, the endurance limit is attained experimentally for 10 to 20 million reversals of stress, and may be considered to hold for an infinite number of reversals.

The conditions of stress concentration must be taken into account for all cases of variable stresses. For ductile materials

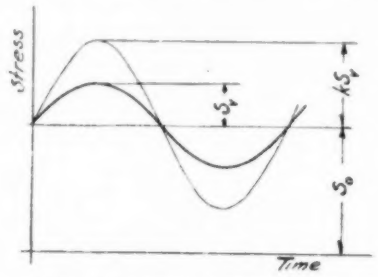

FIG. 5 GENERAL STRESS CYCLE

this applies to the variable component of stress only. Thus, if the stress S_v is obtained by ordinary elementary formulas, the actual variable stress is kS_v, where k is the factor of stress concentration, representing the ratio of maximum variable stress to average variable stress. (See Fig. 5.)

(*a*) *Simple Tension or Compression.* The actual factor of safety of a material under the combined influence of a static stress S_0 and a variable stress S_v (Fig. 5), both expressed as tensions or compressions, is defined in the following manner.

The factor of safety under the static stress S_0 when acting alone is

$$n_0 = S_y/S_0 \quad [14]$$

The factor of safety under the variable stress S_v, when it is acting alone is

$$n_0 = S_e/kS_v \quad [15]$$

where S_y and S_e are the yield point and the endurance limit, respectively. The actual factor of safety n is defined by the relation

$$\frac{1}{n} = \frac{1}{n_0} + \frac{1}{n_y} = \frac{S_0}{S_y} + \frac{kS_v}{S_e} \quad [16]$$

For the derivation of this formula see Appendix No. 2.

(*b*) *Pure Shear.* Let the static and variable components of the shearing stress be S_0 and kS_{sv}. The factor of safety is determined by:

$$\frac{1}{n} = \frac{1}{n_0} + \frac{1}{n_v} = \frac{S_0}{2S_y} + \frac{kS_{sv}}{2S_e} \quad [17]$$

(*c*) *Combined Stresses.* The stress which produces failure is defined by the maximum-shear theory.

For any specific application, the constant and the variable components of the shearing stresses are determined for an arbitrary plane. The factor of safety for this plane is then evaluated by Equation [16] or [17] as a function of the position of the plane. The particular plane which gives a minimum factor of safety is considered as the dangerous plane, and the working stresses are determined from the condition of failure in this plane.

General Case of Variable Principal Stresses (Fig. 6). The actual conditions of each case determine whether the dangerous plane is parallel to S_1, S_2, or S_3. In either case it is inclined 45 deg. to two of the stresses. Assuming it to be the plane indicated on Fig. 6, the factor of safety is determined by

$$\frac{1}{n} = \frac{S_{01} - S_{02}}{S_y} + \frac{k_1 S_{v1} + k_2 S_{v2}}{S_e} \quad [18]$$

from which the working stresses may be determined. This expression may also be written

$$\left(S_{01} + k_1 \frac{S_y}{S_e} S_{v1}\right) - \left(S_{02} - k_2 \frac{S_y}{S_e} S_{v2}\right) = \frac{S_y}{n} \quad [19]$$

In this form the equation compares with Equation [8].

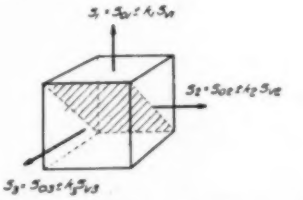

FIG. 6 THREE VARIABLE PRINCIPAL STRESSES

General Case of Variable Tension and Shear (Fig. 7). Using notations suggested in Fig. 7, the tension stress has a constant component S_1, and a variable component $\alpha_1 S_1$, magnified by a factor of stress concentration k_1. The shearing stress has a constant component S_s and a variable component $\alpha_s S_s$, magnified by the factor of stress concentration k_s.

The dangerous plane d–d is found to be determined by

$$\tan 2\theta = \frac{K_1}{K_2} \frac{S_1}{2S_s} \quad [20]$$

where the constants K_1 and K_2 are determined by

$$K_1 = 1 + \alpha_1 k_1 \frac{S_y}{S_e} \qquad K_2 = 1 + \alpha_s k_s \frac{S_y}{S_e} \quad [21]$$

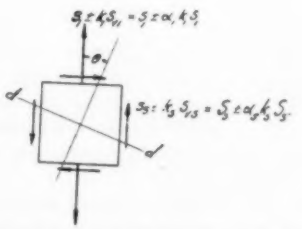

FIG. 7 VARIABLE TENSION AND SHEAR

The working stresses are determined by

$$\sqrt{(K_1 S_1)^2 + (2K_2 S_s)^2} = \frac{S_y}{n} \quad [22]$$

Note that Equation [22] is very similar to the one given for steady stress, Equation [11]. The existence of a variable component of stress merely gives rise to multiplication factors for the stresses, determined from [21].

In ordinary shaft applications the bending stress is completely

[8] For deductions see Appendix No. 2.

alternating with no constant component, and the working stresses are determined by [22], where

$$S_1 = \frac{M_B}{\frac{\pi d^3}{32}}; \quad S_s = \frac{M_T}{\frac{\pi d^3}{16}}; \quad K_1 = k_1 \frac{S_y}{S_e}; \quad K_2 = 1 \ldots [23]$$

that is

$$\sqrt{\left(k_1 \frac{S_y}{S_e} S_1\right)^2 + 4S_s^2} = \frac{S_y}{n} \ldots\ldots [24]$$

In Diesel and single-phase application a certain fraction (α_s) of the torque moment is also variable. In that case

$$K_1 = k_1 \frac{S_y}{S_e} \quad K_2 = 1 + \alpha_s k_s \frac{S_y}{S_e} \ldots\ldots [25]$$

that is, the working stresses are determined by

$$\sqrt{\left(k_1 \frac{S_y}{S_e} S_1\right)^2 + \left[2\left(1 + \alpha_s k_s \frac{S_y}{S_e}\right) S_s\right]^2} = \frac{S_y}{n} \ldots [26]$$

IV—Brittle Materials
(Elongation less than 5 per cent)

1 *Static Stresses.* For all brittle materials the ultimate strength is taken as a basis for determination of the working stress. Most brittle materials behave differently for tension and compression so that it is necessary to specify separately the ultimate strength in tension S_{ut} and the ultimate strength in compression S_{uc}.

The conditions of stress concentration must be taken into account for brittle materials by introducing a factor of stress concentration k, even for static stresses.

(*a*) *Simple Tension or Compression.* The working stress for tension or compression is expressed, respectively, by the formulas

$$S_t = \frac{S_{ut}}{kn} \quad \text{and} \quad S_c = \frac{S_{uc}}{kn} \ldots\ldots [27]$$

(*b*) *Pure Shear.* The ultimate strength in shear for brittle materials has been found by experiments to agree with the ultimate strength in tension S_{ut}. The working stress is thus determined by

$$S_s = \frac{S_{ut}}{kn} \ldots\ldots [28]$$

(*c*) *Combined Stresses.*[9] The failure of most brittle materials under combined stresses depends on more complicated relations between the principal stresses than for the ductile materials. In general, the condition of failure can be expressed as a function of the sum and the difference between the greatest and smallest of the principal stresses.

In the general case of three principal stresses (Fig. 3), it is necessary to consider separately the following cases.

When at least one of the principal stresses is a tension stress, and the maximum compression stress (if there is one) does not exceed the ultimate strength in tension S_{ut}, only the largest tension stress contributes to failure, and the material may be said to fail according to the maximum-strength theory. If the greatest tension stress is S_1, it is limited by

$$S_1 = \frac{S_{ut}}{k_1 n} \ldots\ldots [29]$$

When at least one of the principal stresses is a tension stress, and the maximum compression stress exceeds the ultimate strength in tension S_{ut}, both the tension stress and the largest compression stress contribute to failure, and the material may be said to fail according to a modified form of the maximum-shear theory. If the largest tension stress is $k_1 S_1$ and the largest compression stress is $k_3 S_3 > S_{uc}$, the working stresses are determined by

$$\left(2 - \frac{S_{ut}}{S_{uc}}\right) k_1 S_1 - \frac{S_{ut}}{S_{uc}} k_3 S_3 = \frac{S_{ut}}{n} \ldots\ldots [30]$$

Note that in this equation the stress S_3 is to be taken with a negative sign.

In cases of combination of tensile and shearing stresses (Fig. 4), the principal stresses are first calculated by aid of Equation [9] and then the working stresses are determined from [29] or [30].

2 *Variable Stresses.* In the case of alternating or pulsating stresses in brittle materials, the endurance limit for tension or compression is taken as a basis for the working stress.

Brittle materials have very unfavorable properties under variable stress, however, and their behavior under variable stress cannot be predicted with any degree of certainty. For this reason, brittle materials should be avoided where variable stress is involved. In those exceptional cases where this is not possible, the working stresses should be determined on the basis of the maximum-strength theory, and very large factors of safety must be used.

Appendix No. 2

VARIABLE STRESSES

Introduction

IN THE "Code for Design of Transmission Shafting," approved by the American Standards Association in 1927, certain general formulas and rules are presented, through which the more recent conceptions of the mechanism of failure of ductile materials are incorporated in shafting design.

This pamphlet describes in a clear and concise manner the

[9] The rules for determining working stresses in brittle materials have been based on Mohr's theory, somewhat modified.

In the ordinary Mohr diagram, Fig. 8, draw a circle corresponding to a tension stress S_{ut} and another corresponding to a compression stress S_{uc}. Draw a third circle with radius S_{ut} through the center. Draw a tangent L to this circle and the compression circle. Any stress combination which gives a largest Mohr circle that falls within the line L and the circle S_{ut} will not produce failure. The rules given for brittle materials have been based on this definition.

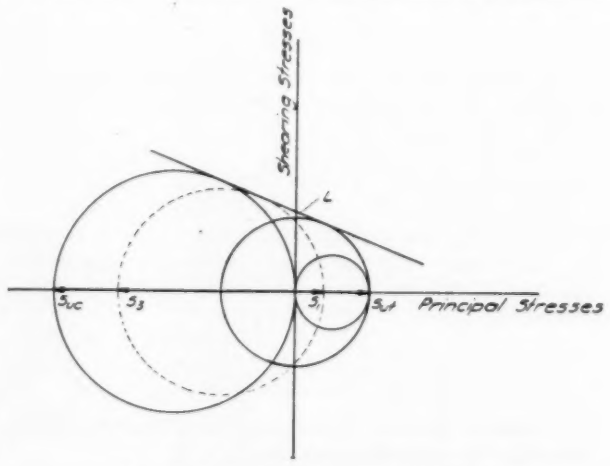

Fig. 8 Failure of Brittle Materials

more important of the existing strength theories. It seems to the author, however, that the subject of variable stresses might be advantageously treated somewhat more fully, particularly since there are many groups of shaft constructions, notably shafts for rotating electrical machines, where the alternating stresses very often are the major stresses. In particular, it seems desirable to establish a more definite distinction between shock and fatigue stresses.

If the word "shock" is taken in its ordinary meaning, a stress applied by shock would grow to its full value in a very minute element of time. For this type of stress application it is questionable whether the ordinary treatment based on the maximum-shear theory holds at all, or whether the qualities expressed by yield point, ultimate strength, endurance limit, and ductility have their ordinary significance.[10] This particular problem, the impact strength of shafts, might form the subject of a separate extension of the Code.

If the word "shock" denotes a suddenly applied load, where the time element is large in comparison with the duration of an impact, as is usually the case in most shafts, there are two possibilities. When the number of shocks during the lifetime of a shaft is small, the application may be considered one of steady stress. When the number of shocks is great, the application must be considered a fatigue problem. In a formal rule, the actual boundary must be established; this might be put at about 10^4 cycles. At any rate, we are forced to coordinate the problem under one or the other of steady or variable stress, unless we are willing to accept the complication of an endurance limit which is a function of the number of cycles to which the shaft will be subjected. This is, indeed, the only logical solution in important cases of mass production of shafts, but for ordinary cases it appears somewhat too complicated.

If we exclude the case of actual impact, therefore, the distinction between shock and fatigue reduces itself to a difference in the actual maximum value of the stresses. The case of shock is characterized by particular uncertainty regarding the maximum stress. This is of practical importance and must be taken care of, but it does not appear logical to modify the working stress in order to take care of this uncertainty; it should be taken care of in the computation of the stress.

It seems logical, therefore, to recognize the following types of stress application: steady stress, impact stress, and variable or fatigue stress.

The first appears to be adequately covered by the Code, as far as shafts are concerned. The second represents a type of stress application which is very imperfectly known and which probably must be covered by empirical short cuts until more knowledge is available. The third type, the fatigue problem proper, which is the subject of the present discussion, might be covered by less empirical rules than those given in the Code.

The method recommended by the Code for evaluating the action of shock and fatigue stresses consists in "weighting" the stress by a factor $K > 1$, which is given different values for different conditions of stress. Thus, if the shaft is subjected to a variable bending stress S_b and a variable torsion stress S_s, computed by ordinary formulas, the working stress is expressed as

$$\sqrt{(K_1 S_b)^2 + (2K_2 S_s)^2}$$

instead of the usual expression derived from the maximum-shear theory

$$\sqrt{S_b^2 + 4S_s^2}$$

It is a very interesting fact that the results obtained by analytical reasoning are exactly the same, and definite formulas are obtained for K_1 and K_2. It is not impossible that the method had its origin in a reasoning of the same kind as the one presented below; if not, it is another example of common sense anticipating the results of mathematical deduction.

Fundamental Laws of Failure

The object of the following discussion is to deduct the consequences of those principles which may be considered established for the failure of ductile materials. Briefly, they can be enumerated as follows.

1 *Steady Stresses.*

(*a*) Failure is predicted by a material constant, the yield point, which for ordinary steels, at least, can be said to be fully defined.

(*b*) Failure is due to the maximum shear stress and consists, in the initial stage, of permanent shearing deformations in the planes of maximum shear.

(*c*) Local concentrations of stress do not contribute appreciably to failure.

2 *Alternating Stress.*

(*d*) When the stress is alternating, the failure is predicted by a material constant, the endurance limit, which can be considered fully defined and measurable, for practical purposes.

(*e*) Failure is due to the maximum alternating shear stress, and consists in ruptures in the plane of maximum shear.

(*f*) Local concentrations of stress contribute to the failure, so that a stress larger than the average stress, but smaller than the maximum stress, is determining the failure.

To the above can be added the results of somewhat less comprehensive experiments for cases of variable stress, that is, when the stress consists of a constant component and a variable component. Here the results are less definite but the tendency is obvious.[11]

Referring to Fig. 5, we assume a test piece in uniform tension subjected to a stress cycle, consisting of the constant component S_0 and the variable component S_v. If S_0 and S_v are varied, and the failure for each combination is observed, it has been found that the stresses contributing to failure are related in the manner shown in Fig. 9. Thus for each value of the constant component S_0, there is a certain value of the variable component S_v which produces failure. The line of failure L varies for different materials, but in general it seems to go through the points corresponding to S_e, the endurance limit, and S_u, the ultimate strength. It appears, then, that most steels have a certain ability to stand alternating stresses even at the yield point. This fact is connected with the difference in the mechanism of failure.

As far as tests on ductile materials have been made, it seems that the above facts hold for compression as well as tension.

The Fundamental Case of Stress Cycle

Assuming the above principles to be established, we next proceed to interpret them for practical application.

If we consider first the case of only one principal stress, such as a test piece in tension and compression, we modify the stress

[10] Attention is here called to the fact that in the Applied Mechanics Division of the A.S.M.E. this subject has been proposed as the principal subject for one or several meetings in 1931.

See also W. Kuntze, "Kerbzähigkeit und statische Kennziffern," *Stahl und Eisen*, March 21, 1929, p. 394. This paper is an abstract of a more complete discussion in *Arch. Eisenhüttenwesen*, 2 (1928–1929), pp. 583–593 (Group E, No. 51).

cycle in accordance with point f, so that the variable component is increased from S_v to kS_v. (See Fig. 5.) The constant k should correctly have a value somewhat less than the factor of stress concentration,[12] but we shall err on the safe side by using for k the factor of stress concentration as far as this is known.

As our next step we remove the uncertainty in the line of failure, Fig. 9, by replacing it with a straight line connecting the endurance limit S_e with the yield point S_y. (See Fig. 10.) This again introduces an error, but as far as experiments indicate, it is also on the safe side. Furthermore, the yield point is already established as a point of failure by (a), so that the end points of the assumed line of failure are definite.

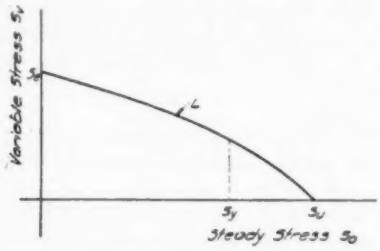

FIG. 9 EXPERIMENTAL LINE OF FAILURE

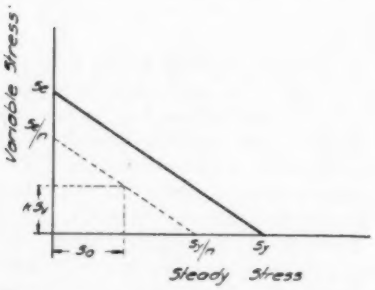

FIG. 10 ASSUMED LINE OF FAILURE

By factor of safety n we define the ratio of the stress which produces failure, to the actual stress. Thus, for a constant stress S_0 we have $n = S_y/S_0$, and for the variable stress kS_v we have $n = S_e/kS_v$. In other words, if the endurance limit and the yield point were reduced to one nth of their actual values, failure would occur under the stress cycle S_0 and kS_v. As a result of this we find that all stress combinations which fall on the straight line S_e/n–S_y/n are characterized by a factor of safety of n. By this reasoning we have extended the definition of factor of safety to any stress combination.

This result may be given a simple mathematical form. If we determine the value of kS_v from the geometrical relations in Fig. 10, we find that

$$kS_v = \frac{\frac{S_e}{n}}{\frac{S_y}{n}}\left(\frac{S_y}{n} - S_0\right)$$

or

$$\frac{1}{n} = \frac{S_0}{S_y} + \frac{kS_y}{S_e} = \frac{1}{n_0} + \frac{1}{n_v} \quad \ldots\ldots\ldots\ldots [31]$$

The expressions n_0 and n_v are known quantities: n_0 is the factor of safety when S_0 is acting alone; n_v is the factor of safety when kS_v is acting alone.

[12] Ragnar Liljeblad, "An Investigation of the Fatigue of Metals Due to Locally Concentrated Stresses." Svenska Ingeniörsvetenskapsakademiens Handlingar No. 47.

The idea underlying the usual definition of the factor of safety is that the stress can be increased in the ratio n:1 before failure occurs. Referring to Fig. 10 we find that the definition expressed by Equation [31] presents a parallel to this idea; both stresses can be increased in the ratio n:1 before failure occurs.

Now, if we define the factor of utilization by $u = 1/n$, Equation [31] becomes

$$u = u_0 + u_v \quad \ldots\ldots\ldots\ldots [32]$$

and this equation expresses the fact that the total utilization of the material is equal to the sum of the utilization due to the stress components.

It might be said, therefore, that the simplification of the line of failure into a straight line is equivalent to bringing the effect of the two stresses S_0 and S_v within the law of superposition.

This is a very desirable simplification, but it is important to bear in mind that it has no other justification than that of experimental results. For example, certain materials have a line of failure which is a curve resembling an ellipse with the axes at S_e and S_y. If this were actually the case, the line of failure might be given the equation

$$\left(\frac{S_0}{S_y}\right)^2 + \left(\frac{kS_v}{S_e}\right)^2 = 1 \quad \ldots\ldots\ldots\ldots [33]$$

Now, if S_e and S_y are reduced to uS_e and uS_y, corresponding to a utilization of the material of u, we obtain a curve of the corresponding stresses S_0 and S_v having the equation

$$\left(\frac{S}{S_0}\right)^2 + \left(\frac{S_v}{S_e}\right)^2 = u^2 \quad \ldots\ldots\ldots\ldots [34]$$

so that in this case

$$u = \sqrt{u_0^2 + u_v^2} \quad \ldots\ldots\ldots\ldots [35]$$

For certain materials this may, in fact, be a more correct definition of u, but it does not lend itself so well to extensions to more complicated cases of stress applications, as does the definition expressed by [32].

THE GENERAL CASE OF THREE PRINCIPAL STRESSES

Having thus established the fundamental consequences of these principles for the simple problem of a bar under uniform stress, the next object is to extend this definition to more complicated cases of stress applications. For this purpose we make use of the result expressed by e, which simply extends the maximum-shear theory to the case of variable stress.

Consider, then, a cube in the material subjected to three components of stress, each having variable and constant parts as indicated in Fig. 6. The $\pm$ sign expresses the fact that the component is alternating, and the constants k_1, k_2, and k_3 are the respective factors of stress concentration. We shall assume that the relative phase positions of the three stresses are unknown so that it is necessary to select the worst combination.

The problem is to find a plane in which the factor of safety is lowest. It is obvious at once that the plane must be inclined 45 deg. to the principal axis, but there is uncertainty as to which diagonal plane of the cube it should be. This can only be established by trial. Assuming it to be the shaded plane in Fig. 6, we find that the shearing stress in this plane is given by

$$\frac{S_1 \pm k_1 S_{v1} - (S_3 \pm k_3 S_{v3})}{2}$$

This shearing stress has a constant component

$$\frac{S_1 - S_3}{2}$$

and a variable component

$$\pm \frac{k_1 S_{v1} \mp k_2 S_{v2}}{2}$$

The factor of safety for this plane is thus expressed by

$$\frac{1}{n} = \frac{S_1 - S_2}{S_y} + \frac{k_1 S_{v1} + k_2 S_{v2}}{S_e} \quad \ldots\ldots [36]$$

and this relation is sufficient to determine the working stresses for this general case.

The General Case of Tension and Shear

The case of tension and shear is of more immediate interest because this is the case upon which working stresses in shafts must be based.

Referring to Fig. 7, we consider a cube of which four sides only are under stress. It is subjected to the tension stress $S_1 \pm k_1 S_{v1}$ and a shearing stress $S_s \pm k_s S_{vs}$.

Again the problem is to find a plane in which the factor of safety is the smallest or the factor of utilization the greatest. Here we know without trial that the plane must be parallel to the surfaces upon which the stresses are acting. Assume that its normal is inclined an angle θ to the direction of S_1. The problem is then reduced to a problem of minimum; θ must be determined in such a manner that the factor of safety for this particular plane is a minimum.

The shearing stress in the plane θ is obtained by projecting all the forces on the plane. This gives

$$S_{s\theta} = \frac{S_1 \pm k_1 S_{v1}}{2} \sin 2\theta + (S_s \pm k_s S_{vs}) \cos 2\theta \ldots [37]$$

This shearing stress consists of a steady component

$$\frac{S_1}{2} \sin 2\theta + S_s \cos 2\theta$$

and a variable component

$$\pm \left(\frac{k_1 S_{v1}}{2} \sin 2\theta \mp k_s S_{vs} \cos 2\theta \right)$$

To establish the factor of safety for the plane θ we have merely to apply Equation [31] with these components. This gives

$$\frac{1}{n} = \frac{S \sin 2\theta + 2S_s \cos 2\theta}{S_y} + \frac{k_1 S_{v1} \sin 2\theta + 2k_s S_{vs} \cos 2\theta}{S_e} \quad [38]$$

when the most unfavorable sign of S_{vs} is selected.

The only operation that remains is to vary θ in such a manner that n becomes a minimum. This is the case when

$$\frac{d\left(\frac{1}{n}\right)}{d\theta} = 0 \quad \ldots\ldots [39]$$

After rearranging, this equation gives the following value of θ:

$$2\theta = \tan^{-1} \frac{S_1 + k_1 S_{v1} \frac{S_y}{S_e}}{2\left(S_s + k_s S_{vs} \frac{S_y}{S_e}\right)} = \tan^{-1} \frac{K_1}{K_2} \frac{S_1}{2S_s} \ldots [40]$$

where

$$K_1 = 1 + k_1 \frac{S_{v1}}{S_1} \frac{S_y}{S_e} \qquad K_2 = 1 + k_s \frac{S_{vs}}{S_s} \frac{S_y}{S_e} \ldots [41]$$

An investigation into the sign of the second derivative reveals the fact, moreover, that this value of θ really gives a minimum.

It is interesting to note that the location of the plane of failure is a function of not only the values of the stresses, as is usually the case, but also of the values of S_e and S_y.

The particular value of n for this plane is obtained by introducing this value of θ into the above equation. This gives

$$\frac{1}{n} = \frac{\sqrt{(K_1 S_1)^2 + (2K_2 S_s)^2}}{S_y} \quad \ldots\ldots [42]$$

The experimental results available on this subject[13] indicate that the results obtained by Equation [42] are considerably on the safe side. From Equation [42] it is evident that the equivalent working stress is given by

$$\sqrt{(K_1 S_1)^2 + (2K_2 S_s)^2}$$

This result is identical with the empirical formula proposed in the Code. We can thus state that the existence of a variable stress component S_0 in addition to the already existing constant component S_0 is satisfactorily taken care of by "weighting" the constant component with the factor

$$1 + k \frac{S_v}{S_0} \frac{S_y}{S_e}$$

The author's proposition for modification of the Code now consists in removing the empirical nature of the constants K, and actually express them as functions of the variables of which they are built up.

It might be argued that neither the constants of stress concentration nor the endurance limit are always known for shaft designs. The only answer that can be given to this objection is that wherever these quantities cannot be estimated, the shaft design must remain guesswork as far as the variable stresses are concerned.

In reality both the constants of stress concentration and the endurance limits for a variety of materials have been determined by several large firms interested in shaft design.

In conclusion, this may be illustrated by a concrete example. In the Westinghouse Electric & Mfg. Co. certain classes of shafts are being designed on the following basis:

(*a*) The bending stress S_1 is completely alternating and the shaft fillets are standardized so as to give a factor of stress concentration $k_1 < 1.7$.

(*b*) The torsion stress is assumed to consist of a constant component S_s plus a variable component $0.1\ S_s$. The factor of stress concentration for torsion has been found to differ very little from that for bending, for standard fillets.

Under these assumptions the constants K_1 and K_2 assume the following values for a few of the most important shaft steels of this form:

Steel	Grade	K_1	K_2
A	Axle steel, normalized	2.40	1.24
B	Forged steel.....	2.50	1.25
C	Ni steel.....	2.30	1.23

The selection of the factor of safety for the different applications of these steels is a matter which is left to the individual judgment of the responsible designer. All that the above reasoning accomplishes is to give, for each case considered, the meaning of the term "factor of safety."

[13] F. C. Lea, "Combined Torsional and Repeated Bending Stresses," *Engineering*, Aug. 20, 1926.

Discussion

R. V. Baud.[14] The writer agrees with the author that the first step in drawing up a code on working stresses will consist of establishing clear definitions of the terms and symbols to be used.

The author makes suggestions in this respect, but he deserves some criticism in that some of them are not clear. In defining the factor of safety, Equation [1] for instance, he uses the expression "actual stress S." Presumably "actual stress" means a computed average stress, since in some of the equations given in the paper S is multiplied by a factor of stress concentration k, which is defined as the ratio between the maximum stress and a computed average stress. The latter stress does not really exist except in very simple cases such as uniform one-axial tension, etc. Therefore, the computed average stress is not an "actual stress" as a rule, but a hypothetical stress and ought to be defined as such. There the trouble begins, however, because it will be difficult to give a definition for this hypothetical stress to hold generally, and consequently designers may interpret it in a different manner. This possibility evidently should be excluded. Any improvement in the foregoing would involve the discussion of the subject matter of Appendixes Nos. 1 and 2, which is beyond the scope of this discussion.

The definition of the "factor of utilization" as proposed by the author would be a useful one provided the numerator and denominator of Equation [2] are each given within a few per cent more or less. In the great majority of engineering problems, however, this is not the case, on account of the large expense involved in making all the numerous tests required in order to obtain the values of numerator and denominator within the accuracy mentioned. The writer therefore does not see any constructive improvement in introducing this new definition, at least so long as so many engineering problems include numerous unknown quantities. He agrees, however, that the engineering profession should attempt to give the factor of safety a well-defined meaning.

A. Nadai.[15] The writer would like to comment on this interesting paper regarding some of the principles which may have a further relation to the limiting factors determining the forces acting on a structure. Although the author himself states that besides stress, different factors have to be taken in account, such as rigidity, wear, etc., if the rules defining "working stresses" shall be established, it seems that the author of the paper gives a preference to one of these factors—that is, to the term "working stress"—and to be more exact, he thinks that failure mostly depends rather on the reaching of a certain stress defined by material properties than on other limiting factors. In the writer's opinion the author limits the subject a little too much to one of the possible and fundamental quantities which affect failure in a structure or which determine the limiting values of the forces acting on a given structure. Even if one does not consider dynamical causes, such as wear or the consequences of vibrations, numerous cases can be mentioned in which the limiting values of the forces acting on a construction do not depend on the actual value of the maximum stress, but on some other mechanical quantities. One is, for example, deformation. In many cases the magnitude of an elastic transverse deformation (deflection of a beam) determines rather the limiting value of a force than a stress. In slender beams, for example, the greatest bending stress may be unimportant, while the greatest deflection may attain values which will be considered as too high. A factor of safety based on stress cannot express the relation of the forces which must hold if the deflection of the beam is to remain between given limits.

Another criterion of importance to which the engineer should devote his attention if the conditions of failure in general are discussed, is the elastic instability of the equilibrium of the forces acting on parts of structures. One of the best-known examples is the buckling of straight bars under axial loads. In more complicated systems many analogous cases of instability are possible and of practical importance. A load may become critical—that is, may cause buckling—and consequently the bending stresses may increase rapidly without an appreciable change of the load. For such types of failure the condition which has to be considered again does not contain quantities depending on limiting stress components, such as yield or breaking stresses.

G. M. Eaton.[16] The points to which the writer would like to call attention in connection with the paper have no direct bearing on the major issue presented by the author. They all bear on the engineer's quantitative factor of safety or of utilization. They are, however, of sufficient importance that no opportunity of bringing them to attention should be permitted to pass.

The first point is internal or residual stress. This is a vital factor, and one requiring constant attention. It becomes of increasing importance as the size of the actual piece under consideration increases. This is due to the fact that a great mass of testing information is based on small test pieces from which residual stress has been, in a great measure, eliminated by the act of machining the test piece.

The next point is a realization of the effect of surface conditions. If the article which is being designed has a finish inferior to the finish of the test piece, it will have physical characteristics which from this cause alone will appear inferior to those appearing from the destruction of the test piece. This is particularly true in connection with fatigue-test results. If the surface of the article is the surface left by hot-forging or rolling operations, surface decarbonization is a factor of vital importance.

Again, the location in the ingot of the piece from which the contemplated article is to be made is important. We know of no concerns who give consideration to the location of steel in the ingot. We believe that a very great advance in the art of steel application could be made, particularly by large companies, if they would purchase the product of entire ingots, having each bar, billet, etc. marked with its location in the ingot in a manner similar to that followed in the production of railroad rails. They could then apply the steel most favorably located in the ingot to the service where results of failure would be most serious, degrading the parts known to be inferior to less vital service. This is a radical procedure, and yet one is more and more impressed as time passes that it is a very logical procedure.

Particularly in heat-treated parts, residual stress resulting from thermal treatments is not all relieved by drawing operations, and there are many cases where it is entirely possible to so adjust the rate of cooling in the quench that the residual stress remaining after the drawing operation is of a friendly nature rather than of a hostile one.

Where what may be termed "pot luck" is accepted—the engineer simply calling for a quench and draw—it is entirely possible, and in fact very frequently happens, that the residual stress is hostile in that it has used up internally much of the fundamental ability of the steel to resist stress. There are many cases where it has been possible to quench a part which persistently fails in tension in service in such a manner that the entire loca-

[16] Commercial Engineer, Molybdenum Corporation of America, Pittsburgh, Pa. Mem. A.S.M.E.

tion of failure is in compression when the piece starts to work. This thought, of course, is old in principle, but is new in many designs.

A. M. WAHL.[17] It should be noted that, as the author points out, the definition of factor of safety, n = ratio of stress which will cause failure to actual stress, is somewhat unsatisfactory. In fact, the value of n depends on the kind of stress involved. For example, the value of stress which will cause failure will usually be smaller if only variable stresses are acting than if only static stresses are acting. Assuming that the material is subjected to a given actual maximum stress, it is plain that the ratio of the stress which will cause failure to the actual stress will depend on whether the stresses which act to cause failure are static or variable.

Assuming that the actual line of failure is as represented by the line $S_e S_y$ in Fig. 10, what the factor of safety n, as defined by the author, really means is that both the variable stress and the constant stress may be increased in the same ratio n before failure will occur. In other words, if we have a factor of safety n as defined, we can increase the variable stress to a value n times its actual value at the same time that we increase the constant stress to a value n times its actual value before failure will occur.

Regarding Mr. Eaton's remarks on the effect of surface finish, it seems to the writer that this factor is very important. Recently fatigue tests have been made in England on spring-steel plates in the unmachined condition. It was found that the actual endurance limit was one-half to one-third of that estimated on the bases of fatigue tests of machined bars of spring steel. The writer knows of several other instances where this effect has been noted.

Therefore it seems that the value of n as defined by the author should be determined wherever possible on the basis of fatigue tests made with the surfaces as in the actual condition. If such tests are not available, then a factor of safety n of a value sufficiently large to cover all uncertainties must again be used.

S. TIMOSHENKO.[18] The problem of choosing an adequate factor of safety in design is of the utmost practical importance. If this factor is taken too low, making the working stress too high, the structure may prove weak in service. On the other hand, if the working stresses are too low, the structure becomes unnecessarily heavy and uneconomical. The factor of safety depends on the accuracy with which we know the external loads acting on a structure, on the homogeneity of the material, and on the accuracy of the formula which gives the maximum stress. In the paper it is assumed that the forces are established on the basis of experience with past practice, and that the mechanical properties of the material are known. Methods are then considered for determining the effect of various kinds of stress conditions on the choice of working stresses. This knowledge enables us to design a structure in such a manner as to have the same factor of safety in all parts of the structure. It is obvious that this latter requirement must always be fulfilled if the design is to be economical, because the ultimate strength of a structure is determined by the strength of the weakest part. As a basis for comparing various stress conditions, the yield point together with the maximum-shear theory is chosen for the condition of constant stresses, and the endurance limit together with the maximum-shear theory[19] for the case of variable stress. These methods of comparison on the basis of stress conditions are supported by experiment, and it seems logical to introduce them into design practice. The rules of the Westinghouse Company represent one of the first attempts in this direction to develop a logical system of working stresses in machine design.

It will be of great practical importance to have, in the future, a discussion of the effect of these rules on the design. The choosing of the straight line in Fig. 10 as a basis for determining the factor of safety in the case of variable stresses simplifies the problem and enables a designer to obtain working stresses for the more complicated cases, such as combined bending and torsion, in which both components are usually variable.

In the paper it is assumed that the dimensions are determined by strength considerations only. There are sometimes additional requirements which must be considered in design. There are cases in which a limiting deflection is prescribed and where this must be taken as a basis for calculating the dimensions. The rigidity is especially important for cases in which vibration of the system is to be considered. Sometimes there are requirements regarding the maximum deflection of beams or girders. Shafts must sometimes satisfy requirements regarding the angle of twist per unit length.

Sometimes the stresses are not proportional to the external loads, and in these cases it is logical to determine the factor of safety with respect to the load producing failure rather than to the stress-producing failure. We have examples of such conditions in discussing simultaneous action of bending and direct loads.

In the case of slender bars and thin plates submitted to the action of compression, the stability of the structure may be the controlling factor, and the working stress must be chosen on the basis of the critical stress rather than the yield point of the material.

From the foregoing discussion it may be seen that the choice of working stresses is a very complicated problem. In establishing the factor of safety, the designer must always be guided by past experiences. The methods outlined in the paper giving a comparison of the working stresses for various stress conditions are not intended to replace the use of past experience, but may be helpful in interpreting this experience. They may be useful also in making comparisons of different designs and in comparing the strength of existing structures.

The study of actual failures and the investigation of the causes of these failures in the light of such theory, as presented by the author, form a very useful method for acquiring a better knowledge of the strength of our structures. Combining such an analysis of failures with theoretical investigations of the stress distribution in various cases and with laboratory investigations of the strength of materials under various stress conditions, will enable us to accumulate a more reliable knowledge of the actual strength of structures. When we have such knowledge, the present specifications for working stresses in the various branches of engineering can be considerably improved. This will, without doubt, result in an economy of material and in greater reliability for structures and machines.

HAROLD C. CLAUSEN.[20] The writer would like to draw attention to the question of working stresses in connection with the section "Fundamental Laws of Failure," paragraph (*d*), which says: "When the stress is alternating, the failure is predicted by a material constant, the endurance limit, which can be considered fully defined and measurable, for practical purposes."

Now in engineering practice such as occurs in railroad work, we have many examples where the stress is not subject to a complete reversal and where it is repeated many times, varying from a tension to zero or a compression or zero, or it may vary

[17] Research Department, Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa. Jun. A.S.M.E.

[18] Professor of Mechanical Engineering, University of Michigan, Ann Arbor, Mich. Mem. A.S.M.E.

[19] The writer agrees with using this theory in design, although the statement that failure due to alternating stress consists of ruptures in the plane of maximum shear is not correct.

[20] Mechanical Engineer, Union Switch and Signal Company, Swissvale, Pa. Mem. A.S.M.E.

from a high value of tension or compression to a low value of tension or compression. In these cases it will be necessary to multiply the endurance limit by some factor. This factor has been put forward in the shape of a formula in two recent papers: (1) "What Happens When Steel Gets Tired," by D. D. Ewing, *Electric Railway Journal*, August, 1929, and (2) "Materials in Machine Construction," by H. F. Moore, *Mechanical Engineering*, October, 1929. The writer would be glad to learn what value the author of the paper suggests.

A further factor may be necessary to take account of the nature of the way the piece is manufactured: for instance, whether the piece is a forging and is sheared on some part of its surface by a trimming die, or is a piece completely machined and polished. There is also the question of size and of the inclusion of foreign matter. These latter points have been brought up very forcibly by Mr. Eaton, and the writer thinks they are of primary importance.

A still further factor may be necessary to take into account the fact that there may be some periods of rest between repeated loadings.

H. F. Moore.[21] The author's suggestion that the term "factor of safety" be discarded and that its reciprocal be used under the name "factor of utilization," is very interesting and is worthy of consideration. Of course, even if the new term seems to be the better one, it will have to overcome a great deal of inertia of common usage before it can come into use.

In considering the sample codes which the author quotes (without definite recommendation for adoption), the opinion of the writer would be quite different as to (1) their practical value and reliability and (2) the rigid correctness of the theories of failure which they rather dogmatically state to be true.

As practical codes for determining working stresses both appendixes seem good, with the possible exception of the statement in Appendix No. 1: "When at least one of the principal stresses is a tension stress, and the maximum compression stress (if there is one) does not exceed the ultimate strength in tension S_{ut}, *only the largest tension stress contributes to failure*,[22] and the material may be said to fail according to the maximum-strength theory."

This statement the writer believes to be lacking in confirmatory experimental evidence and to be on the "danger" side of the maximum-shear theory, the maximum-strain theory, and the maximum strain-energy theory. The principle implied in both appendixes of codifying the relative magnitudes of factor of safety for different stress combinations, while leaving the determination of the actual numerical value to the judgment of the designing engineer, seems thoroughly sound.

However, the writer thinks it doubtful whether it has been rigidly proved that the failure of ductile materials is always due to shearing stress, as is stated in Appendix No. 2, or whether under certain combinations of tensile and compressive stresses at right angles the maximum-stress theory holds rigidly, as seems to be indicated in Appendix No. 1.

It is doubtful whether any theory of failure based on the theory of elasticity, with its obviously inaccurate assumptions of homogeneity and indefinite divisibility of material, will be found to be rigidly true. It would seem that the rather dogmatic statements concerning the truth of the shear theory for ductile materials and of the truth of the maximum-stress theory for certain stress combinations in brittle materials might well be modified slightly, without detracting at all from the usefulness of the codes developed.

In connection with theories of failure, attention may be called to the theory advanced by Prof. Parker Haigh, the British metallurgist,[23] which holds that the criterion of failure of a material is the amount of energy stored up per cubic inch at any region of a stressed machine or structural part. This theory seems to come nearer agreeing with test data for the whole range of possible combinations of stress than does any other single theory of failure.

John C. Wattleworth.[24] In the author's statement regarding the two subdivisions of the strength calculation of machine parts, a third subdivision might be added, namely, a determination of the amount of the factor of safety. Much of the value of the immense amount of theoretical and experimental work on the determination of stresses and mode of failure is invalidated by lack of definite thought on this point. In other words, analytic or semi-analytic methods of evaluating the conditions peculiar to the service of a machine part into a factor of safety are desirable. It is fully realized that much of empiricism must exist in this direction.

Regarding the author's remarks on the probable insistence on specifications for working stresses being given definitely for the various subtitles in his classification, Fig. 1, and standard materials, the writer can sympathize heartily with the author's statements on this point. An experience in the teaching of machine design inevitably involves questions by members of the classes asking for recommendations for factors of safety. Some of the texts on this subject attempt to give such values, based on the classification the author suggests. It is the writer's feeling that this practice should be discouraged; and the writer has evolved a semi-analytic method, which at least for his own purposes appears to be highly satisfactory. This is given at the end of the discussion. In this connection it may be remarked that the writer started using this method six years ago in his classes and that he is fully aware of several similar analyses which have appeared from time to time. He, however, cannot claim indebtedness to any of the other similar methods for his treatment of the subject.

The author's phrase "factor of utilization" is preferable to the term "factor of safety." It is recognized, as the author states, that no fundamental advantage other than clarity of expression can result; but the advantages of the train of thought provoked by the phrase are so great that it seems highly desirable that it should attain widespread use.

An extremely useful purpose is served by the author's arbitrary classification of materials as ductile or brittle, with the limiting value of 5 per cent permanent elongation as the division line.

Regarding the material constants on which working stress is based, although every one is agreed that from the standpoint of deformation of a machine part no stress should exceed the yield point, it would seem that long-established practice might better be deferred to, and that even in the case of ductile materials the ultimate strength might properly be employed as the material constant from which to derive working stress.

Apart from the thought that an abandonment of a long-used constant might retard the adoption of the proposed rules, several practical considerations might be brought forward to support the claim. First, the correlation of endurance data with ultimate strength is much better than with yield point. If attention were focused on the latter, some sacrifice in the matter of safe values of endurance limit might result. Second, from the standpoint of the phrase "utilization factor" the ratio (yield point—ultimate strength) expresses the thought that the utilization of the material is enhanced by (*a*) the properties of the material itself or

(*b*) the properties with which the material may be endowed by treatment. Such a factor, or rather its reciprocal, is in fact used in the writer's procedure for the derivation of factor of safety.

Regarding the treatment of the problem in Appendix No. 2, under "The Fundamental Case of Stress Cycle," several questions arise. First, is the simplification, that is, the transition shown in Figs. 9 and 10, warranted? The writer feels that on this point the arguments against the abandonment of the ultimate strength may be brought forward and that sufficient simplification will be accomplished by merely straightening the line S_e–S_u of Fig. 9. Such a procedure is in good agreement with older investigations on the effect of range of stress, as opposed to completely reversed stress. The only proviso necessary is that the active part of the diagram be restricted to that portion to the left of a vertical line passing through S_y, located on the axis of the abscissas.

A second point is as to the general form of the treatment. In the older work on the subject the term "range of stress" occupied a prominent place in the discussion, and the conclusion reached was that as the range decreased the maximum stress might increase. The numerous diagrams proposed all bore witness to this point of view.

The treatment outlined in the author's paper, that of superimposing a variable stress upon a constant stress, seems preferable. This is because the method presents clearly the picture of the effect of the degree of utilization possible by the one stress caused by the presence of the other.

The procedure in determining factors of safety which the writer has been using is given herewith, employing the author's symbols. It is hoped that it may be considered as a supplement to the author's paper on the point of assistance in the derivation of numerical values of factors of safety. No numerical values are given, for the very obvious reasons already cited and in the author's paper. On points of difference which have arisen, no great difficulty should exist.

1 The selection of a working stress involves much uncertainty which is generally met by empirical overall factors of safety. It is proposed to substitute for such factors of safety a semi-analytic method of selection. The central thought is that of expressing quantitatively the effect of each of the elements of the total factor of safety. Numerical values cannot be given as each case carries with it its own special considerations.

As ordinarily used, the factor of safety is employed to derive a working stress by the expression:

$$S_w = S_u + n$$

where S_w = working stress
S_u = ultimate stress
n = factor of safety.

Let us regard n as the product of several factors, $n_1, n_2, \ldots . n_n$ and write

$$n = n_1 \times n_2 = n_3 \ldots . n_n$$

where each of the factors n_1, n_2, etc., is intended to be given a quantitative value expressing the effect of a single consideration upon the working stress.

2 For static loads the following are suggested:

Let n_1 be the ratio $S_u + S_y$, where S_u = ultimate strength, and S_y = yield point.

In the case of brittle materials, an arbitrary value must be assumed corresponding to the yield point in ductile materials. It is of course obvious that no consideration can be given to working stresses beyond the yield point from the standpoint of permanent deformation of machine parts.

Let n_2 be a uniformity factor, which shall take account of variations of the properties to be expected in an individual piece from the average, for a given material. This may be expressed as

$$n_2 = \frac{P + t}{P}$$

where P = property in question
t = tolerance to be expected in the property.

Let n_3 be a factor which will take into consideration the well-known fact that a variation of properties may be expected on account of size. Thus, a test on which a determination of properties is made may come from a small section where favorable conditions may prevail in the matter of forging or other working. This is particularly true in the case of pieces which are to be heat-treated. Generally test specimens of such pieces are more responsive to heat treatment because of better penetration than larger pieces subject to the same treatment.

Let n_4 be taken as an insurance factor. Assuming the preceding factors as having been applied, the presumption is then that the stress in a piece so designed will, in an unfavorable case of uniformity, be on the verge of the elastic limit. Quite obviously even apart from the standpoint of deformation on the part of structure under consideration, cases where such high stresses would be satisfactory are very rare. Hence most cases require the use of excess material in order to reduce the stress in the part to a point where the designer feels secure. This excess material may be considered in the light of a premium which is paid for the sake of insurance against failure.

This factor is one which is dependent either on the designer's own judgment or on precedent. As a suggestion, several cases may be mentioned, not so much in an effort to provide numerical values for these factors as to crystallize the thought on this. These may be:

(*a*) Cases where failure involves danger to life
(*b*) Cases where failure involves risk to valuable property
(*c*) Cases where failure will interrupt extensive production processes
(*d*) Cases where the operation of the machine only is interrupted by failure.

A stress concentration factor may be called n_5. The elementary formulas for stress do not take into account local stresses of high value. In the case of static loads considered here, stress concentrations are not of much consequence for ductile materials, but are a source of danger for brittle materials. It is recommended that the designer classify such sources of local stress concentration, working out factors which he may apply to his design calculations.

To cover the case of anticipated wastage or corrosion of a machine element in service, n_6 may be introduced. This is largely a matter for the judgment of the designer.

Then n_7 may finally be termed the factor of ignorance. Even with the excellent tools at our disposal, in the form of ever-extended methods of calculations, cases occasionally arise in which the computation of stress is either impossible or in which the designer feels the computation is at best only an approximation.

In this event, whether the suggested procedure is followed or not, the designer's instinct or judgment must lead him somehow to evaluate this uncertainty into a factor which shall take the situation into account to his satisfaction.

3 For the case of repetitive loads, fatigue stresses must be considered. There is just as much reason for the application of a factor of safety to the endurance limit in this case as to the ultimate strength in the case of static loads. The factor of safety in the case of fatigue stresses, however, is formed somewhat differently.

The factor n_1 has now no meaning and may be omitted. The starting point for this work is then the endurance limit, and the

other factors $n_2 \ldots . n_7$ are effective. The stress concentration factor n_8 is to be applied in its full effect for both ductile and brittle materials.

Where stress reversal is not complete, a direction computation of the working stress from the endurance limit for reversed stresses may be rather severe. In such cases recourse may be made to one of the diagrams or formulas proposed for maximum strength expressed as a function of range of stress. To this value, then, rather than to the endurance limit for completely reversed stresses, the factor of safety may be referred.

4 Many cases arise where stiffness is of great importance, so much so that it is probable that whatever proportions will produce a design possessing the required rigidity will certainly produce sufficient strength. In such problems it is necessary to compare the stresses required from the standpoint of safety with those required by rigidity.

5 Assuming for the present that the designer has assigned values to each of the foregoing factors for a particular case, he is in a position to obtain a working stress. Let us examine the result of this analysis.

It is perfectly true that he may, in his judgment, eliminate certain of the factors mentioned, or, for the particular case under consideration, introduce new factors. In any event probably the chief arguments which will be raised against his selection by the foregoing method are that many of the factors have depended on his judgment entirely, and this being the case he might as well have applied his judgment to the whole factor of safety at once, with at least as satisfactory results.

This may be granted, but an answer to the objection is, first, that he may still apply an overall judgment, so to speak, to his result; and, second, that by using the process outlined he has considered separately the tangible and the more or less intangible elements, and he has allowed himself the opportunity of evaluating separately, and each on its own merits, every one of the considerations on which the experienced designer's judgment is the only available guide. It would seem a reasonable conclusion that the foregoing method should produce a factor of safety more rationally determined than the ordinary method.

M. Stone.[25] Having been associated with the author and others in codifying our knowledge of the behavior of materials under various working conditions, the writer would like to add to and elaborate on some of the ideas expressed in the paper.

The author's opening statement divides the subject of properly designing a mechanical structure for strength into two parts: (1) calculation of stresses and (2) significance of stress as regards failure. It is essentially the second part that this subject properly deals with. It is often in men's minds that, let us say, mild carbon steel fails at 60,000 lb. per sq. in., and that safe stress values should not exceed 25,000 lb. per sq. in. in a structure. These ideas are based on experiments made by testing such steels in tension, and form a basis for most design work. However, when such ideas are contrasted with the facts that stresses in roller bearings approach 200,000 lb. per sq. in., and in ball bearings 400,000 lb. per sq. in., along the areas of contact, and that gear teeth operate regularly close to 100,000 lb. per sq. in. at the pitch circle, the significance of the stress is quite apparent. A close investigation into the reasons for the persistence of such stress values without destruction reveals the fact that steels under three-dimensional stress may be stressed to values approaching the cohesive forces of the molecules before rupture. Joffé, in a classical experiment, lowered the temperature of a steel ball slowly to the temperature of liquid air, and on quickly drawing it out into atmospheric temperature, by dint of the rapid heating of the external surface, exceeded the yield point of the material, placing the center portion into very high three-dimensional tension.

Subsequent cutting and examination of the material showed no failure at stress values far in excess of ordinary ultimate strengths.

Very often the stress at the edge of a hole, where a pin is pulling against one side, exceeds the yield point of the material, and such a condition is considered satisfactory design practice. The appreciation of the extreme localization of stress and inability to spread are the guiding principles in such applications.

In a dovetail, the mechanical element used to fasten an electrical field pole to the armature body, stress values in excess of the yield point are tolerated at the fillets because it is realized that concentrations of stress do not enhance the possibility of failure under static stressing.

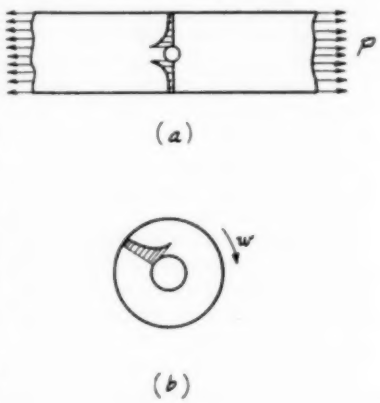

Fig. 11

The examples that have been discussed here served to emphasize the complexity of general ideas regarding applications of materials, but in the same sense must be regarded as strong arguments for a simplification of working-stress rules.

The last point, in particular, gives evidence of a certain element of difficulty in generalization. Although it is indeed a worthy goal to be able to say stress concentrations have no meaning for static applications but must be fully considered under varying stress, the question is immediately raised, when can a stress distribution be called a "concentration of stress?" This point may be illustrated by comparing the stress distributions shown in Fig. 11 (*a*) and (*b*). It is the dictate of safe designing to judge (*a*) a condition of stress concentration, while in (*b*) the design must be limited by the peak stress at the inner bore. This point could be further developed, but is introduced here only as one of the difficulties encountered in generalizing.

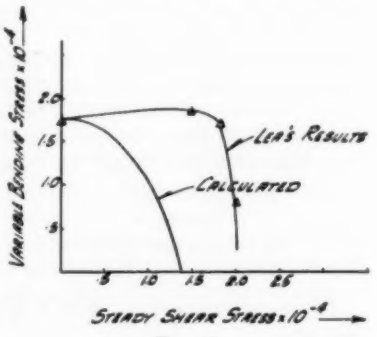

Fig. 12

In Appendix No. 1 the author has reproduced rules and arguments as to interpretation of materials under various complex stress applications. It must be realized that all such relations have as their experimental basis the failure of materials under combined steady and variable stresses in one plane only; and the failure under stress combinations on various planes and with shear have been worked out on the basis of stress combinations that follow from the theory of elasticity. This, it must be admitted, is all that can be offered in a rational treatment of the complex subject until further tests are made of the failure of materials under combined stresses, and it is only when such rather profound material researches are carried out that more definite ideas may be had.

[25] Mechanical Engineer, Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa.

Professor Lea[26] in England has already made a beginning in determining the failure of shaft material under steady torsion (shear stress) and alternating bending (direct stress). His tests show rather startling results, and although not investigated for confirmation by other engineers as yet, are worth discussing further. In Fig. 12 it is seen that comparatively large values of steady shear stress may be superimposed on an already existing bending stress without precipitating failure, until a certain critical value is reached. In this same figure has been drawn the curve of failure as predicted from the discussion in Appendix No. 1. It will be noticed that the rules proposed are distinctly on the side of safety.

Probably the most important result given in the paper is that discussed under "The Fundamental Case of Stress Cycle." This has been reported on earlier[27,28] and still retains certain alternative interpretations. As the author has given it, it will be appreciated that the same factor of safety has been chosen in variable stress relative to the endurance limit as for static stress relative to the yield point. However, when it is considered that endurance limit means actual rupture while yield point means only an increase in strain, it is conceivable that a larger factor of safety might well be applied to the variable stress. Equation [31] then becomes

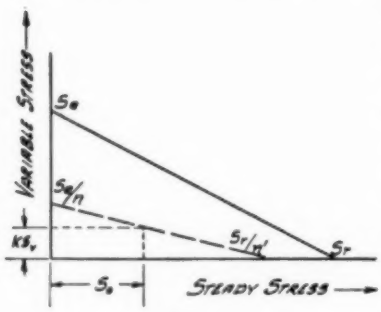

FIG. 13

$$\frac{S_s}{S_y} + \frac{N'}{N}\frac{KS_y}{S_e} = \frac{1}{N}$$

when N = static factor of safety.
N' = fatigue factor of safety ($N' > N$)

This modifies Fig. 10 to that shown in Fig. 13. However, a certain simplicity of use is lost if this modification is introduced, and it must be left to the designer to estimate the exigencies of his case. The intrinsic value of the arguments under this paragraph are very valuable and far-reaching in so far as they simplify the use of a great mass of experimental data for design purposes.

In closing, it must still be realized that in addition to the best interpretation of material properties and load stresses, there always exists some uncertainty as to the conditions that may occur in the future life of a structure. If, for instance, in a three-bearing set, the foundation were to "set" under an outer pedestal, comparatively high bending stresses would be set up in the shaft. Non-uniform temperature distributions in a structure are conducive to additional, usually non-predictable stresses. For such exigencies, actual factors of safety reaching as high as 3 must still be retained, depending on experience with particular structures.

However, the general reaction to the author's suggestion regarding organized action on "working stresses" must be a positive one, and it is well established that with the beginning that has been made and the future work that is indicated much benefit will result.

AUTHOR'S CLOSURE

Mr. Baud's criticism with respect to the vague meaning of the term "actual stress" is justified, but the author would like to point out that the definition of factor of safety put forward in the paper is not new and has always been afflicted with this ambiguity, nor will anything short of a complete solution of the entire problem disperse it. To be able to define the factor of safety (or factor of utilization) in a general statement means that there should always exist a single stress which, when increased to a certain limit, causes failure in the sense that this term is understood. Such a stress can be said to exist only in simple stress applications such as straight tension, bending, torsion, and a few cases of combined stresses. For ductile materials under constant loads the stress that comes nearest to this in significance is the stress figured by ordinary elementary formulas. Local concentrations of stress apparently have appreciable influence only in the case of variable stresses and in brittle materials. Under these circumstances it seems defensible to base the definition of factor of safety upon some such average stress, which must be defined separately for each case. Obviously, Equation [1] presupposes the existence of such a stress, and although this may be debatable in many cases, it is justified by the many important simple ones where experience shows the supposition to be essentially correct.

With respect to the remark by Dr. Nadai that too much significance has been given to stress among numerous other design factors, the author wishes to point out that the paper is limited intentionally to a discussion of stresses as causes of failure. This has not been done with the implication that the term "working stress" should be given general preference over other factors such as deflection, vibration properties, stability, etc. These are matters to be decided in each case by the responsible designer. The statements of the paper apply to such cases where stresses are the dominating elements.

The number of cases where stress is the deciding factor is so great, however, that the term "working stress" might well be given a preferred place in the list of factors which have to do with failure. In the electrical industry in particular, where expensive materials are applied to very large units, the rational utilization of these materials is a problem of real economical importance.

Mr. Eaton's remarks on internal stress, surface condition, and location in the ingot are to the point and illustrate the difficulties that obstruct the path toward quantitative evaluation of the factor of safety. All three subjects must necessarily influence the designer's judgment as to the utilization of the properties of strength, but it seems that the method of defining this utilization quantitatively need be influenced by the internal stresses only. Where surface conditions and location in the ingot are of deciding importance, the tests must be made in such a manner that the material constants, upon which the utilization is ultimately based, reflect the influence of these factors.

Referring to the question propounded by Mr. Clausen on the working stress for combinations of constant and variable stress, it seems that the rule given by Equation [16] might be used as a guide.

The author agrees with the statements of Dr. Timoshenko and Professor Moore that certain more or less doubtful phases of the theory of failure have been somewhat too dogmatically stated to be true. It certainly has not been proved that fatigue failures always occur in the plane of maximum shear, nor is the maximum-shear theory unassailable. Least of all can there be said to exist a definite experimental justification for the treatment of brittle materials given in Appendix No. 1. Until more knowledge is collected on the subject, however, it is difficult to obtain equally simple and safe rules which more accu-

rately follow the general trend of the experimental results. The author is prepared to admit that the wording of a possible code on the subject may have to take the form of more or less arbitrary assumptions, justified by references to recognized experimental results. Naturally, a code must not mean stagnation of progress; it should be merely a medium through which the latest results are interpreted in a simple form for the practical engineer.

Professor Wattleworth's proposal to base working stresses on ultimate strength rather than yield point seems to the author to do injustice to the case of constant stress. Here the yield point is a true limiting stress for the most important ductile materials, and represents 100 per cent utilization of the properties of strength. It is true that in some cases endurance data may be correlated with ultimate strength rather than yield point, but this does not appear to the author a sufficient reason, particularly since many cases are on record where the line of failure of Fig. 9 does head for the yield point. Well-established customs should be left alone as far as possible, but it seems that the idea of basing failure under constant stress in ductile materials upon the ultimate strength should form an exception to this rule. The fundamental conception of utilizing a certain percentage of the possibilities of the materials is otherwise lost. The quantitative method of arriving at the factor of safety proposed by Professor Wattleworth seems very sound, particularly because it forces the designer to take stock of the various factors in operation. Intuitive judgment is certainly strengthened by quantitative reasoning of this general type.

Mr. Stone's proposal to "weight" the endurance limit in Equation [31] by a separate factor of safety is equivalent to reducing the endurance limit a certain arbitrary amount. The fundamental soundness of Mr. Stone's reasoning is admitted, but it is questioned whether the same result might not be obtained more easily by agreeing on some constant fraction of the endurance limit to be used in the equation.

Stresses and Deflections in Flat Circular Plates With Central Holes

By A. M. WAHL,[1] EAST PITTSBURGH, PA., AND G. LOBO, JR.,[2] NEW YORK, N. Y.

Simplified formulas are derived for calculating maximum stress and maximum deflection of flat circular plates having central holes. Eight different loading and edge conditions are considered. These formulas are presented in a usable form for the practical designer. Approximate solutions are given for purposes of checking the formulas. Using the principle of superposition, a simple method of superimposing fundamental cases is developed for calculating cases other than those considered in the paper. Experimental determinations of stress and deflection for certain cases indicate that the formulas are sufficiently accurate for practical work where the edge conditions are determinate. For indeterminate edge conditions, as for example so-called built-in edges, the tests indicate that, while there is good agreement in the case of stress, the measured deflection is considerably greater than the theoretical.

FLAT circular plates with central holes are structures which are widely used in engineering work. To name a few of the more common applications, there may be mentioned Kingsbury thrust-bearing plates, diaphragms of all kinds as used in telephones, loud-speakers, steam turbines, diffusers, piston heads, certain types of cylinder head, etc.

For calculating the strength or stiffness of these structures, the ordinary flat-plate theory,[3] usually known as the Grashof theory, may be applied. The application of this flat-plate theory by the use of formulas commonly given in textbooks will, when applied to flat circular plates, be found in most cases to entrail long and laborious computation, with much chance for error and such as to make practical men and designers skeptical of the final results. In reviewing the literature on flat-plate theory, the authors were unable to find any simple formulas that may be applied easily and quickly to such commonly used cases as flat circular plates with central holes and having various loading and edge conditions.

The reason, therefore, for undertaking this investigation was to obtain, if possible, simple formulas for these cases of flat plates, such that practical men and designers could use the results of flat-plate theory without long and tedious computation. It was also desired to develop, if possible, a more simple procedure for calculating specific cases of flat plates other than those considered in this paper. This was done by the use of the principle of superposition of fundamental cases. This method, as finally developed, will require less calculation than the ordinary method. Finally, it was desired to obtain experimental verification of at least part of the formulas given in this paper. To this end the paper is divided into four major parts:

Part I Simplified Formulas for Eight Common Cases of Flat Plates With Holes.

Part II Approximate Solutions of the Plate Problem.

Part III The Principle of Superposition of Fundamental Cases, With Applications.

Part IV Experiments and Comparison With Theory.

PART I SIMPLIFIED FORMULAS FOR EIGHT COMMON CASES OF FLAT PLATES WITH HOLES

In order to obtain a formula for the maximum stress and deflection of a flat circular plate with a central hole, symmetrically loaded, it is necessary to integrate the general differential equation[4] for the deflection of a symmetrically loaded flat circular plate, and so determine the integration constants as to satisfy the edge conditions of the actual plate. These values of maximum stress and maximum deflection in the plate may thus be obtained in the form of comparatively simple formulas, as given farther on.[5] In order to simplify the formulas as much as possible in this work, the value of Poisson's ratio $1/m$ was assumed equal to 0.3 (the commonly accepted value for steel). However, it is believed that the results will be reasonably accurate even where Poisson's ratio is considerably different from 0.3.

The following nomenclature is used in all cases:

a = outer radius of plate = $^1/_2$ outer diameter
b = inner radius of plate = $^1/_2$ inner diameter
α = ratio $\frac{a}{b} = \frac{\text{outer radius}}{\text{inner radius}}$
P = total load uniformly distributed along edge of plate (for those cases having this condition)
p = pressure per square inch of plate surface (for those cases having a uniformly distributed pressure acting on the plate)
t = thickness of plate, inches
E = modulus of elasticity of the material, lb. per sq. in.
S = maximum stress in the plate, lb. per sq. in.
y = deflection of one edge with respect to the other, inches.

Cases Considered With Simplified Formulas

Eight different cases which commonly occur in practice were worked up. These cases are represented schematically in Fig. 1. The final formulas for maximum stress and maximum deflection as derived for each case are also given. It will be seen that in all cases the maximum stress is given by a formula of the type $S = \frac{Kpa^2}{t^2}$ or $\frac{KP}{t^2}$, depending on whether the applied load is uniformly distributed over the surface or concentrated along the

[3] The fundamental differential equation for calculating the strength of flat circular plates symmetrically loaded is derived in several textbooks, including "Applied Elasticity," by Timoshenko and Lessells, p. 275, and also "Strength of Materials," by Case, p. 489. Very complete studies, not only on circular plates, but also on rectangular plates, are given in "Elastische Platten," by A. Nadai. Some tests and theory of circular plates without holes are reported by Max Ensslin, Dingler's Polytechnishes Journal, vol. 318, 1903. The general theory of bending of plates is also given in a paper by Westergaard and Slater, Proc. Am. Concrete Inst., 1921.

Contributed by the Applied Mechanics Division and presented at the Akron Meeting, Akron, Ohio, October 21 to 23, 1929, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

[4] See, for example, "Applied Elasticity," p. 274, mentioned in footnote 3, for the derivation of this equation.

[5] An illustration of this method is given in Appendix 1, which includes the derivation of the formulas for Case 1, cited farther on.

edge. Likewise, the deflection y as shown is given by a formula of the type $y = \frac{Mpa^4}{Et^3}$ or $y = \frac{MPa^2}{Et^3}$. The constant K in the stress formula depends on the ratio α of outside to inside radius of the plate and may be taken from the curves of Fig. 2. Thus for case 1 the formula for maximum stress is $S = \frac{K_1 P}{t^2}$ where K_1 depends on the ratio $\alpha = \frac{a}{b}$ for the plate considered, and is taken from the curve marked K_1 in Fig. 2; likewise the constants M in the deflection formula depend on the ratio α of the radii and may be taken from the curves of Fig. 3. Thus for case 3 the deflection is $M_3 \frac{pa^4}{Et^3}$, where M_3 again depends on the ratio $\alpha = a/b$ and is taken from the curve marked M_3 in Fig. 3.

For values of α near to unity the curves do not, in most cases, give the values of K or M accurately. In such cases a radial strip of the plate may be considered as a beam with end conditions and loading as in the actual plate. As shown farther on, this method is accurate for values of α near to unity.

Limitations of Foregoing Formulas

It should be noted that the flat-plate theory, by means of which the foregoing formulas were derived, assumes that the thickness of the plate is small relative to the diameter and that deflections are small relative to thickness. This means that deflections due to shear as well as stresses set up by stretching the middle surface of the plate were neglected. It is, however, believed that where the deflection is not over one-half the thickness and where the thickness is less than one-third the difference between inside and outside diameters for simply supported edges and less than one-sixth the difference between inside and outside diameters where one or more edges are built in, the foregoing formulas hold with sufficient accuracy for practical work. It should, however, be noted that a truly built-in edge does not exist in practice, and for this reason the formulas for deflection of plates with built-in edges must be considered as approximations only, although it is probable the stress formulas for such cases are more accurate. Where the thickness is greater than one-third difference in diameters for simply supported edges or one-sixth the difference in diameters for built-in edges the deflection due to shear may be taken into account by adding on to the deflection as found by the foregoing plate formulas the following deflections,[6] G being the shear modulus of elasticity:

$$y_s = \frac{0.239P \log_e \alpha}{tG}$$ (for plates with load P uniformly distributed along edges, cases 1, 6, and 8)

$$y_s = \frac{0.375pa^2}{tG}\left[1 - \frac{1}{\alpha^2} - \frac{2 \log_e \alpha}{\alpha^2}\right]$$ (for plates with uniform load p on surface and supported on outer edge, cases 4 and 7)

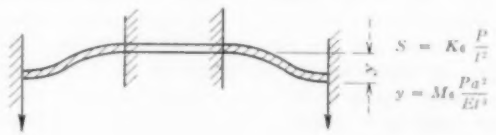
$$y_s = \frac{0.375pa^2}{tG}\left[2 \log_e \alpha - 1 + \frac{1}{\alpha^2}\right]$$ (for plates with uniform load p on surface and supported on inner edge, cases 2, 3, and 5)

Moreover, as mentioned, for values of α near to unity the curves of Figs. 2 or 3 do not, in most cases, give the values of K or M accurately. In such cases the procedure recommended may be used.

Case 1 Loaded along inner edge; simply supported at outer edge; P = total load on edge.

Case 2 Uniformly loaded; simply supported at inner edge; p = uniform load on surface (lb. per sq. in.).

Case 3 Uniformly loaded; built-in at inner edge; p = uniform load on surface (lb. per sq. in.).



Case 4 Uniformly loaded; simply supported at outer edge; inner edge prevented from rotating; p = uniform load on surface (lb. per sq. in.).

Case 5 Uniformly loaded; built-in at inner edge; outer edge prevented from rotating; p = uniform load on surface (lb. per sq. in.).

Case 6 Loaded along outer edge; built-in at inner edge; outer edge prevented from rotating; P = total load on edge.

Case 7 Uniformly loaded; simply supported at outer edge; p = uniform load on surface (lb. per sq. in.).

Case 8 Loaded along outer edge; built-in at inner edge; P = total load on edge.

Fig. 1 Various Cases of Loading and Edge Conditions Considered
(a, outer radius; b, inner radius; t, thickness in inches.)

Practical Example

As an example of the application of these simplified formulas, consider a loud-speaker diaphragm of 0.017-in. steel sheet with

[6] See Appendix 2 for method of derivation of these equations.

an outer radius $a = 1.12$ in. and an inner radius $b = 0.5$ in. The inner edge is clamped, and the load applied by electromagnetic forces is 5.8 lb., uniformly distributed along the outer edge. Required: the maximum stress and deflection of the diaphragm.

It will be noticed that these are the edge and loading conditions of case 8. In this case $\alpha = a/b = 2.25$. From the curve of Fig. 2 we find for $\alpha = a/b = 2.25$ a value $K_8 = 0.9$. Hence the maximum stress (from the formula given opposite case 8, Fig. 1) is:

$$S = K_8 \frac{P}{t^2} = \frac{0.9 \times 5.8}{(0.017)^2} = 18{,}000 \text{ lb. per sq. in.}$$

Also from the curve of Fig. 3 we find for $\alpha = a/b = 2.25$ a value $M_8 = 0.12$. Hence the maximum deflection (from the formula opposite case 8, Fig. 1) is:

$$y = M_8 \frac{Pa^2}{Et^3} = \frac{0.12 \times 5.8 \times (1.12)^2}{30 \times 10^6 \times (0.017)^3} = 0.006 \text{ in.}$$

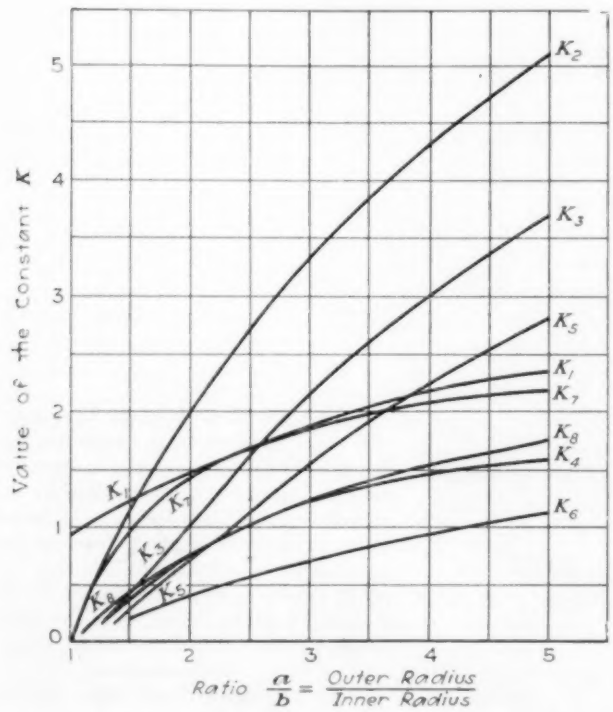


FIG. 2 CURVES FOR FINDING K IN THE STRESS FORMULA FOR FLAT PLATES $S = K\frac{P}{t^2}$ OR $S = K\frac{pa^2}{t^2}$

In this a modulus $E = 30 \times 10^6$ lb. per sq. in. is assumed.

The foregoing example should make clear the procedure in calculating similar cases.

ALGEBRAIC VALUES OF THE CONSTANTS K AND M

The values of the constants K_1, K_2, ... K_8 and M_1, M_2, ... M_8, from which the curves of Figs. 2 and 3 were plotted, were found, as mentioned, from the ordinary flat-plate theory, taking Poisson's ratio $1/m = 0.3$. The final results in algebraic form were as follows:

$$K_1 = 0.3343 + \frac{1.242\alpha^2 \log_e \alpha}{\alpha^2 - 1}$$

$$K_2 = \frac{3.9\alpha^2 \log_e \alpha + \frac{0.525}{\alpha^2} + 0.9 - 1.425\alpha^2}{\alpha^2 - 1}$$

$$K_3 = \frac{3.9\alpha^2 \log_e \alpha + \frac{0.525}{\alpha^2} - 1.425\alpha^2 + 0.9}{0.7 + 1.3\alpha^2}$$

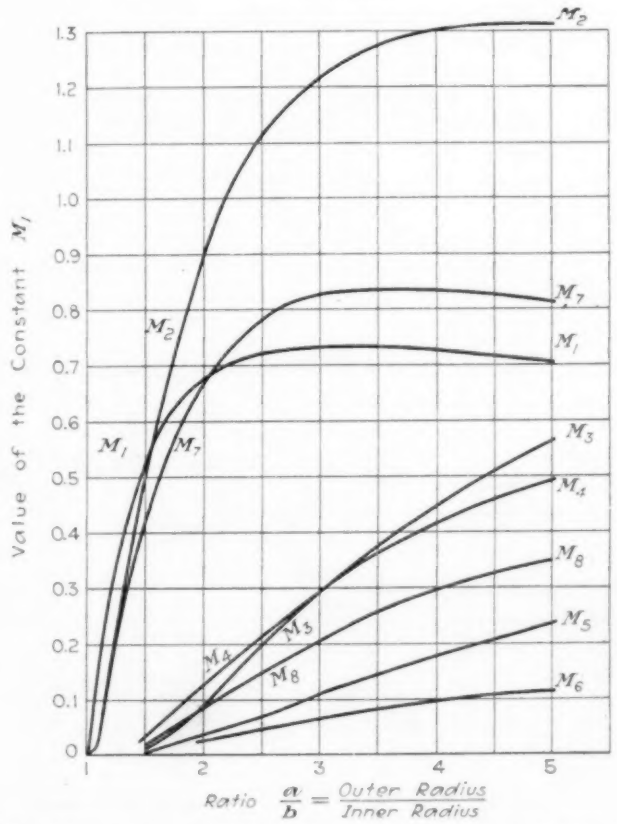

FIG. 3 CURVES FOR FINDING M IN THE DEFLECTION FORMULA FOR FLAT PLATES $y = M\frac{Pa^2}{Et^3}$ OR $y = M\frac{Pa^4}{Et^3}$

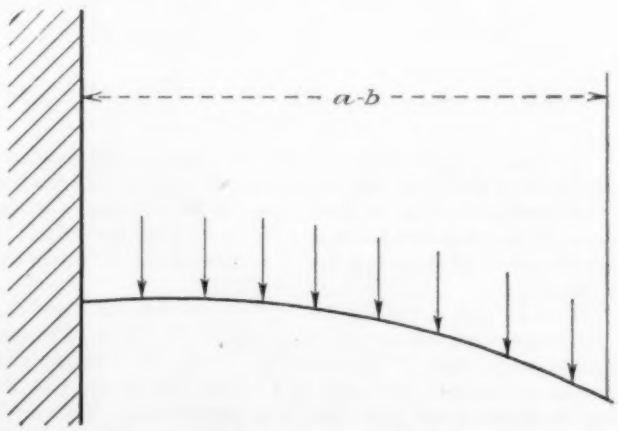

FIG. 4 LOAD ACTING ON CANTILEVER STRIP

$$K_4 = \frac{\frac{0.525}{\alpha^2} - 3.9\log_e \alpha - 3 + 2.475\alpha^2}{1.3\alpha^2 + 0.7}$$

$$K_5 = \frac{3\alpha^2 \log_e\alpha + 3 - 2.25\alpha^2 - \dfrac{0.75}{\alpha^2}}{\alpha^2 - 1}$$

$$K_6 = \frac{0.9549\alpha^2 \log_e\alpha}{\alpha^2 - 1} - 0.4775$$

$$K_7 = \frac{-3.9 \log_e\alpha + 2.475\alpha^2 - 3 + \dfrac{0.525}{\alpha^2}}{\alpha^2 - 1}$$

$$K_8 = \frac{1.241\alpha^2 \log_e\alpha + 0.3342\alpha^2 - 0.3342}{1.3\alpha^2 + 0.7}$$

$$M_1 = 0.5514\left(\frac{\alpha^2 - 1}{\alpha^2}\right) + \frac{1.614\,(\log_e\alpha)^2}{\alpha^2 - 1}$$

$$M_2 = \frac{-1.037\alpha^2 + 2.770 - \dfrac{2.428}{\alpha^2} + \dfrac{0.695}{\alpha^4} - 5.07\,(\log_e\alpha)^2 + 3.22\log_e\alpha + \dfrac{3.22\log_e\alpha}{\alpha^2}}{\alpha^2 - 1}$$

$$M_3 = \frac{0.529 - 1.348\alpha^2 + \dfrac{0.938}{\alpha^2} - \dfrac{0.119}{\alpha^4} + 3.21\log_e\alpha + 3.55\,(\log_e\alpha)^2 + \dfrac{0.888\log_e\alpha}{\alpha^2}}{1.3\alpha^2 + 0.7}$$

$$M_4 = \frac{0.905\alpha^2 - 3.498 + \dfrac{2.235}{\alpha^2} + \dfrac{0.358}{\alpha^4} + \dfrac{6.35\log_e\alpha}{\alpha^2} - 2.25\log_e\alpha + \dfrac{3.55\,(\log_e\alpha)^2}{\alpha^2}}{1.3\alpha^2 + 0.7}$$

$$M_5 = \frac{-0.512\alpha^2 + 1.195 - \dfrac{0.854}{\alpha^2} + \dfrac{0.171}{\alpha^4} + 2.73\,(\log_e\alpha)^2 - 0.683\log_e\alpha + \dfrac{0.683\log_e\alpha}{\alpha^2}}{\alpha^2 - 1}$$

$$M_6 = \frac{0.217\alpha^2 - 0.434 + \dfrac{0.217}{\alpha^2} - 0.868\,(\log_e\alpha)^2}{\alpha^2 - 1}$$

$$M_7 = \frac{-2.425\alpha^2 + 2.768 - \dfrac{1.037}{\alpha^2} + 0.694\alpha^4 + 3.22\alpha^2\log_e\alpha - 3.22\log_e\alpha - 5.07(\log_e\alpha)^2}{\alpha^2(\alpha^2 - 1)}$$

$$M_8 = \frac{1.129\,(\log_e\alpha)^2 + 1.738\log_e\alpha - 0.7169\alpha^2 + 0.5648 + \dfrac{0.1521}{\alpha^2}}{1.3\alpha^2 + 0.7}$$

PART II APPROXIMATE SOLUTIONS OF THE PLATE PROBLEM

In order to check up the numerical values of the constants K and M of Part I, an approximate solution to the plate problem was developed. The method consisted in assuming a radial strip of the plate as a beam with end conditions and loading as in the actual plate, and on this basis determining the stress and deflection.

Thus for case 3, a radial strip of the plate was considered as a cantilever subjected to a uniformly distributed load. For case 4, the radial strip is assumed a beam supported at one end, uniformly loaded, and acted on by a bending moment at the other of such value as to keep it in equilibrium. For case 5, the elementary radial strip is taken as one-half a beam with ends built in and loaded with a uniform load. The radial strip for case 6 is assumed one-half a beam with ends built in and loaded by a load in the middle, while for case 8, it is assumed a cantilever beam with load in the end. In the other cases the approximate solution is obtained on the basis that a radial section of the plate remains undistorted during bending,[7] deflection consisting entirely of a rotation of the section. It will be noted that these assumptions are accurate only for ratios of α which approach unity. The values of the constants K' and M' corresponding to the constants K and M were determined in this way; they were then compared with those obtained by the exact theory.

As an example of the application of this method, take case 3. In this case we may imagine a cantilever strip cut out from the plate by two radial planes normal to the plate and subtending a small angle $\delta\theta$ (Fig. 4). The total load acting on this elementary cantilever will be

$$L = \frac{\delta\theta\pi p\,(a^2 - b^2)}{2\pi}$$

Assuming this load to act at the middle point of the cantilever, the bending moment will be

$$M = \frac{L\,(a - b)}{2}$$

from which the stress at the built-in end will be:

$$S = \frac{6L\,(a - b)}{2\delta\theta b t^2} = \frac{1.5pa^2\,(\alpha^2 - 1)\,(\alpha - 1)}{t^2\,\alpha^2}$$

or

$$S = K'_3\frac{pa^2}{t^2}$$

where

$$K'_3 = \frac{1.5(\alpha^2 - 1)\,(\alpha - 1)}{\alpha^2}$$

If the curve for K'_3 be plotted as a function of α it will be found to practically coincide at small values of α with the curve for K_3 given in Fig. 2, determined by the more exact flat-plate theory. At larger values of α the discrepancy between the exact and the approximate solution becomes more and more pronounced, which is what we should expect, since the beam action of elementary strips, on which the approximate solution is based, is no more predominant.

In a similar way a value of M'_3 may be found which may be compared with the value of M_3 given by the exact solution (Fig. 3).

Values of K'_1, K'_2, K'_3, etc., and M'_1, M'_2, M'_3, etc., determined in this way for the various cases 1 to 8, are given in Table 1, for various values of $\alpha = a/b$. For comparison, the more exact values of the K's and the M's, K_1 to K_8, and M_1 to M_8 are given.

An examination of this table shows that for values of α near to unity the agreement between the approximate and the exact solutions is very good. This of course would be expected, since as α approaches unity a radial strip of the plate approaches nearer and nearer to the conditions assumed in the approximate solutions. At larger values of α the agreement is surprisingly good in some cases, while in others it is very poor.

[7] For details of this method, see S. Timoshenko's discussion of paper by Waters and Taylor, "The Strength of Pipe Flanges," *Mechanical Engineering*, 1927, p. 1343.

TABLE 1 VALUES OF K, K', M, AND M', FOR CASES 1 TO 8

α =	1	1.25	1.5	2	3	4	5

M_1'	0	0.343	0.524	0.689	0.773	0.775	0.760
M_2	0	0.202	0.491	0.902	1.220	1.300	1.310
M_2'	0	0.194	0.487	0.902	1.260	1.369	1.400
M_3	0	0.00231	0.0183	0.0938	0.2925	0.448	0.564
M_3'	0	0.00218	0.0168	0.0853	0.2683	0.432	0.559
M_4	0	0.00343	0.0313	0.1250	0.2910	0.417	0.492
M_4'	0	0.00364	0.0281	0.1420	0.4470	.....	.....
M_5	0	0.00077	0.00618	0.0329	0.1096	0.1792	0.2338
M_5'	0	0.00073	0.00562	0.0284	0.0894	0.1440	0.1864
M_6	0	0.00129	0.00637	0.0237	0.0619	0.0923	0.114
M_6'	0	0.00129	0.00644	0.0241	0.0644	0.0975	0.124
M_7	0	0.18410	0.41390	0.6640	0.8237	0.8296	0.813
M_7'	0	0.20200	0.42600	0.7210	0.8990	0.9130	0.891
M_8	0	0.00510	0.02490	0.0877	0.2090	0.2930	0.350
M_8'	0	0.00515	0.02570	0.0965	0.2575	0.3890	0.494

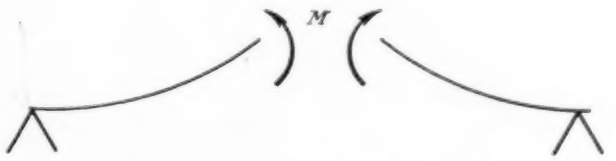
The approximate solution thus offers a check on the correctness of the calculations since at values of α near to unity the agreement between the value of a constant K or M and the corresponding value of K' or M' must be good or a mistake in calculation has been made.

PART III THE PRINCIPLE OF SUPERPOSITION OF FUNDAMENTAL CASES, WITH APPLICATIONS

In order to do away with the necessity of solving the fundamental differential equation with different boundary conditions for each different case, each case can be resolved into its component simple loadings, and the formulas for the simple loadings combined to give the desired result. These simple, or fundamental, cases are five in number, and almost any case of flat plates with central holes may be solved by combining two or more of these cases in the manner which will be shown later. These five cases are shown schematically in Fig. 5, as A, B, C, D, and E.

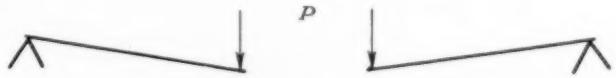
In order to be able to combine these cases, it is necessary to find six quantities for each case. These are:

1 Slope of plate surface at outer edge $(\phi)_a$
2 Slope of plate surface at inner edge $(\phi)_b$
3 Deflection of plate at outer edge $(W)_a$
4 Deflection of plate at inner edge $(W)_b$
5 Radial bending moment at inner edge $(M_1)_b$
6 Tangential bending moment at inner edge $(M_2)_b$

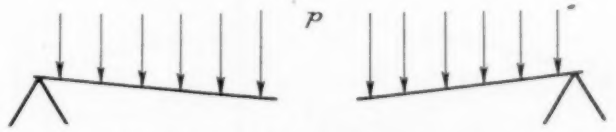


Having these values, the cases which must be superimposed to give the desired result are determined by inspection. Then, if the slope at one edge is zero, the formulas for the slope of the component cases at this edge are added algebraically,[8] equated to zero, and solved for one load in terms of the others. These results are then substituted in the summations of deflections and moments which give the deflection and bending moment for the case being investigated. If one edge is simply supported or free, then the radial bending moment M_1 at this edge must equal zero, and the equation may be derived with this as a start.

There are two methods of applying this principle of superposition. The first consists of combining the complete equation algebraically, and arriving at complete formulas for the desired case. The second method consists of arbitrarily taking certain values of the ratio of inner to outer radius α, finding the numerical value for the coefficients of each equation, and then combining them. Both of these methods are illustrated later.



The formulas derived by the method of Appendix 1 for each of the fundamental cases are given, with the numerical values of the coefficients for various values[9] of α, in Tables 2, 3, and 4.



CASE A Loaded by a bending moment of M lb. in. per in. along outer edge; simply supported along inner edge.

CASE B Loaded by a bending moment of M lb. in. per in. along inner edge; simply supported along outer edge.

CASE C Loaded along inner edge; simply supported along outer edge; P = total load on edge.

CASE D Uniformly loaded on surface; simply supported on outer edge; p = uniform load on surface, lb. per sq. in.

CASE E Uniformly loaded on surface; simply supported on inner edge; p = uniform load on surface, lb. per sq. in.

FIG. 5 THE FIVE FUNDAMENTAL CASES

TABLE 2 SLOPE, DEFLECTION, AND STRESS IN PLATES

	Case A	Case B	Case C	Case D	Case E
$(\phi)_a$	$(n_A)_a \frac{Ma}{Et^3}$	$(n_B)_a \frac{Ma}{Et^3}$	$(n_C)_a \frac{Pa}{Et^3}$	$(n_D)_a \frac{pa^3}{Et^3}$	$(n_E)_a \frac{pa^3}{Et^3}$
$(\phi)_b$	$(n_A)_b \frac{Ma}{Et^3}$	$(n_B)_b \frac{Ma}{Et^3}$	$(n_C)_b \frac{Pa}{Et^3}$	$(n_D)_b \frac{pa^3}{Et^3}$	$(n_E)_b \frac{pa^3}{Et^3}$
$(W)_a$	$(m_A)_a \frac{Ma^2}{Et^3}$	0	0	0	$(m_E)_a \frac{pa^4}{Et^3}$
$(W)_b$	0	$(m_B)_b \frac{Ma^2}{Et^3}$	$(m_C)_b \frac{Pa^2}{Et^3}$	$(m_D)_b \frac{pa^4}{Et^3}$	0
$(M_1)_b$	0	M	0	0	0
$(M_2)_b$	$(S_A)_2 M$	$(S_B)_2 M$	$(S_C)_2 P$	$(S_D)_2 pa^2$	$(S_E)_2 pa^2$

With the formulas and figures given in these tables, we are now ready to obtain almost any desired case by superposition. As an example, a case will be taken up which has already been solved analytically, so as to have a check on both methods.

[8] It is understood that the proper sign is taken for the various quantities.

[9] In these tables the sign of the various quantities is disregarded. In combining the cases the proper sign may be determined by inspection.

TABLE 3 VALUES OF COEFFICIENTS FOR TABLE 2

Case A

$$(n_A)_a = \frac{8.4\alpha^2 + 15.6}{\alpha^2 - 1}$$

$$(n_A)_b = \frac{24\,\alpha}{\alpha^2 - 1}$$

$$(m_A)_a = \frac{4.2(\alpha^2 - 1) + 15.6 \log \alpha}{\alpha^2 - 1}$$

$$(m_A)_b = 0$$

$$(S_A)_1 = 0$$

$$(S_A)_2 = \frac{2\alpha^2}{\alpha^2 - 1}$$

Case B

$$(n_B)_a = \frac{24}{\alpha^2 - 1}$$

$$(n_B)_b = \frac{8.4 + 15.6\,\alpha^2}{\alpha(\alpha^2 - 1)}$$

$$(m_B)_a = 0$$

$$(m_B)_b = \frac{4.2\left(1 - \frac{1}{\alpha^2}\right) + 15.6 \log \alpha}{\alpha^2 - 1}$$

$$(S_B)_1 = 1$$

$$(S_B)_2 = \frac{\alpha^2 + 1}{\alpha^2 - 1}$$

Case C

$$(n_C)_a = \frac{2.483 \log \alpha + 0.6685(\alpha^2 - 1)}{\alpha^2 - 1}$$

$$(n_C)_b = \frac{2.483\alpha^2 \log \alpha + 0.6685(\alpha^2 - 1)}{\alpha(\alpha^2 - 1)}$$

$$(m_C)_a = 0$$

$$(m_C)_b = \frac{0.5515\left(\alpha^2 + \frac{1}{\alpha^2}\right) - 1.1029 + 1.614(\log \alpha)}{\alpha^2 - 1}$$

$$(S_C)_1 = 0$$

$$(S_C)_2 = \frac{0.2069\alpha^2 \log \alpha + 0.0557\,\alpha^2 - 0.0557}{\alpha^2 - 1}$$

Case D

$$(n_D)_a = \frac{1.05\alpha^2 + 1.8 - \frac{7.8 \log \alpha + 2.85}{\alpha^2}}{\alpha^2 - 1}$$

$$(n_D)_b = \frac{4.95\alpha^2 - 6 - 7.8 \log \alpha + \frac{1.05}{\alpha^2}}{\alpha(\alpha^2 - 1)}$$

$$(m_D)_a = 0$$

$$(m_E)_a = \frac{-1.0369\alpha^2 + 2.7694 - \frac{2.4281}{\alpha^2} + \frac{0.6956}{\alpha^4} - 5.07(\log \alpha)^2 + 3.217 \log \alpha - \frac{3.217 \log \alpha}{\alpha^2}}{\alpha^2 - 1}$$

$$(m_D)_b = \frac{-2.428\alpha^2 + 2.769 - \frac{1.039}{\alpha^2} + 0.694\alpha^4 + 3.22(\alpha^2 \log \alpha - \log \alpha) - 5.07(\log \alpha)^2}{\alpha^2(\alpha^2 - 1)}$$

$$(S_D)_1 = 0$$

$$(S_D)_2 = \frac{-0.65 \log \alpha + 0.4125\alpha^2 - 0.5 + \frac{0.0875}{\alpha^2}}{\alpha^2 - 1}$$

Case E

$$(n_E)_a = \frac{7.8 \log \alpha + 1.05\alpha^2 - 6 + \frac{4.95}{\alpha^2}}{\alpha^2 - 1}$$

$$(n_E)_b = \frac{7.8\alpha^2 \log \alpha - 2.85\alpha^2 + 1.8 + \frac{1.05}{\alpha^2}}{\alpha(\alpha^2 - 1)}$$

$$(m_E)_b = 0$$

$$(S_E)_1 = 0$$

$$(S_E)_2 = \frac{0.65\alpha^2 \log \alpha - 0.2375\alpha^2 + 0.15 + \frac{0.0875}{\alpha^2}}{\alpha^2 - 1}$$

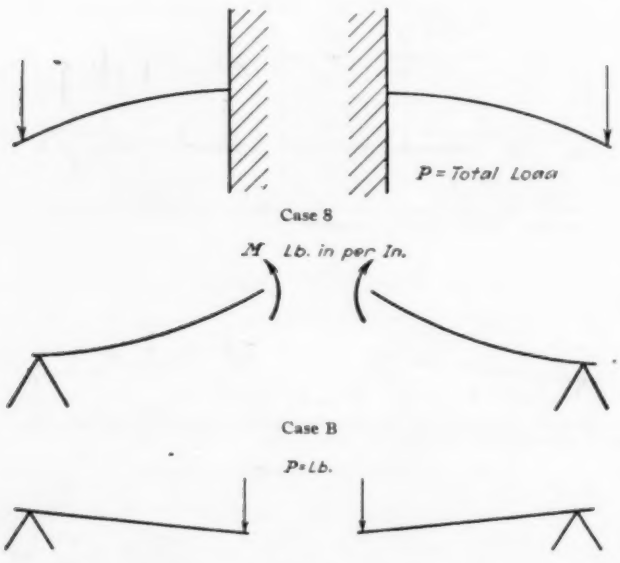


FIG. 6 A CASE OBTAINED BY SUPERPOSITION. CASE 8 OF PART I IS SHOWN TO BE A COMBINATION OF CASES B AND C

Case 8 of Part I, which is the case of a loud-speaker diaphragm, is chosen for this. This is the case of a plate fixed at the inner edge and loaded by a load distributed along the outer edge. A sketch of this case and of the component simple cases is shown in Fig. 6, this case being considered as a combination of cases B and C.

The stress and deflection formulas will be determined by two methods:

Method 1. Since the slope due to the radial bending moment $(M_1)_8$ at the inner edge (case B) is such as to annihilate that due to the applied load P (case C), we have:

$$(\phi_B)_b = (\phi_C)_b$$

TABLE 4 NUMERICAL VALUE OF COEFFICIENTS OF TABLE 2

CASE A

α	$(n_A)_a$	$(n_A)_b$	$(m_A)_a$	$(m_A)_b$	$(S_A)_1$	$(S_A)_2$
1.1	122.6862	125.71	11.280	0	0	11.524
1.25	51.0667	53.33	10.389			5.555
1.5	27.6000	28.80	9.260			3.600
2	16.4000	16.00	7.804			2.667
3	11.4000	9.00	6.342			2.250
4	10.0000	6.40	5.642			2.133
5	9.4000	5.00	5.246			2.083

CASE B

α	$(n_B)_a$	$(n_B)_b$	$(m_B)_a$	$(m_B)_b$	$(S_B)_1$	$(S_B)_2$
1.1	114.286	118.078	0	10.551	1	10.524
1.25	42.666	46.613		8.877		4.556
1.5	19.200	23.200		6.927		2.600
2	8.000	11.800		4.654		1.667
3	3.000	6.200		2.609		1.250
4	1.600	4.300		1.704		1.133
5	1.000	3.320		1.214		1.083

CASE C

α	$(n_C)_a$	$(n_C)_b$	$(m_C)_a$	$(m_C)_b$	$(S_C)_1$	$(S_C)_2$
1.1	1.7953	1.8472	0	0.1660	0	0.1693
1.25	1.6534	1.7659		0.3416		0.1857
1.5	1.4738	1.6537		0.5187		0.2067
2	1.2421	1.4815		0.6721		0.2469
3	1.0094	1.2457		0.7337		0.3114
4	0.8979	1.0850		0.7238		0.3616
5	0.8349	0.9658		0.7035		0.4024

CASE D

α	$(n_D)_a$	$(n_D)_b$	$(m_D)_a$	$(m_D)_b$	$(S_D)_1$	$(S_D)_2$
1.1	0.4797	0.4929	0	0.04419	0	0.04518
1.25	0.8937	0.9470		0.1838		0.09865
1.5	1.1922	1.3022		0.4130		0.1628
2	1.3120	1.4427		0.6819		0.2404
3	1.2477	1.2541		0.8237		0.3135
4	1.1831	1.0409		0.8296		0.3470
5	1.1418	0.8770		0.8132		0.3654

CASE E

α	$(n_E)_a$	$(n_E)_b$	$(m_E)_a$	$(m_E)_b$	$(S_E)_1$	$(S_E)_2$
1.1	0.4992	0.5143	0.04605	0	0	0.04715
1.25	0.9709	1.0502	0.2023			0.1094
1.5	1.3881	1.5840	0.4913			0.1980
2	1.6147	2.0481	0.9016			0.3414
3	1.5711	2.2246	1.2252			0.5561
4	1.4615	2.1546	1.3022			0.7182
5	1.3748	2.0358	1.3084			0.8483

Substituting in this equation the proper values of $(\phi_B)_b$ and $(\phi_C)_b$, as determined from Tables 2 and 3, and solving, the radial bending moment at the inner edge becomes:

$$(M_1)_b = P\left[\frac{0.2069\alpha^2 \log\alpha + 0.0557\alpha^2 - 0.0557}{0.7 + 1.3\alpha^2}\right]$$

Substituting this in the formula for deflection for case B, we get

$$(W_B)_b = \frac{Pa^2}{Et^3}\left[\frac{20.86(\log_e\alpha)(\alpha^2 - 1) + 38.71\alpha^2(\log_e\alpha)^2 + 2.805\left(\alpha^2 - 2 + \frac{1}{\alpha^2}\right)}{(8.4 + 15.6\alpha^2)(\alpha^2 - 1)}\right]$$

The actual deflection in this case is found by subtracting the deflection $(W_B)_b$, due to the bending moment $(M_1)_b$, from that due to the load P, thus:

$$W_b = (W_C)_b - (W_B)_b$$

Substituting and solving for W_b:

$$W_b = \frac{Pa^2}{Et^3}\left[\frac{1.129(\log_e\alpha)^2 + 1.738\log_e\alpha - 0.7169\alpha^2 + 0.5648 + \frac{0.1521}{\alpha^2}}{1.3\alpha^2 + 0.7}\right]$$

This corresponds to the value of M_b given in Part I.

The maximum bending moment in this case is the radial bending moment at the inner edge, which, as found, is:

$$(M_1)_b = P\left[\frac{0.2069\alpha^2 \log_e\alpha + 0.05570\alpha^2 - 0.05570}{1.3\alpha^2 + 0.7}\right]$$

and the maximum stress is:

$$S_b = \frac{6(M_1)_b}{t^2} = \frac{P}{t^2}\left[\frac{1.241\alpha^2 \log_e\alpha + 0.3342\alpha^2 - 0.3342}{1.3\alpha^2 + 0.7}\right]$$

This formula corresponds to the value of K_b as given in Part I.

Method 2. As before, we have:

$$(\phi_B)_b = (\phi_C)_b$$

Using the values given in Table 2 in this equation:

$$+ (n_B)_b \frac{Ma}{Et^3} = (n_C)_b \frac{Pa}{Et^3}$$

Since M in this case is $(M_1)_b$, we have by solving this equation:

$$(M_1)_b = + \frac{(n_C)_b}{(n_B)_b} P$$

Substituting in the formula for the deflection $(W_B)_b$ of case B (Table 2):

$$(W_B)_b = (m_B)_b \frac{(n_C)_b}{(n_B)_b} \frac{Pa^2}{Et^3}$$

As before:

$$W_b = (W_C)_b - (W_B)_b$$

$$W_b = -(M_B)_b \frac{(n_C)_b}{(n_B)} \frac{Pa^2}{Et^3} + (m_C)_b \frac{Pa^2}{Et^3}$$

$$= \frac{Pa^2}{Et^3}\left[-(m_B)_b \frac{(n_C)_b}{(n_B)_b} + (m_C)_b\right]$$

$$= \frac{Pa^2}{Et^3}(M_b) \text{ where } M_b = (m_C)_b - (m_B)_b \frac{(n_C)_b}{(n_B)_b}$$

and

$$S_b = \frac{6(M_1)_b}{t^2} = \frac{6(n_C)_b}{(n_B)_b} \frac{P}{t^2}$$

Then from Table 4 we get the values of the coefficients for various values of α and combine them. For example, for $\alpha = 1.25$, we have:

$$(n_B)_b = 46.613$$
$$(n_C)_b = 1.7659$$
$$(m_B)_b = 8.877$$
$$(m_C)_b = 0.3416$$

then the deflection is:

$$W = \left[-8.877 \times \frac{1.7659}{96.613} + 0.3416\right]\frac{Pa^2}{Et^3} = 0.0051\frac{Pa^2}{Et^3}$$

$$S = 6 \times \frac{1.7659}{46.613} P = 0.227P$$

Repeating for various values of α, Table 5 is obtained.

TABLE 5

	1.1	1.25	1.5	2	3	4	5

M_b.....	0.00045	0.0051	0.0249	0.0877	0.209	0.293	0.350

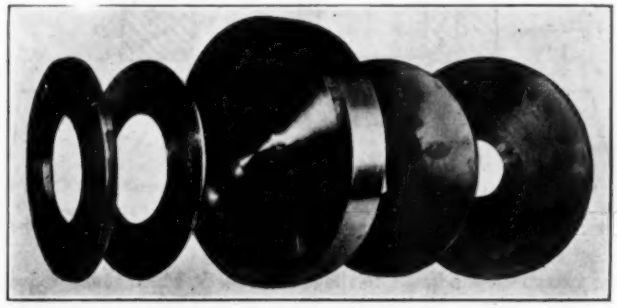

FIG. 7 CIRCULAR PLATES TESTED

By plotting curves from these values of K and M, the coefficients for any intermediate value of α may be obtained by interpolation. It will be noted that these values of K_b and M_b found by this method coincide with those given in Table 1, thus affording a check on the numerical calculations, as well as the method.

In a similar way, other cases of flat plates may be solved. It will be found as a rule that the method of combining the numerical coefficients is the simpler to carry out in practice. The use of this method will in many cases be found to simplify greatly the calculation of flat circular plates with holes and having loading and edge conditions different from those given in Part I.

PART IV EXPERIMENTS AND COMPARISON WITH THEORY

While all formulas derived for each case were checked by means of approximate equations, it was considered desirable to make measurements of stresses and deflections on actual plates for confirmation of the theory. Although most of the cases are very difficult of exact duplication for test purposes, it was believed to be sufficient if one or two of the cases were checked by experiment, since the general method of attack is the same for all cases.

Cases 1 and 6 were chosen as being those whose loading and edge conditions could best be simulated by test. Four plates

were made to represent the conditions of case 1, with different thicknesses and values of ratio of inner to outer radii, and one representing the conditions of case 6. The plates as photographed are shown in Fig. 7, and the dimensions are given in Table 6.

TABLE 6

Plate	a	b	t	α
1	3.873	2.000	0.125	1.91
2	3.813	1.031	0.125	3.70
3	3.813	2.000	0.375	1.91
4	3.813	1.031	0.375	3.70
5	4.000	1.000	0.125	4.00

Method of Test

Plates 1 to 4, inclusive, were tested as shown in the schematic sketch of Fig. 8. Load was applied in a testing machine through

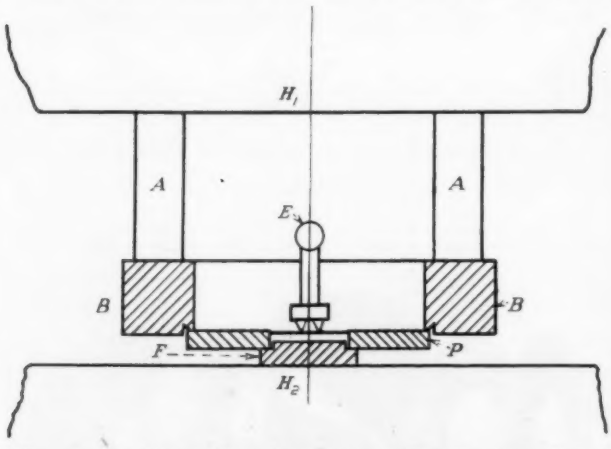

Fig. 8 Diagram of Test Arrangement Representing Case 1 (A, Two Steel Cylinders; B, Heavy Ring; P, Plate; E, Extensometer; F, Supporting Cylinder; H_1, Upper Head of Testing Machine; H_2, Lower Head of Testing Machine.)

the two steel cylinders A to the heavy ring B, which thus applied a load uniformly around the outer circumference. The plate is supported by the cylinder F, resting on the lower head of the machine. Sufficient clearance was allowed between the edges of the plate and the cylinder F and ring B, respectively, to allow a slight lateral movement of the edges. Also the supporting surfaces were slightly beveled, as shown considerably exaggerated, in order that the point of load application be made very definite. The extensometer E was attached along the inner edge where the maximum stress occurs. A photograph of the test as set up in an Amsler testing machine is shown in Fig. 9. The cylinders A, the ring B, and the extensometer E are here clearly shown. The plate is also visible below the ring B. In Fig. 10 the ring is shown resting on the plate with the extensometer in position.

Plate 5, representing case 6, was tested as shown schematically in Fig. 11. The plate is shown in section, being machined integral with two heavy rings; in this way the condition of built-in edges of case 6 was simulated. The position of the extensometer is also shown, being as near as possible to the inner edge.

In all cases strain readings on a 1-cm. gage length were taken on opposite sides of the test plates to be sure of central load application. No trouble, however, was experienced because of non-central application of load. Deflections were measured by dial gages attached so as to record the relative travel of the heads of the machine.

Results of Tests

The results of the tests on plates 1 to 4, tested as in Fig. 9, are shown on the curves of Figs. 12 to 19, inclusive. Those on plate 5 representing case 6 are shown on the curves of Figs. 20 and 21. In all cases the stresses were determined from the measured strain, the average value taken on diametrically opposite positions being used. This was done to eliminate the effect

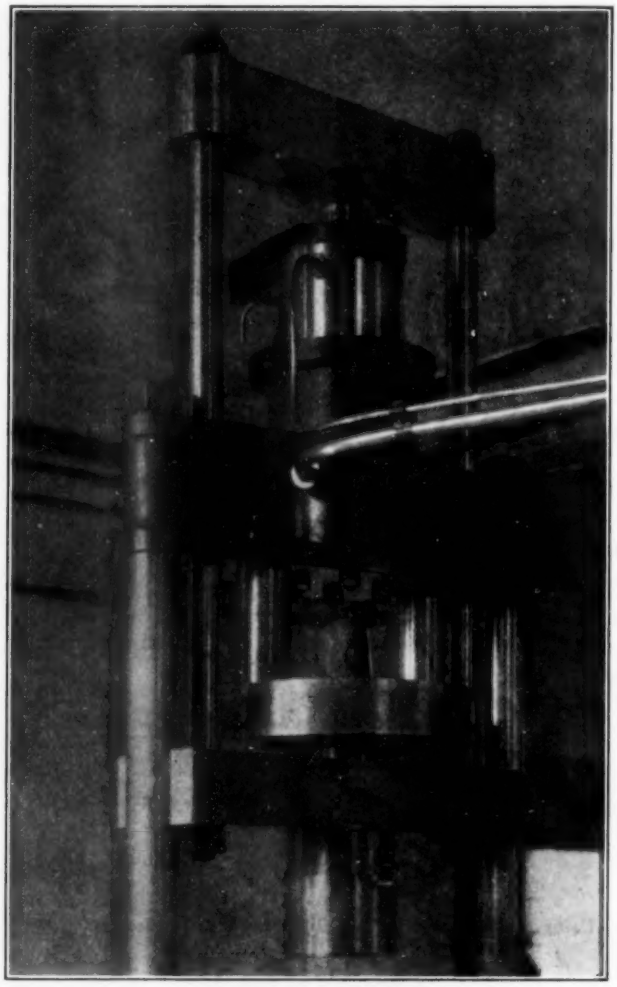

Fig. 9 Photograph of Test Arrangement Representing Case 1

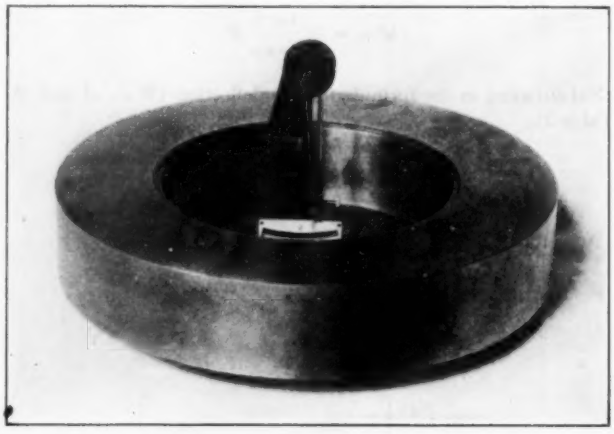

Fig. 10 Extensometer and Ring in Position on Plate

of any slight eccentricity of load. A modulus of elasticity $E = 30 \times 10^6$ lb. per sq. in. for steel was taken. In case two stresses were acting at right angles the stress was determined from the well-known formulas for two-dimensional stress conditions:[10]

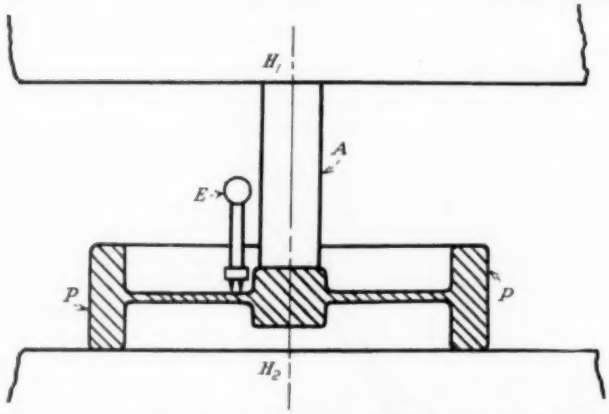

FIG. 11 DIAGRAM OF TEST ARRANGEMENT REPRESENTING CASE 6 (*A*, Cylinder; *P*, Plate; *E*, Extensometer; H_1, Upper Head, and H_2, Lower Head of Testing Machine.)

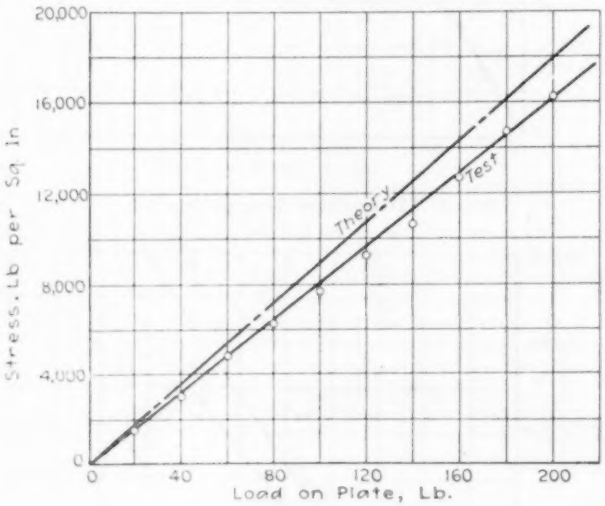

FIG. 12 STRESS TEST ON PLATE 1

$$S_r = E\left[\frac{e_r + \frac{1}{m}e_t}{1 - \frac{1}{m^2}}\right]$$

$$S_t = E\left[\frac{e_t + \frac{1}{m}e_r}{1 - \frac{1}{m^2}}\right]$$

where

E = modulus of elasticity (assumed 30×10^6 lb. per sq. in.)
e_r = measured radial strain, inches per inch
e_t = measured tangential strain, inches per inch
S_t = tangential stress, lb. per sq. in.
S_r = radial stress, lb. per sq. in.
$\frac{1}{m}$ = Poisson's ratio.

[10] See, for example, "Applied Elasticity," Timoshenko and Lessells, p. 12.

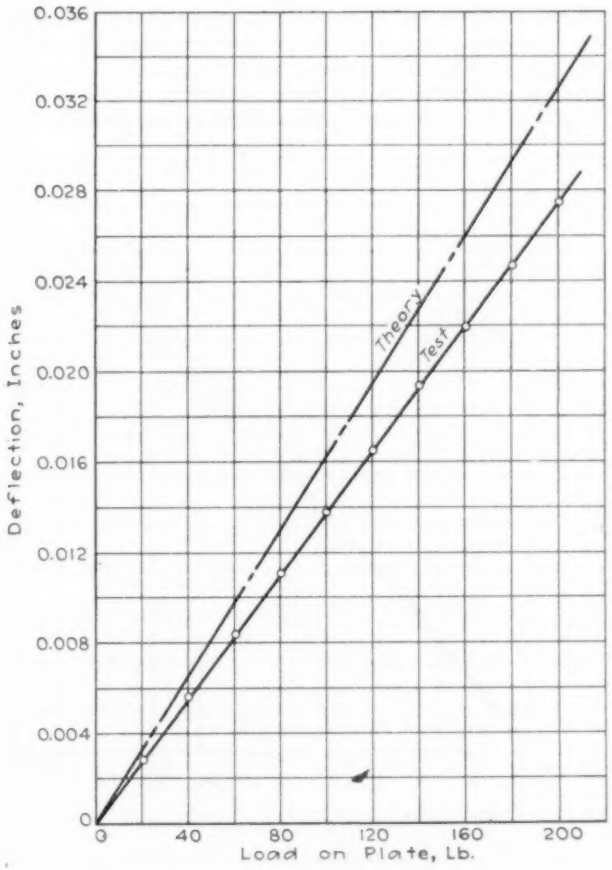

FIG. 13 DEFLECTION TEST ON PLATE 1

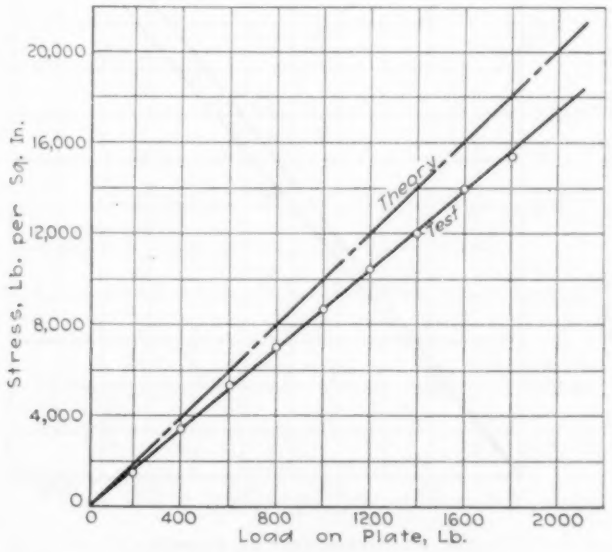

FIG. 14 STRESS TEST ON PLATE 2

For plates 1 to 4, the stress and deflection were computed using the stress and deflection formulas of case 1 (Figs. 2 and 3), a slight correction being necessary due to the fact that the point of application of the load was not exactly along the circumference, but displaced slightly inward. It may be seen that for these plates the agreement between test and theory was fairly good,

an error of 15 per cent being the maximum. In addition, the stress found for each test was below that calculated, thus indicating that the formulas are on the safe side.

For the case of plate 5 (case 6) the stress was measured about $^3/_8$ in. from the inner edge and the general formulas for

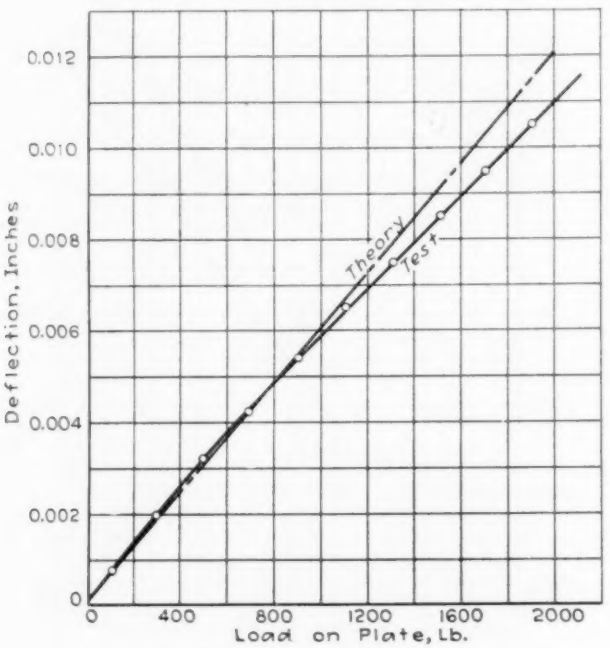

FIG. 15 DEFLECTION TEST ON PLATE 2

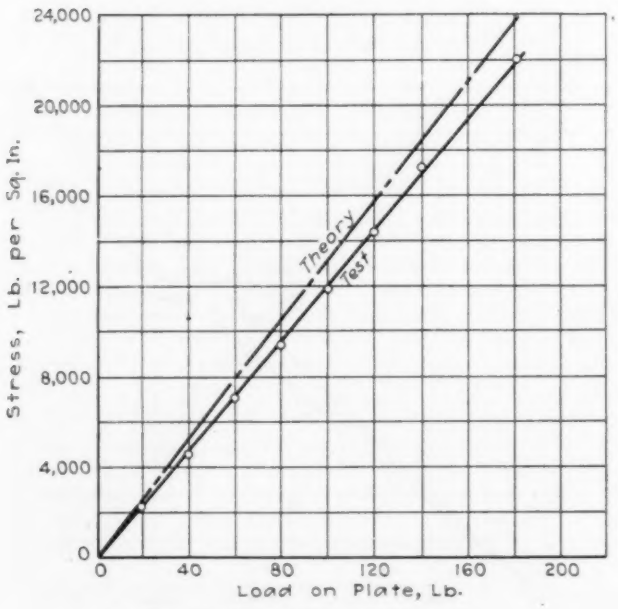

FIG. 16 STRESS TEST ON PLATE 3

slope and deflection along a radius used to obtain the theoretical stress curve (Fig. 21). It may be seen that the stress found by test (shown in full lines) agrees very well with that found theoretically. In the case of deflections, however, the actual deflection, as shown on the curve of Fig. 21, was much greater than that calculated using the formulas of case 6. It is reasonable to assume that the portion *AB* of the test curve (Fig. 21) was due to taking up slack in the apparatus, so that the true load deflection curve has the same slope as the portion *BC* of the test curve. On this basis we have a corrected test curve as shown. Even with this correction the test curve is considerably above the theoretical curve (shown with the dot-and-dash line). A

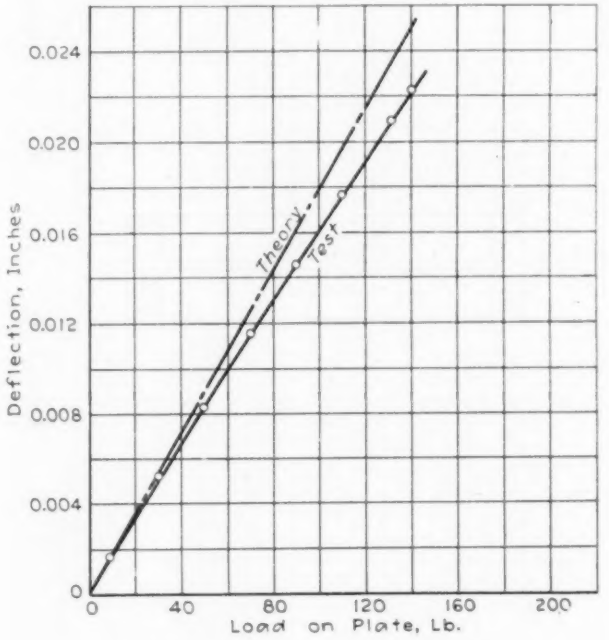

FIG. 17 DEFLECTION TEST ON PLATE 3

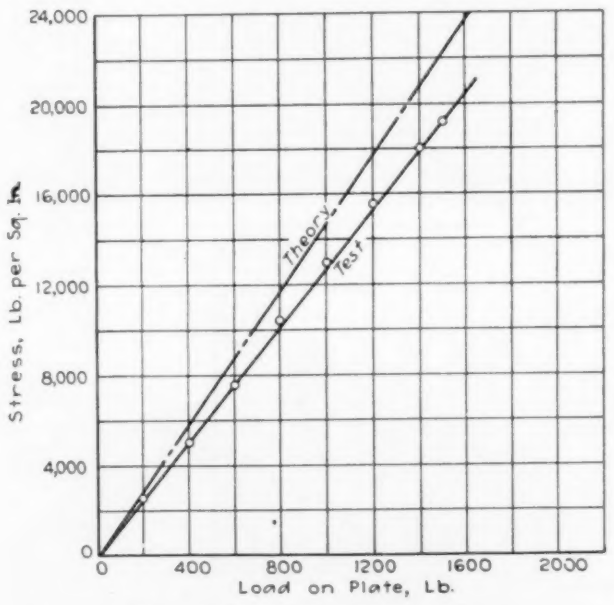

FIG. 18 STRESS TEST ON PLATE 4

correction to the theoretical curve was made by taking into account the bending of the rim *A* (Fig. 11), but this correction was only a few per cent and is therefore not shown. It may therefore be concluded that the fixity of the edges in this case was far from perfect (as assumed in the derivation of the formulas), and hence the true deflection is considerably greater than the theoretical. The matter of fixity of the edges is not so im-

portant for stress, and hence the theoretical and test stress curves agree quite well. In this respect the plate is similar to a cantilever beam fixed at one end and loaded at the other. If the fixity of the one end is imperfect, the deflection will be considerably greater, although the stress will be about the same as that given by the cantilever formula.

Taking the tests as a whole, it appears that a fairly good check between theory and test is obtained where the edges of the plate are simply supported; but where the edges are built in, the theoretical results, while approximately correct for stress, give values much too low for deflection. In all cases the calculated stresses were on the safe side. The refinement of these tests was also not great; more refined tests would probably show a somewhat better agreement with theory than was the case with these tests, which were made mainly to show that the formulas for certain cases were sufficiently accurate for practical engineering work.

Conclusions

The tests therefore indicate that the simplified formulas given in this paper are sufficiently correct for practical purposes

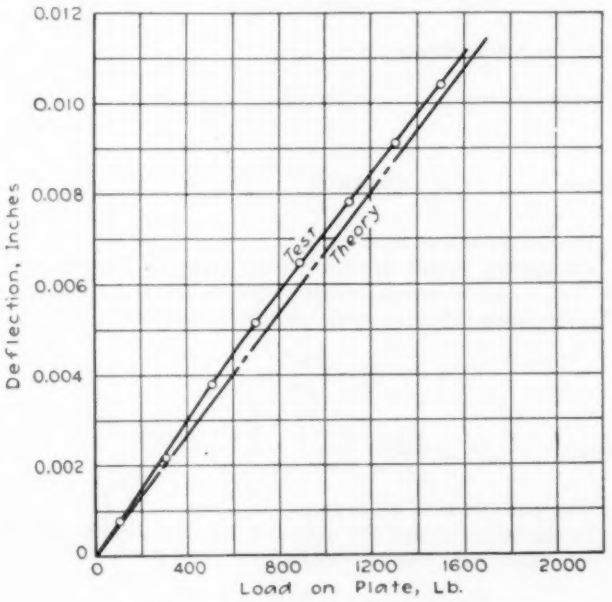

Fig. 19 Deflection Test on Plate 4

for the cases where the edge conditions are determinate, such as free or simply supported edges. For the case of so-called built-in edges the tests indicate that, while the formulas are probably satisfactory for computing stress, the actual deflection in such cases may be much larger than that calculated, because of imperfect fixity of the edges.

These simplified formulas take no account of shear or of the stretching of the middle surface of the plate. Hence, it is believed that they will be reasonably accurate for practical work for a plate with simply supported or free edges only where the thickness is less than about one-third the difference in diameters, and deflections are less than one-half the thickness. Where one or more edges are built-in, the tentative limit is a thickness of one-sixth the difference in diameters. It should be noted, as the tests show, that the formulas for built-in edges are somewhat inaccurate anyway because of imperfect fixity of the edges.

The limits of thickness equal to one-third and one-sixth the difference in diameters are, as mentioned, merely tentative; an idea of the error involved because of neglecting shear may be obtained by using the formulas for deflection due to shear.

In practical work where the fixity of the edges is indeterminate, the safest procedure would be to assume the worst edge conditions and calculate on this basis. If the worst conditions are

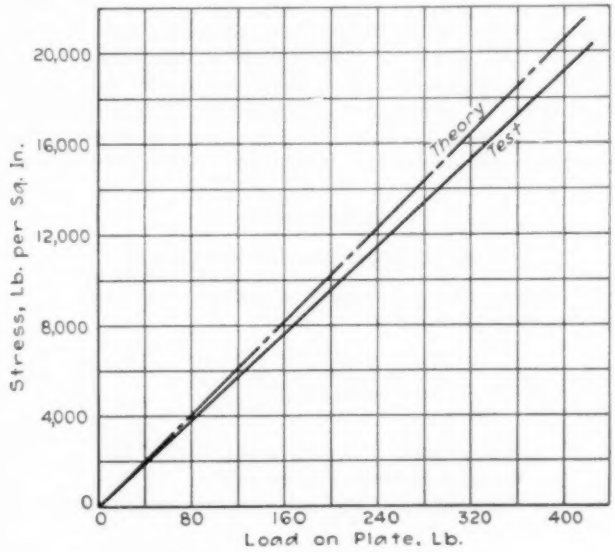

Fig. 20 Stress Test on Plate 5

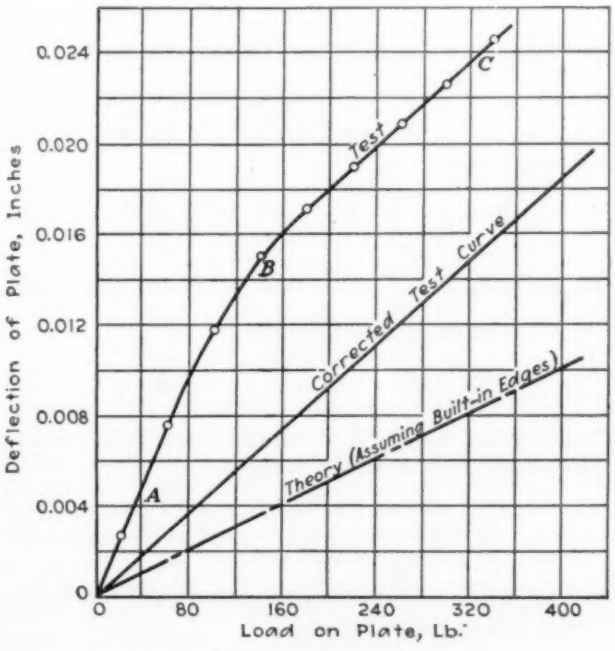

Fig. 21 Deflection Test on Plate 5

not known, the stresses may be computed by assuming various edge conditions, and the maximum stress thus obtained taken as a basis.

It should be noted that this paper is mainly confined to presenting the results of elastic-flat-plate theory, as applied to circular plates, in a simple and usable form for the designer. Therefore, no account was taken of the effect of overstraining the plate material or the effect of plastic flow, which may make possible a higher elastic limit for the plate and therefore a higher

working stress. A complete treatment of the plate problem should of course include such questions, as well as the question of working stress, but these are problems beyond the scope of this paper.

ACKNOWLEDGMENTS

The authors wish to express their indebtedness to Dr. S. Timoshenko, professor of Engineering Mechanics, University of Michigan, and to Dr. A. Nádai, of the Research Department of the Westinghouse Company, for many valuable suggestions made during the preparation of this paper. They are also indebted to Messrs. G. Runke and W. Cory for checking the numerical work involved in the formulas for the various cases.

Appendix 1

DERIVATION OF FORMULAS FOR CASE 1

The differential equation for the slope ϕ of a circular plate symmetrically loaded is:[11]

$$\frac{d^2\phi}{dx^2} + \frac{1}{x}\frac{d\phi}{dx} - \frac{\phi}{x^2} = -\frac{Q}{D} \quad \ldots\ldots\ldots\ldots [1]$$

In this

ϕ = slope at radius x from axis of plate
x = radius at which slope is considered
Q = shearing force per unit circumferential length at radius x
D = flexural rigidity of the plate $= \dfrac{Et^3}{12\left(1 - \dfrac{1}{m^2}\right)}$

For case 1 where a load P is uniformly distributed along the edges, $Q = \dfrac{P}{2\pi x}$ (dividing the total shearing load by the total circumferential length). Using this value in Equation [1] and integrating, we get

$$\phi = -\frac{Px}{8\pi D}[2\log_e x - 1] + \frac{C_1 x}{2} + \frac{C_2}{x} \quad \ldots\ldots [2]$$

Since the slope $\phi = \dfrac{dW}{dx}$, where W is the deflection at the radius x, we may integrate [2] to get W, thus:

$$W = \frac{Px^2}{8\pi D}(\log_e x - 1) - \frac{C_1 x^2}{4} + C_2 \log_e x + C_3 \ldots [2a]$$

The following boundary conditions for case 1 enable the determination of the integration constants C_1, C_2, C_3:

$$\left.\begin{array}{l} \text{When } x = a,\ (M_1)_{x=a} = 0 \\ \text{When } x = b,\ (M_1)_{x=b} = 0 \\ \text{When } x = a,\ W = 0 \end{array}\right\} \quad \ldots\ldots\ldots [3]$$

In this M_1 is the radial bending moment per unit length. From the well-known plate theory[12]

$$M_1 = D\left(\frac{d\phi}{dx} + \frac{1}{m}\frac{\phi}{x}\right) \quad \ldots\ldots\ldots\ldots [4]$$

Therefore, at $x = a$, $\left(\dfrac{d\phi}{dx} + \dfrac{1}{m}\dfrac{\phi}{x}\right)_{x=a} = 0$

at $x = b$, $\left(\dfrac{d\phi}{dx} + \dfrac{1}{m}\dfrac{\phi}{x}\right)_{x=b} = 0$

Using these conditions, we get:

$$\left.\begin{array}{l} C_1 = \dfrac{P}{5.2\pi D}\left\{\dfrac{2.6\,(a^2\log_e a - b^2\log_e b)}{a^2 - b^2} + 0.7\right\} \\ C_2 = \dfrac{2.6P}{5.6\pi D}\left[\dfrac{a^2b^2}{a^2 - b^2}\log_e \alpha\right] \\ C_3 = -\dfrac{Pa^2}{8\pi D}(\log_e a - 1) + \dfrac{C_1 a^2}{4} + C_2 \log_e a \end{array}\right\} \quad \ldots\ldots [5]$$

The tangential bending moment is (from the well-known theory):

$$M_2 = D\left(\frac{\phi}{x} + \frac{1}{m}\frac{d\phi}{dx}\right) \quad \ldots\ldots\ldots\ldots [6]$$

Putting the constants given by Equation [5] in [2], differentiating, and substituting in [6], we find a value of M_2 in terms of x. The maximum value of the bending moment M_2 occurs when $x = b$ and is:

$$(M_2)_{x=b} = \frac{0.7P}{4\pi}\left[1 + \frac{3.714\,\alpha^2\log_e \alpha}{\alpha^2 - 1}\right]$$

The maximum stress will be

$$S = \frac{6[M_2]_{x=b}}{t^2} = \frac{P}{t^2}K_1$$

where $$K_1 = 0.3343 + \frac{1.242\alpha^2\log_e \alpha}{\alpha^2 - 1}$$

This is the value of K_1, as given.

Putting the values of the constants given by Equation [5] in [2a], we get a formula for the deflection W at any radius x. The maximum deflection occurs when $x = b$ and is:

$$y = \frac{Pa^2}{Et^3}M_1$$

where $$M_1 = 0.5514\frac{\alpha^2 - 1}{\alpha^2} + \frac{1.614\,(\log_e \alpha)^2}{\alpha^2 - 1}$$

This is the value of M_1, as given.

In this same manner the values of the constants K and M for the other cases may be determined.

Appendix 2

DEFLECTION OF PLATE DUE TO SHEAR

As an example of the method of taking into account the deflection due to direct shear, consider a plate with load concentrated along the edges (cases 1, 6, and 8). We may imagine an elementary radial strip cut out of the plate, as was done in the approximate solution. This strip, bounded by two radial planes passing through the axis of the plate and subtending an angle $\delta\theta$, will be subjected to shearing forces of magnitude:

$$Q = \frac{P\delta\theta}{2\pi}$$

We now consider a small element of this strip at a distance x from the center of the plate and having a length dx. Since the cross-section of this strip is rectangular and of area $A = \delta\theta x t$, the deflection due to shear of this element will be:[13]

[11] See "Applied Elasticity," p. 276.
[12] See "Applied Elasticity," p. 274.
[13] This formula is the ordinary one for shearing deflection in a bar of rectangular cross-section. See "Applied Elasticity," p. 94.

$$dy_s = \frac{1.5Qdx}{AG} = \frac{1.5Pdx}{2\pi xtG},$$

G being the modulus of rigidity. The total deflection of this elementary strip will then be:

$$y_s = \int_b^a dy_s = \frac{0.239P \log_e \alpha}{tG}$$

which is the formula given for cases 1, 6, and 8.

Other formulas for shearing deflection are derived similarly.

Discussion

E. O. Waters.[14] The critically minded reader, after glancing over this paper, might raise the objection that the material here presented is not original. The eight cases illustrated in Fig. 1, for example, have all been discussed, and appropriate formulas derived, in a series of articles by Max Ensslin in *Dingler's Polytechnisches Journal*, vol. 319 (1904), in which several other cases are considered which are not mentioned in the present paper. By way of rebuttal to any such objection, the writer feels that the authors deserve great commendation for their method of approach to the problem and the system used for presenting the stress and deflection formulas. Any such arrangement is a boon to the designer, and places the calculation of flat rings on a par with that of beams, shafts, and other common machine elements.

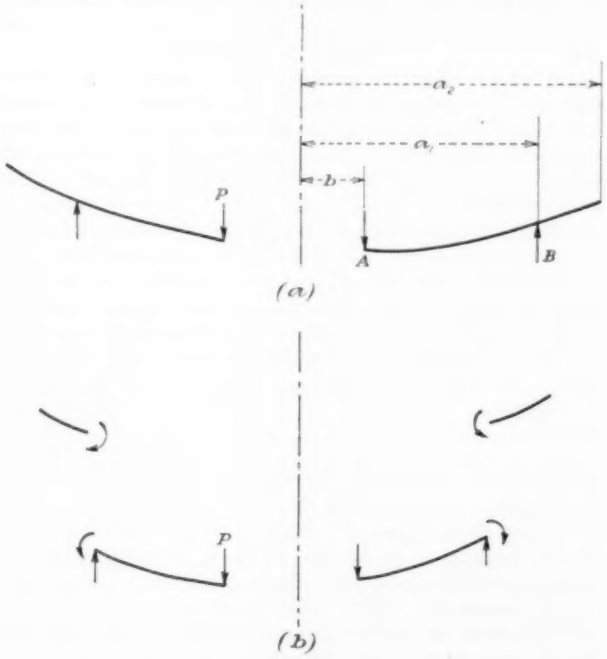

Fig. 22

The experimental work shows that the formulas are sound, at least as far as simply supported rings are concerned. This checks with the writer's experience with pipe flanges and proves that the precise formulas should be used, rather than the approximate ones, except for values of α close to unity. With regard to the built-in rings, it is apparent that there was imperfect fixity at the edges, as stated by the authors. Furthermore, even though the extensometer readings showed stresses corresponding closely with the theoretical values, it should be remembered that the readings were taken at an appreciable distance away from the edge, and there may well have been much higher stresses at the fillets. It is impossible to go into this quantitatively without a knowledge of the fillet radius. The writer believes that it would be worth while to make further tests of some of the built-in cases, with various different fillet radii, and derive if possible some relation between the size of fillet, thickness of plate, and degree of fixity as shown by a comparison of computed and measured deflections.

The authors state that an attempt was made to reconcile the theoretical and test deflections on plate 5 by taking into account the bending of the rim, but without success. The writer would

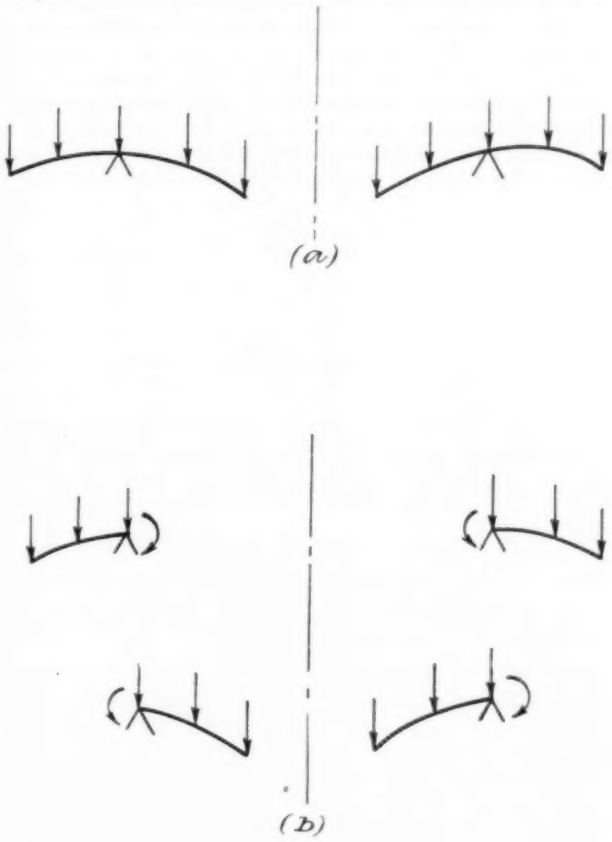

Fig. 23

suggest that, in this case, the outer radius of the plate be taken at the center of the rim; this will increase α and a to 4.47 (scaling dimensions from Fig. 11) and change the theoretical deflection from 0.0025 in. per 100 lb., as per Fig. 21, to 0.0035 in. per 100 lb. This will account for half the discrepancy between the theoretical and the test curves, and bending of the rim will remove part of the remaining discrepancy. In his analyses of pipe flanges with hubs, the writer made this assumption and obtained a very good agreement between the calculated and the measured deflections. It is of course an approximation, and would be quite inaccurate if there were much difference between the thickness of the plate and that of the rim.

The method of superposition, treated in Part III, opens up an unlimited variety of possible combinations of loading. In fact, the five fundamental cases (A to E) are really of much more importance than the eight cases considered in the first part of the paper, and the writer would recommend that the coefficients of Table 2 be charted against α, in a series of curves corresponding to those in Figs. 2 and 3, so that problems involving combinations of the fundamental cases may be solved rapidly and accurately with a minimum of slide-rule manipulations.

[14] Associate Professor of Mechanical Engineering, Yale University, New Haven, Conn. Assoc-Mem. A.S.M.E.

The superposition principle is based upon the theorem that stress and deflection due to several loads applied simultaneously are equal to the sum of the stresses and deflections due to these loads when applied separately. A somewhat similar theorem, which may be called the principle of juxtaposition, states that the stress and deflection in a member are equal to the stress and deflection of a group of connected members, provided that the connected members are geometrically identical with the single member and that the moments, slopes, and deflections are mutually equal at the points of connection. By means of this principle innumerable other combinations may be built up from the five fundamental cases. Take the loading in Fig. 22*b*, herewith, as an example. This arrangement is the same as a ring loaded along the inner edge, simply supported along the outer edge, and loaded by a bending moment along the outer edge (cases A and C) fastened to another ring loaded by a bending moment along the inner edge (case B), the slopes, moments, and deflection sat point B being equal. (See Fig. 22*b*.) From Table 2:

$$(nC)_a \frac{Pa_1}{Et^2} - (nA)_a \frac{Ma_1}{Et^2} = (nB)_b \frac{Ma_2}{Et^3}$$

$$(M_2)_b = (S_c)_2 P - (S_A)_2 M$$

Furthermore,

$$(S_2)_b = \frac{6(M_2)_b}{t^2}$$

Obviously, M and $(M_2)_b$ may be eliminated from the foregoing, and a solution obtained for $(S_2)_b$, the tangential stress at point A, Fig. 22*a*, in terms of P, a_1, a_2, b, and t. In like manner, the radial stress and the deflection at the inner edge may be computed.

Another possibility is shown in Fig. 23, *a* and *b*. In this instance, it is seen that cases D and E are involved, together with two fundamental cases (load consisting of a bending moment at the inner or outer supporting edge) similar to cases A and B.

A. NADAI.[15] The paper contains a valuable application of the bending theory of flat plates. As the authors have mentioned, the bending theory of flat circular plates (with or without a concentric circular hole) was established a long time ago and can be considered in its main parts as perfected. It may be found in old and new textbooks on strength of materials or on applied elasticity. The main reason why engineers who have to calculate the dimensions of plates or similar elements of construction which require a two-dimensional analysis do not apply the results of the theory of elasticity seems to be that the results of this theory have often not been presented in a manner to enable an engineer to apply the results directly to a practical case and without an extensive additional analysis. It seems therefore to the writer that besides the value of the bending theory of flat plates which consists in establishing more or less general expressions for the functions expressing the stresses or the deflections of flat plates, a special value of the theory is to give to the designer the possibility to apply directly the results of a more exact analysis to special applications. It should be emphasized that this is often possible, and in many cases of practical importance, if the engineer will make a study of how to apply the general results of the theory to special cases. Many results of the theory for circular or rectangular plates can be expressed in formulas of such a form as:

$$\text{Maximum bending stress of plate } s = \alpha \cdot \frac{pa^2}{t^2} \quad \text{or} \quad s = \beta \cdot \frac{P}{t^2}$$

In this formula, p or P indicates the load acting on the plate (in case of a uniform pressure, p; in the case of a single force, P); a, a principal dimension of the plate; t, the thickness. All that the theory should furnish to the designer is, in many cases, only the numerical value of the parameter α or β. It is therefore very valuable that the authors have endeavored to calculate the values of these parameters for some of the most frequently occurring cases of bending of circular plates and that they have tabulated and plotted them in the form of curves showing how they depend, in the case of a circular plate with a central hole, for example, on the ratio a/b of the outer to the inner radius of the plate.

It would be valuable and useful if engineers would apply more the theory of bending of plates and of two-dimensional systems of stresses from this point of view. It will help to find the numerical values of such parameters as α or β, which are of a practical importance when stresses in plates are to be calculated, and will allow other engineers to use the results without elaborate, numerical, or analytical work.

Some time ago efforts in other directions had been made which may be mentioned perhaps in connection with these remarks. In th se efforts it was tried to replace the more complicated analysis of two-dimensional stress problems by solving the same cases approximately as one-dimensional problems. For example, efforts have been made to apply to the case of a circular plate loaded in the center a similar method as used in the theory of one-dimensional bending of a straight bar. It is not thought today that this was the right way to find more exact expressions for the stresses. It is felt that by such a proceeding the beautiful symmetry in many of the given problems would be destroyed. Also, in this way, the character of a singularity in the functions, which possibly has to be considered in a problem, would remain concealed. Compare, for example, the two cases of the bending of a straight bar and of a circular plate—the one simply supported at its ends and loaded at the middle, and the other simply supported on its circumference and loaded by a single force at its center. There is a definite difference between the two cases. In the first, the maximum stress always remains a finite quantity and is given by the ratio of the maximum bending moment at the middle point of the bar to the section modulus. On the other hand, in a circular plate loaded in the middle point by a single force P, the bending stress at the center of the plate becomes, as is well known, infinite. It would be hopeless to try to replace the part in the solution containing the singularity of the deflected middle surface

$$w = cx^2 lnx$$

by some other analytical expression derived from an approximate method to calculate bending stresses. Although this part of the complete solution (see Equation [2a]) contributes a term to it which gives in a solid disk infinite stress at the center, it is of the greatest practical importance to retain the corresponding term in the solution, as it would otherwise not be possible to establish a formula for the greatest stress in the case that the single force P is distributed over a finite area; for example, over a small circle. A further knowledge and discussion of such special solutions as the aforementioned seem to be very valuable to engineers who have to calculate stresses in plates with loads concentrated in small parts of the surface of the plate.

Regarding the results of the bending tests of the authors with plates with a circular hole, other experimenters and the writer have found that the deflections of circular plates loaded in their center by a single force and simply supported on their circumference are always found to be greater than the theory would predict. Contrary to this, the authors found the calculated deflections (with the exception of one case) always greater than the observed deflections. This discrepancy seems to be a consequence of the fact that the authors have used comparatively rigid

[15] Mechanics Section, Research Department, Westinghouse Electric & Manufacturing Co., East Pittsburgh, Pa.

plates (with a great ratio a/b) and that they have loaded these plates along two concentric circles lying on the surface of the plate. Through this method of supporting the plate additional moments are introduced through the friction which acts in radial direction when the plate is loaded in axial direction and bends out of its plane. It can easily be seen that these radial bending moments tend to diminish the deflection of the plate. Correspondingly, the authors found smaller deflections than predicted for the same case by the bending theory of plates.

The authors' work has contributed a valuable extension to the well-known theory of the bending of circular plates, and it should therefore be appreciated by engineers that they have worked out the results of the theory in a way which allows the application of the results of it directly to the practical cases of design.

S. Timoshenko.[16] The theory of bending of symmetrically loaded circular plates was developed a hundred years ago by Poisson,[17] but it has not found a broad application in engineering because the final results have not been given in a simple form for numerical calculations. The authors have done a very useful work in presenting the formulas for deflection and for maximum stress in an extremely simple form and in giving graphs for the numerical factors in the formulas. The formulas were checked by making derivations in two different ways, thus excluding the possibility of errors.

Regarding the experiments described in the paper, the writer would like to state that it is always difficult to realize simply supported edges which are free to move in the plane of the plate. Considering this, the results obtained by the authors for this type of support seem satisfactory. The case of fixed edges seems to be simpler to realize. Although it is impossible to have an absolutely fixed edge, the writer thinks that in the case represented in Fig. 11 the condition of a fixed edge is realized with sufficient accuracy. This makes it difficult to explain the large discrepancy between theory and experiment shown by Fig. 21. The small deformations spreading into the heavy boundary ring cannot be responsible for such a large discrepancy, and the writer considers it desirable to repeat the experiment in such a way that the deflections of the plate are measured directly and the deformation in the testing machine is completely eliminated. This can easily be done with the instruments mentioned in the paper.

Authors' Closure

Regarding the remarks made by Drs. Timoshenko and Nadai relative to the difficulty of loading plates with simply supported edges, so that the edges are free to move in the plane of the plate, the authors agree with this. It is very probable that the small discrepancies obtained between test and theory, in the case of plates with simply supported edges, may be largely explained if the friction between the edges is taken into account. Since it was beyond the scope of this investigation to carry out elaborate tests where this friction was eliminated, the authors made the simpler tests, which show that the plate formulas for these cases are sufficiently accurate for most practical work.

Regarding the tests on plate 5, having built-in edges, the authors have repeated the tests on this plate as suggested by Dr. Timoshenko, using a dial gage mounted on a frame in such a way that only the deflections of the plate itself were measured. In this way the deformations of the testing machine itself were eliminated. The load-deflection curve determined in this way came about 10 per cent below the curve determined by measuring the travel of the head of the testing machine.

[16] Professor of Mechanical Engineering, University of Michigan, Ann Arbor, Mich. Mem. A.S.M.E.

[17] Paris, Mém. de l'Acad., vol. 8, 1929.

The curve marked "corrected test curve," as shown in Fig. 21, gives a deflection of 0.0148 in. at 320-lb. load. Repeating the test by measuring the head travel of the machine after the irregularities had been smoothed out, the deflection was 0.0141 in. at 320-lb. load. The test was then repeated, with the dial gage mounted on a frame in such a way as to eliminate the distortion of the testing machine, and this gave a deflection of 0.0127 in. at 320-lb. load, or about 10 per cent less than that found before.

This indicates that there was some distortion in the testing machine amounting to about 10 per cent, so that the true deflections in this case were about 10 per cent less than those found by measuring the head travel. However, this 10 per cent error in measuring the deflection does not appear to invalidate the conclusions drawn in the paper regarding the imperfect fixity of the edges, since the theoretical deflection at 320-lb. load, assuming perfectly built-in edges, was only 0.008 in. Comparing this with the accurate test value of 0.0127 in., as previously found, it is seen that the true deflection is around 60 per cent greater than the calculated, thus indicating imperfect fixity of the edges.

It is possible that a partial explanation of this lack of fixity is the fact that the fillets for plate 5, Fig. 11, were made of very small radii, so that they were practically sharp corners. The authors had another plate made having a large fillet and with the same ratio of outer to inner radius. This plate gave a deflection only about 15 per cent greater than the theoretical deflection, calculated from the formulas for case 6. This tends to indicate that the size of fillet does have a considerable effect on the fixity of the edge, as suggested also by Professor Waters in the discussion.

In order to show that the flange on plate 5 was sufficiently large, another plate was made up identical with plate 5, but with a much larger flange, and with the same size fillets. This plate when tested gave results practically the same as those obtained on plate 5. This therefore indicates that the flange on plate 5 was sufficiently large, and hence the discrepancy between test and theory may not be accounted for on the basis of distortion of the flange.

The whole subject of the effect of ratio of outer to inner diameter, fillet radii, thickness, etc., on the fixity of the edges is quite involved, and, as Professor Waters remarks, this subject could properly form the basis of another investigation. It would certainly be desirable to develop a method whereby allowance for the imperfect fixity of the edges could be carried out. One such method might be to assume the plate built-in at some point inside the rim, say at a distance from the edge equal to some constant times the thickness. Such an empirical method, as well as the method suggested by Professor Waters for plate 5, would, however, involve a large amount of experimental work before a sufficiently comprehensive solution could be found. This, however, is beyond the scope of this paper.

In regard to Professor Waters' statement relative to the articles by Ensslin, it should be noted that the tests carried out by Ensslin were either on plates without holes or on plates having holes with diameters less than one-tenth the diameter of the plate. For such cases, the holes were so small that, in the authors' opinion, for practical purposes these might be considered almost as plates without holes. Also, no tests were reported by Ensslin on plates with built-in edges. Furthermore, Ensslin was unable to make any strain measurements on his plates, because of the lack of appropriate instruments, and hence the formulas for stress in the plates could not be verified by direct strain measurements. This, however, was possible in the present paper.

APM-52-4

The Radially Tapered Disk Spring

By W. A. BRECHT[1] and A. M. WAHL,[2] EAST PITTSBURGH, PA.

In this paper disk springs, both flat and dished, having radially tapered cross-sections are considered. The advantages of such springs are discussed. Equations are developed by approximate and more exact methods for calculating the strength and flexibility of such springs. The theoretical work is checked up by numerous tests, including both strain and deflection measurements. It is concluded that springs of this type may be of advantage in certain applications.

IN ENGINEERING problems the need is frequently felt for a "frictionless" spring where space or other limitations do not permit of the use of springs of conventional design such as the helical spring. For one such application, flat or dished circular disks of spring steel, of uniform thickness, having concentric circular holes, and loaded uniformly at the inner and outer edges, were considered. Such disks could be used singly, or in stacks with suitable spacers to secure the desired flexibility. In computing deflections and stresses in these disks an approximate method suggested by Dr. S. Timoshenko was first used. In this method the deformation is considered to consist purely of a rotation of the section, cross-bending being neglected. This was found to give results practically identical with those given by the elastic-flat-plate theory.[3] Referring to Fig. 1,

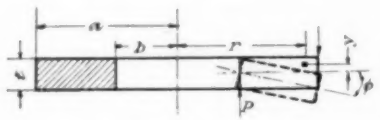

FIG. 1 PLATE OF CONSTANT THICKNESS

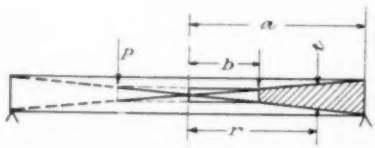

FIG. 2 DISK SPRINGS OF VARIABLE THICKNESS
($t = 2kr$, where k = thickness constant.)

P' = force per unit length of inner circle

ϕ = angle of rotation of the disk section under load.

The radial displacement of any element will equal $y\phi$, and the unit elongation, $y\phi/r$, from which

$$\text{Stress} = E\frac{y\phi}{r} \quad \ldots\ldots\ldots\ldots\ldots\ldots [1]$$

The stress in each element of the disk will be a tangential tensile or compressive stress, depending on whether the element moves radially inward or outward when the section is rotated under load. From [1] it is seen that the stress will be a maximum at the inner corners, where $y = \pm t/2$ and $r = b$.

From an inspection of [1] it will be seen that if the disk thickness t, instead of being made constant, is varied so that t/r is a constant, the stress will be independent of r and (for small values of ϕ) uniform over the entire disk surface under the above assumptions. Such a disk (Fig. 2) would be tapered radially, so that its thickness at any point would be a linear function of the radius of that point.

The advantage of the radially tapered section over a disk of uniform thickness lies in the very materially increased flexibility that can be secured where space is limited in the direction of load application. A series of radially tapered disks, such as shown in Fig. 3, can often be advantageously substituted for helical springs, especially where loads are high and relatively small deflections are required. In such cases the advantages of the radially tapered disk spring may be summarized as follows:

1 The disk spring is adjustable in height and flexibility by adding or taking off disks.

2 It will withstand lateral loading as well as axial loading.

3 It can be so designed that no disk will be overloaded. Failure of one disk will not cause the complete loss of flexibility, nor will it increase the load on the remaining disks. A failure of one disk would not require replacement of the whole spring.

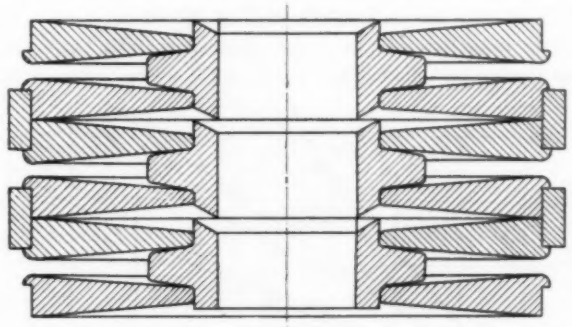

FIG. 3 STACK OF RADIALLY TAPERED DISKS

4 Helical springs of large size are difficult to heat treat uniformly—a disadvantage that can be overcome with the disk spring.

5 Disk springs can be designed to occupy very little space in the direction of load application.

Helical springs are the cheaper to manufacture unless production of the disks is high enough to warrant making forging dies. It may be noted that radially tapered disks have been successfully die forged from 0.90 to 1.00 carbon spring steel so that no machining was required on the disk faces.

I—THE DESIGN OF DISK SPRINGS

Formulas Derived by Approximate Theory

Formulas have been developed for deflection and stress of radially tapered disks using both the approximate theory (Appendix No. 1) and the more exact flat-plate theory (Appendix No. 2). The approximate theory is developed both for flat and dished disks. Since the flexibility decreases rapidly with dishing, the formulas given here apply to flat disks of radially tapered section only. Fig. 4 shows load-deflection curves for three disks similar in every respect except the dish angle. The dotted lines show the curves calculated by the use of the formulas developed farther on. Deflections are 50 per cent larger for the flat disk than for the one having a dish angle of 0.1 radian, and

[3] Discussion by S. Timoshenko of paper by Waters and Taylor, "The Strength of Pipe Flanges," *Mechanical Engineering*, vol. 49 (1927), p. 1343.

Sponsored by the A.S.M.E. Special Research Committee on Mechanical Springs and presented at its session during the Annual Meeting, New York, N. Y., December 2 to 6, 1929, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

150 per cent larger than for the one with a dish angle of 0.15 radian. Formulas developed from the approximate theory for flat disks are as follows:

$$P = \frac{4}{3}\pi E\phi k\left[\frac{\phi^2}{8}(a-b)^2 + \frac{k^2}{3}(a^2+ab+b^2)\right] \quad [2]$$

$$S = Ek\phi \quad [3]$$

$$\delta = \phi(a-b) \quad [4]$$

where a = outer radius of disk
b = inner radius of disk
α = ratio of a to b
t = disk thickness at radius r
t_b = disk thickness at radius b
k = thickness constant, where $t = 2kr$
ϕ = angle of rotation of disk section under load, radians
P = total axial load
δ = axial deflection of disk
S = maximum stress, and
E = modulus of elasticity.

Formula [2] may be modified as follows:

$$P = \frac{4.19\,Ek\delta}{a-b}\left[\frac{\delta^2}{8} + \frac{k^2}{3}(a^2+ab+b^2)\right] \quad [5]$$

Comparison of Approximate Theory With Elastic-Flat-Plate Theory

The preceding formulas were derived on the basis of the assumption that diametral sections of the springs rotate without

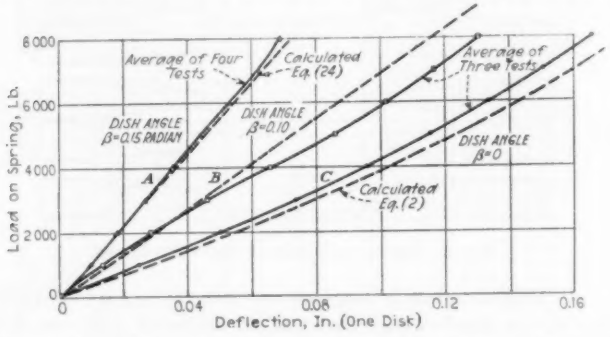

Fig. 4 Load-Deflection Curves on Three Disks Similar Except for Dish Angle

(a = 3.875 in.; b = 1.50 in.; k = 0.0445. Elastic limit not exceeded in any of these tests.)

distortion, deformation consisting principally of a rotation of these sections. This assumption, while very nearly correct for springs having ratios of outer to inner diameters less than about 2, is evidently not correct for springs with comparatively large ratios of diameters. In order to get an idea of the magnitude of the error involved by using this assumption, the elastic-flat-plate theory was applied to the case of a flat disk as shown in Fig. 2. (See Appendix No. 2.) The final results were as follows:

The maximum stress is

$$S = C\frac{P}{t_b^2} \quad [6]$$

where C is a factor depending on the ratio α of outer to inner radius and which may be taken from the curve of Fig. 5.

The maximum deflection is

$$\delta = M\frac{Pa^2}{Et_b^3} \quad [7]$$

where the factor M depends on the ratio α of outer to inner radius and may be taken from the curve of Fig. 6.

It should be noted that the elastic-flat-plate theory assumes small deflections. Therefore in order to compare the results of the approximate method as given by Equations [2] and [3] with those given by the more exact flat-plate theory, it is necessary to assume small deflections, i.e., that the angle ϕ in Equations [2] and [3] is small. The approximate Equations [2] and

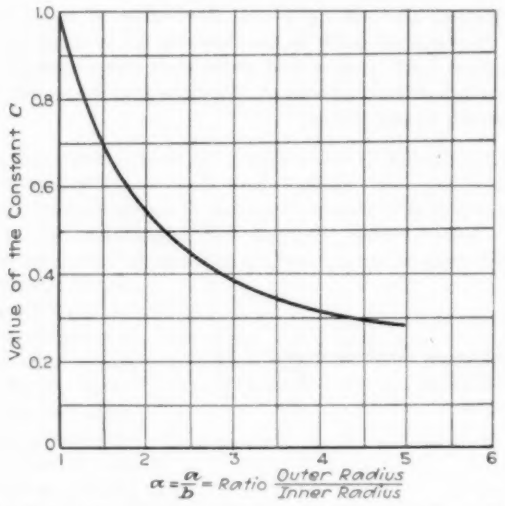

Fig. 5 Stress Constant for Radially Tapered Disk Springs

[3] (substituting for ϕ its value in terms of P) can then be written as follows:

$$S = C'\frac{P}{t_b^2} \quad [8]$$

where

$$C' = \frac{2.86}{\alpha^2+\alpha+1} \quad [8a]$$

and

$$\delta = M'\frac{Pa^2}{Et_b^2} \quad [9]$$

where

$$M' = \frac{5.73}{\alpha^2}\left[\frac{\alpha-1}{\alpha^2+\alpha+1}\right] \quad [9a]$$

Values of C, C', M, and M' are given in Table 1.

TABLE 1 VALUES OF THE CONSTANTS C, C', M, AND M'

For α =	1	1.25	1.5	2	3	4	5
C =	0.985	0.819	0.696	0.536	0.382	0.315	0.280
C' =	0.954	0.75	0.602	0.408	0.22	0.136	0.092
M =	0	0.243	0.271	0.213	0.110	0.062	0.039
M' =	0	0.242	0.268	0.205	0.098	0.0506	0.0296

An examination of this table shows that for values of the ratio α of outer to inner diameters less than 3 there is agreement between the constants M and M' within 10 per cent. This indicates that where α is less than 3, the approximate theory is sufficiently accurate for practical purposes. However, the constants C and C' agree within 10 per cent only for values of α less than about 1.4. Therefore, in computing the stress in disk springs it is usually necessary to use the more exact Equation [6], in order to obtain sufficiently accurate results for practical work.

It will be noted that the elastic-flat-plate theory assumes small deflections; consequently it does not take into account the effect of dishing of the plate as the deflection increases. This

effect tends to cause a stiffening of the plate with increasing load. The approximate theory, however, as shown by Equation [5], takes this effect into account. This equation may be rewritten as follows:

$$P = \frac{E\, t_b^3 \delta}{M' a^2}\left[1 + \frac{1.5\ \delta^2}{t_b^2(\alpha^2 + \alpha + 1)}\right] \ldots\ldots\ldots [10]$$

where M' is as given in Equation [9a].

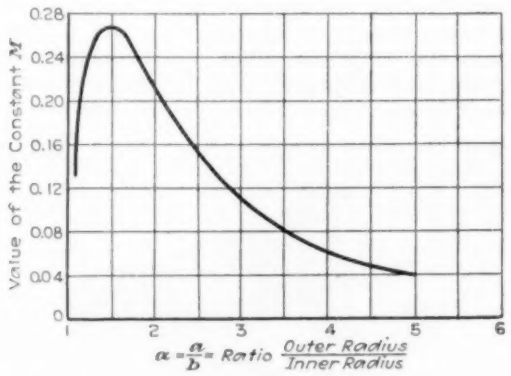

FIG. 6 DEFLECTION CONSTANT FOR RADIALLY TAPERED DISK SPRINGS

If δ is small, this equation reduces to Equation [9]. If now in this equation M' be arbitrarily replaced by M,

$$P = \frac{E\, t_b^3 \delta}{M a^2}\left[1 + \frac{1.5\ \delta^2}{t_b^2(\alpha^2 + \alpha + 1)}\right] \ldots\ldots\ldots [11]$$

For small deflections, i.e., where the second term in the brackets may be neglected, this equation agrees with that obtained by elastic-flat-plate theory. For large deflections the equation corrects for the effect of dish in the same proportion as is done in the approximate equation.

It should be noted that for ratios of diameters α less than 2, which includes most practical cases, results computed by this equation will agree with those calculated by Equation [5] within about 4 per cent in most cases. Hence for practical work Equation [5], in general, is sufficiently accurate.

CORRECTION FOR INWARD DISPLACEMENT OF LOAD

It should be noted that in actual practice the load on the spring does not act exactly at the edge as shown in Fig. 2, but is displaced inward somewhat as shown in Fig. 7. In calculating the actual stress or deflection, sufficient accuracy will be had if the actual load P is reduced in the ratio $d/(a - b)$ (Fig. 7). This takes into account the fact that these loads are displaced inwardly as shown.

PROPORTIONS OF SPRINGS FOR MAXIMUM FLEXIBILITY

It has been found that in designing a disk for a given load and a given stress the deflection varies with α, or the ratio of the outer radius a to the inner radius b. Fig. 8 shows how the deflections of a series of disks, all with the same outside diameter and designed for the same load, vary with α. The variation of α also produces a change in the thickness constant k. Deflections are a maximum when $\alpha = 2$. It has been found that this maximum always falls somewhere between $\alpha = 1.95$ and $\alpha = 2.05$. This value of α not only gives a maximum deflection, but results in disks of greater lateral stability and of better proportions for forging and heat treating than disks having larger ratios of outer to inner diameter.

II—TESTS AND COMPARISON WITH THEORY

DESCRIPTION OF TEST APPARATUS

In order to check up the theory developed in Part I by actual test, a test arrangement was designed as shown schematically in Fig. 9. In this arrangement, load was applied in a testing

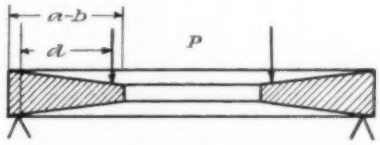

FIG. 7 APPLICATION OF LOAD ON ACTUAL DISK SPRING

machine through the two steel cylinders A to a heavy ring B, which applied the load uniformly around the outer circumference of the disk spring C. The disk spring was supported by the cylinder F resting on the lower head of the testing machine. Sufficient clearance was allowed between the edges of the disk spring and the cylinder F and ring B, respectively, to make certain there would be no binding during application of the load. In most of the tests the supporting edge of the ring was beveled as shown, greatly exaggerated, so that the point of load application was very definite. Special extensometers E placed along the inner edge of the spring made possible the measurement of maximum stress. At the same time it was possible to read the extensometers while the spring was loaded. In all cases strain measurements were made on diametrically opposite sides of the spring to determine whether or not the load was central. For measuring deflections a dial gage D was used.

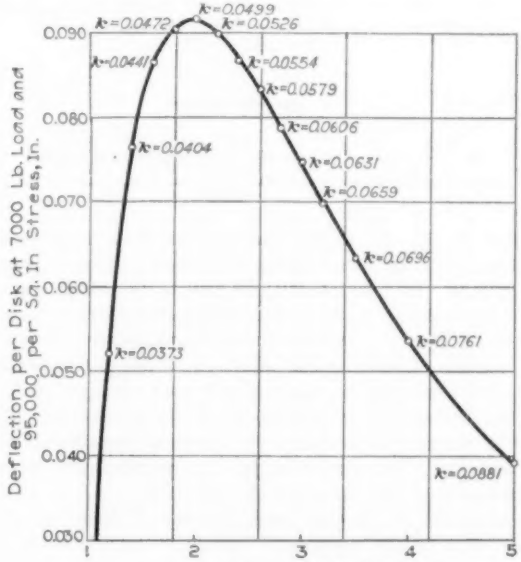

FIG. 8 DISK-SPRING DEFLECTION AS FUNCTION OF RATIO OF OUTER TO INNER RADIUS

(k = thickness constant where $t = 2kr$; a = outer radius = 4 in. in all cases.)

A photograph of the test arrangement in the machine is shown in Fig. 10. The disk spring C, the heavy ring B, the extensometer E, and the two cylinders A are here plainly visible.

TESTS ON FLAT DISK SPRINGS

A series of flat disk springs having various ratios of outer to inner diameter and various values of the thickness constant k

were tested. Data relative to these springs, including dimensions and method of fabrication, are given in Table 2.

TABLE 2 DATA ON SPRINGS TESTED

Spring designation	Outer radius a, inches	Inner radius b, inches	Outer thickness t_a, inches	Inner thickness t_b, inches	Method of making
A′	3.81	1.5	0.305	0.120	Machined, heat treated, and ground
C	3.81	1.5	0.339	0.133	Forged, heat treated, and ground
D	3.81	1.5	0.267	0.105	Machined, heat treated, and ground
I	3.81	2.54	0.220	0.330	Machined and heat treated
VI	3.81	1.91	0.193	0.388	Machined, heat treated, and ground
E	4.25	1.563	0.667	0.246	Machined, heat treated, and ground
F	3.87	1.50	0.344	0.133	Machined, heat treated, and ground

The results of the tests on these springs are shown graphically in the load-deflection and load-stress curves of Figs. 11–21 and

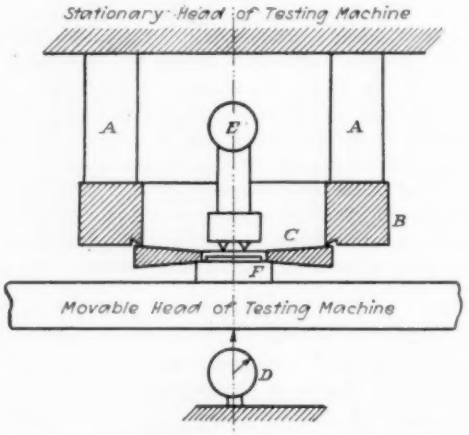

FIG. 9 ARRANGEMENT FOR TESTING DISK SPRINGS
(*A*, steel cylinder; *B*, ring; *C*, disk spring; *D*, dial gage; *E*, extensometer; *F*, cylinder.)

on curve *C*, Fig. 4. In all cases the test results are shown in full lines, while the theoretically calculated curves are shown in dotted lines. In calculating these curves allowance was made for the fact that the loads on the springs were displaced inwardly as shown in Fig. 7. All deflections were calculated on the basis of a modulus of elasticity $E = 30 \times 10^6$ lb. per sq. in., since tensile-test results on this material indicated a value close to this.

In calculating the theoretical curves for springs A′, C, D, I, and VI, the more exact theory as given by Equations [6] and [10] was used. In calculating the theoretical deflection curves for springs E and F, Equation [5] was used.

In all cases the stresses were determined from the strains, using a value of the modulus of elasticity equal to 30×10^6 lb. per sq. in. The strains were measured at the inside edge of the spring where the maximum stress is indicated theoretically. This was done especially since failure of these springs usually starts under fatigue loading at the inner edge.

Examination of the test curves shows that there is very good agreement between theory and test, in the case of stress, for the flat springs. For deflection, at the lower loads, theory and test agree quite well, but at higher loads the test curve in certain cases deviated somewhat from the theoretical. This deviation was caused by the line of application of the load tending to move inward in certain cases, i.e., the distance d (Fig. 7) becomes less. Consequently the spring becomes relatively stiffer at the higher loads. This effect was not so pronounced in springs C, A′, D, F, and I, where the location of the supporting edge was quite definite. However, in the case of springs VI and E the inner ring supporting the springs had a sloping shape similar to that shown on the sketch of Fig. 3. This accounts for the steepness of the deflection and stress curves at the higher loads in these cases.

Duplicate tests were made on part of these springs with practically the same results.

TESTS ON DISHED SPRINGS

Deflection tests were also made on dished disk springs of the type shown in Fig. 22. The results of the deflection tests on these disk springs are shown on curves *A* and *B*, Fig. 4. The dotted lines show the theoretical curves as computed using Equation [24], Appendix No. 1. It may be seen that the approximate Equation [24] gives satisfactory results for the case of deflection of these types of spring.

Experimental verification of the stress formulas for dished disk springs, given in Appendix No. 1, has not yet been obtained. Because of the assumptions made in the derivation, it is doubtful

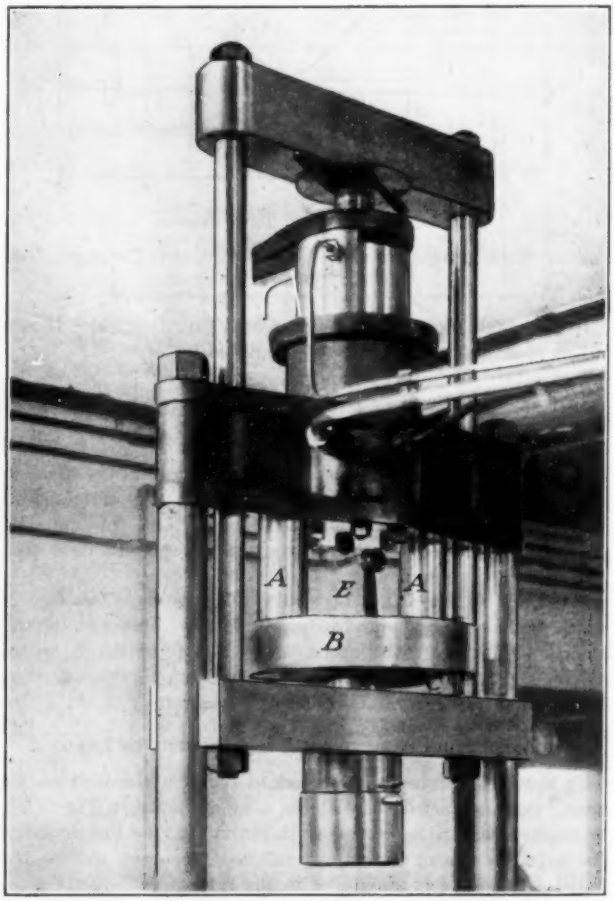

FIG. 10 VIEW OF TESTING ARRANGEMENT

if these formulas are very accurate; however, they at least give the designer an idea of the stress involved.

III—CONCLUSIONS

Since the stress distribution along a radial section of these disk springs is approximately constant for values of the ratio α of outer to inner diameter less than about 2, it may be said that these springs utilize the material about as efficiently as do transverse elliptic springs (which may be considered as bars under a constant moment). They therefore do not utilize the material quite as efficiently as helical springs, but, on the other hand, have certain advantages over helical springs which may make them preferable for certain applications.

The flat tapered spring, because of its greater flexibility and better stress distribution, is, in general, preferable to the dished tapered spring or the Belleville type spring of constant thickness.

Test results, including both strain measurements and deflection tests, indicate that the formulas given by the elastic-flat-plate theory (Equations [6] and [11]) are sufficiently accurate for use in the practical design of flat disk springs of this type. Test results also indicate that the formulas given for the deflection of both flat springs by approximate theory (Equations [2] and [5]) are sufficiently accurate for most practical work, as is Equation [24] in the case of dished springs.

Acknowledgments

The authors wish to acknowledge their indebtedness to Messrs. C. Bethel and J. M. Lessells of the Westinghouse Company for encouragement received in this work. They are also indebted to Dr. S. Timoshenko of the University of Michigan and Dr. A. Nadai of the Westinghouse Company for valuable suggestions, and to Mr. M. Karelitz of the Westinghouse Company for preparing some of the springs for test.

Appendix No. 1

Derivation of Stress and Load-Deflection Formulas for Flat and Dished Radially Tapered Disks—Approximate Theory

IN ADDITION to the symbols used heretofore,

β = dish angle (= 0 for flat disks) in radians

c = radius at point of rotation of the disk section under load

$c - x$ = radius of any point.

The complete disk is shown in Fig 22(*a*). It is assumed in the approximate theory that cross-sections remain plane under load, and that their boundaries remain undistorted. Deformation thus consists of rotation of the section about some point O, at a radius c, through a small angle ϕ.

Consider element G [Figs. 22(*b*) and 22(*c*)]. Its initial length equals l_1.

$$l_1 = d\theta(c - x\cos\beta + y\sin\beta) \quad [12]$$

After deformation this length becomes $l_2 = d\theta[c - x\cos(\beta - \phi) + y\sin(\beta - \phi)]$ or

$$l_2 = d\theta[\,c - x\cos\beta\cos\phi - x\sin\beta\sin\phi + y\sin\beta\cos\phi - y\cos\beta\sin\phi] \quad [13]$$

Subtract [13] from [12] and let $\cos\beta = 1$, $\cos\phi = 1$, $\sin\beta = \beta$, and $\sin\phi = \phi$, since β and ϕ are small; then

$$l_1 - l_2 = d\theta[\phi(\beta x + y)] \quad [14]$$

This equals the elongation, and since $S = eE$,

$$S = \frac{E\phi(\beta x + y)}{c - x} \quad [15]$$

The moment of the forces acting on the element G [Fig. 22(*c*)] about an axis through O perpendicular to the paper is:

$$dM' = d\theta\, S\, dx\, dy\,(\beta x + y) \quad [16]$$

Substituting [15] in [16],

$$dM' = \frac{d\theta\, E\phi\,(\beta x + y)^2}{c - x}\, dx\, dy \quad [17]$$

Then the total moment will be

$$M' = \int_{c-a}^{c-b}\int_{-k(c-x)}^{k(c-x)} \frac{d\theta\, E\phi(\beta x + y)^2}{c - x}\, dy\, dx \quad [18]$$

Integrating and substituting limits,

$$M' = d\theta\, E\phi\,\frac{2k}{3}\,(a - b)\left\{\left(\beta^2 + \frac{k^2}{3}\right)\left[3c^2 - 3c\,(a + b) + a^2 + ab + b^2\right] - k^2c(2c - a - b) + k^2c^2\right\} \quad [19]$$

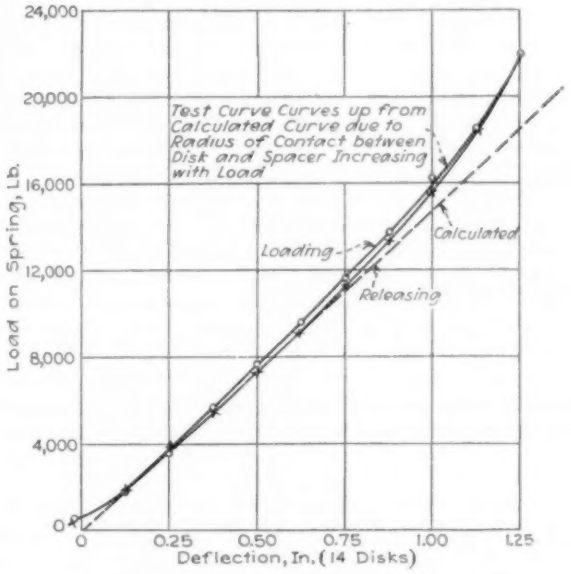

Fig. 21 Deflection Test on Disk Spring "E"
(a = 4.25 in.; b = 1.56 in.; t_b = 0.246 in.; t_a = 0.667 in.)

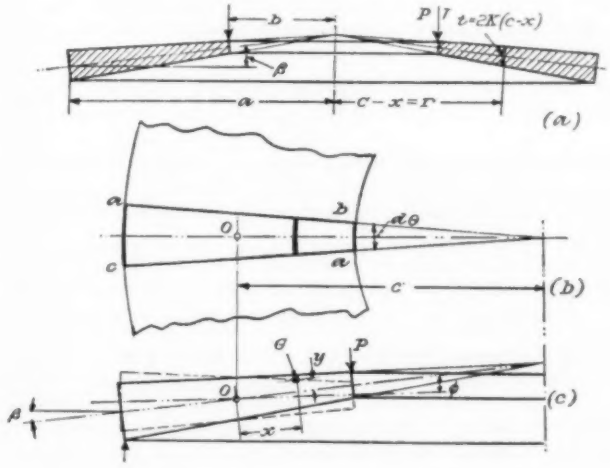

Fig. 22 Dished Disk Spring

The two unknowns are ϕ and c. To evaluate these, we know from statics [Fig. 22(*b*)], that

(*a*) The moment M' found in [18] equals the external moment; and

(*b*) The resultant of all forces acting on the element equals zero.

From (*a*), letting $\cos\beta = 1$,

$$M' = d\theta\,\frac{P(a - b)}{2\pi} \quad [20]$$

This substituted in [19] gives

$$P = \frac{4}{3}\pi E\phi k\left\{\left(\beta^2 + \frac{k^2}{3}\right)\left[3c^2 - 3c\,(a+b) + a^2 + ab + b^2\right] - k^2c\,(2c - a - b) + k^2c^2\right\} \quad [21]$$

Next considering (*b*),

$$d\theta \int_{c-a}^{c-b}\int_{-k(c-x)}^{k(c-x)} S\,dy\,dx = 0$$

or

$$d\theta \int_{c-a}^{c-b}\int_{-k(c-x)}^{k(c-x)} \frac{\beta x + y}{c - x}\,dy\,dx = 0 \quad [22]$$

Solving,

$$c = \frac{a+b}{2} \quad [23]$$

Substituting [23] in [21],

$$P = \frac{4}{3}\pi E\phi k\left[\frac{\beta^2}{4}(a-b)^2 + \frac{k^2}{3}(a^2 + ab + b^2)\right] \quad [24]$$

From Fig. 22(*c*), the axial deflection $\delta = \phi(a - b)$. From [15], when the dish angle $\beta = 0$ (flat disk),

$$S = \frac{E\phi y}{c - x}$$

or as $y = t/2 = k\,(c - x)$,

$$S = E\phi k \text{ (for flat disks)} \quad [25]$$

Equation [25] indicates that the stress is a constant in the outermost fibers, and maximum material economy obtains. In the case of dished plates the maximum stress will be at the upper, inner edge, or

$$S = E\phi\left(\beta\frac{a-b}{2b} + k\right) \quad [26]$$

This does not give maximum material economy, but gives much better economy than a disk of uniform thickness. The shape of a dished disk for maximum material economy would be $t = 2k\,(c - x) - 2\beta x$.

The above formulas are approximate because they are based on certain assumptions given at the beginning of Appendix No. 1. A somewhat different result can be obtained as follows:

$$l_1 - l_2 = d\theta[x\cos\beta\,(\cos\phi - 1) + x\sin\beta\sin\phi + y\sin\beta\,(1 - \cos\phi) + y\cos\beta\sin\phi] \quad [27]$$

But $(1 - \cos\phi) = 2\sin^2\phi/2$, and letting $\cos\beta = 1$, $\cos\phi = 1$, $\sin\beta = \beta$, $\sin\phi = \phi$, and $\sin^2\phi/2 = \phi^2/4$,

$$l_1 - l_2 = d\theta\left[x\phi\left(\beta - \frac{\phi}{2}\right) + y\phi\left(\frac{\beta\phi}{2} + 1\right)\right]$$

Neglecting $y\beta\phi^2/2$ since all factors are small,

$$l_1 - l_2 = d\theta\left\{\phi\left[\left(\beta - \frac{\phi}{2}\right)x + y\right]\right\}$$

Solving as before,

$$P = \frac{4}{3}\pi E\phi k\left[(\beta - \phi)\left(\beta - \frac{\phi}{2}\right)\frac{(a-b)^2}{4} + \frac{k^2}{3}(a^2 + ab + b^2)\right] \quad [28]$$

or, when $\beta = 0$ (flat disks),

$$P = \frac{4}{3}\pi E\phi k\left[\frac{\phi^2}{8}(a-b)^2 + \frac{k^2}{3}(a^2 + ab + b^2)\right] \quad [29]$$

and

$$S = E\phi\,\frac{\left(\beta - \frac{\phi}{2}\right)x + y}{c - x} \quad [30]$$

or for flat disks,

$$S = E\phi\left[\frac{\phi(a-b)}{4b} + k\right] \quad [31]$$

Appendix No. 2

DERIVATION OF MORE EXACT FORMULAS FOR DISK SPRINGS USING FLAT-PLATE THEORY

IN THIS appendix, formulas for maximum stress and deflection are derived for a flat circular plate with a central hole, loaded uniformly along the edges, and having a thickness which is directly proportional to the radius (see Fig. 2). In addition to the nomenclature previously given, let

ν = Poisson's ratio (= 0.3 for steel)
r = radius of element considered
$s = \sqrt{\frac{13}{4} - 3\nu}$
m_1 = radial bending moment per unit length at radius r
m_2 = tangential bending moment per unit length at radius r
w = deflection at radius r
$\phi = -\frac{dw}{dr}$ = slope in radial direction at radius r
D = flexural rigidity of the plate at radius r
$D = K_1r^3$

where $K_1 = \frac{2Ek^3}{3(1 - \nu^2)}$

The equilibrium of the forces acting on a small element of the plate at radius r gives the following equations:[4]

$$m_1 + \frac{dm_1}{dr}r - m_2 + \frac{P}{2\pi} = 0 \quad [32]$$

$$m_1 = D\left(\frac{d\phi}{dr} + \nu\frac{\phi}{r}\right) \quad [33]$$

$$m_2 = D\left(\frac{\phi}{r} + \nu\frac{d\phi}{dr}\right) \quad [34]$$

It should be noted that in this case the flexural rigidity is:

$$D = K_1r^3 \quad [35]$$

Differentiating [33] with respect to r gives

$$\frac{dm_1}{dr} = K_1r^3\left(\frac{d^2\phi}{dr^2} + \frac{\nu}{r}\frac{d\phi}{dr} - \frac{\nu\phi}{r^2}\right) + 3K_1r^2\left(\frac{d\phi}{dr} + \nu\frac{\phi}{r}\right) \quad [36]$$

Substituting these equations in [32] gives

$$\frac{d^2\phi}{dr^2} + \frac{4}{r}\frac{d\phi}{dr} + (3\nu - 1)\frac{\phi}{r^2} = -\frac{P}{2\pi K_1r^4}$$

The complete solution to this equation is[5]

[4] See, for example, "Applied Elasticity," by Timoshenko and Lessells, p. 274, for derivation of these equations.

[5] The authors are indebted to Dr. Nadai of the Research Department for suggesting the method of integration of this equation.

$$\phi = C_1 r^{-\frac{3}{2}+s} + C_2 r^{-\frac{3}{2}-s} - \frac{P}{2\pi K_1 (\nu - 1) r^2} \ldots [37]$$

The boundary conditions are:

$$\text{For } r = a,\ m_1 = 0, \text{ and } \left(\frac{d\phi}{dr} + \nu \frac{\phi}{r}\right)_{r=a} = 0$$

$$\text{For } r = b,\ m_1 = 0, \text{ and } \left(\frac{d\phi}{dr} + \nu \frac{\phi}{r}\right)_{r=b} = 0$$

Using these equations, the values of the constants C_1 and C_2 are obtained:

$$C_1 = \frac{P(2-\nu)}{6\pi K_1(1-\nu)(-\frac{3}{2}+s+\nu)}\left[\frac{a^{-\frac{1}{2}}b^{-s} - b^{-\frac{1}{2}}a^{-s}}{\alpha^s - \alpha^{-s}}\right]. [38]$$

$$C_2 = \frac{P(2-\nu)}{6\pi K_1(1-\nu)(-\frac{3}{2}-s+\nu)}\left[\frac{a^s b^{-\frac{1}{2}} - b^s a^{-\frac{1}{2}}}{\alpha^s - \alpha^{-s}}\right]. . [39]$$

The maximum stress in the plate will be

$$S = \frac{6(m_2)_{r=b}}{t_b^2} \ldots\ldots\ldots\ldots\ldots [40]$$

Using Equations [34], [37], [38], and [39] and the derivative of [37] in [40] and taking $r = b$, the maximum stress becomes

$$S = \frac{CP}{t_b^2} \ldots\ldots\ldots\ldots\ldots [41]$$

where

$$C = \frac{1}{\pi(1-\nu)}\left[\frac{\left(2-\nu\right)\left(1-\frac{3\nu}{2}+s\nu\right)\left(\alpha^{-\frac{1}{2}} - \alpha^{-s}\right)}{-\frac{3}{2}+s+\nu} - \frac{\left(2-\nu\right)\left(1-\frac{3\nu}{2}-s\nu\right)\left(\alpha^{s} - \alpha^{-\frac{1}{2}}\right)}{-\frac{3}{2}-s+\nu}}{\alpha^s - \alpha^{-s}} + 1 - 2\nu\right] \ldots [41a]$$

To get the deflection w of the plate the following equation is used:

$$\phi = -\frac{dw}{dr}$$

or

$$w = -\int \phi dr + C_3$$

Using the value of ϕ given by [37] and integrating, the deflection becomes

$$w = -\frac{C_1 r^{-\frac{1}{2}+s}}{-\frac{1}{2}+s} - \frac{C_2 r^{-\frac{1}{2}-s}}{-\frac{1}{2}-s} - \frac{P}{6\pi K_1(\nu-1)r} + C_3 . . [42]$$

For determining C_3, the condition that when $r = a$, $w = 0$ is used; hence

$$C_3 = \frac{C_1 a^{-\frac{1}{2}+s}}{-\frac{1}{2}+s} + \frac{C_2 a^{-\frac{1}{2}-s}}{-\frac{1}{2}-s} - \frac{P}{6\pi K_1(\nu-1)a}$$

Using this value of C_3 in [42] and taking $r = b$ (since the maximum deflection will occur where $r = b$), the maximum deflection becomes

$$\delta = M\frac{Pa^2}{Et_b^3} \ldots\ldots\ldots\ldots\ldots [43]$$

where

$$M = \frac{0.637(1+\nu)}{\alpha^3}\left[\frac{\nu-2}{\alpha^s - \alpha^{-s}}\left\{\frac{-\alpha^{1-s} - \alpha^s + 2\sqrt{\alpha}}{(-\frac{1}{2}+s+\nu)(-\frac{1}{2}+s)} + \frac{\alpha^{s+1} + \alpha^{-s} - 2\sqrt{\alpha}}{(-\frac{3}{2}-s+\nu)(-\frac{1}{2}-s)}\right\} + \alpha - 1\right] \ldots . [43a]$$

Discussion

DR. ING. A. NADAI.[6] The authors have not only contributed a comparatively simple method to the calculation of the deformations of flat disks, but also have found an exact solution of a comparatively difficult problem in the theory of the bending of flat plates with variable thickness. It is known that, under the latter circumstances, in most cases which are of a practical interest for the engineer, it is not possible to find an exact solution of the differential equation for the deflected middle surface of the plate. One case where this was possible is the case of a circular plate with a varying thickness which is proportional to the distance of the point from the center of the plate.

With regard to the approximate method the authors use for the tapered plates and dished springs, the good agreement they find between the results of their calculations and the tests is due to the fact that they had to deal with freely supported annular plates in which the radial stress is zero, both on the inner and outer circle, and therefore also a negligible quantity throughout the plate. In some other cases, the agreement of their approximate theory with actual cases might perhaps not be quite so satisfactory. An example in which the radial stress could not be neglected is the bending of a circular plate which does not contain any hole and in which both the radial and the tangential stresses must become gradually equal if one approaches the center of the disk.

HAROLD C. CLAUSEN.[7] The writer is interested in the possible use of the radially tapered disk spring in railroad work where heavy helical springs are now in use. In order to estimate the value of the particular type of spring, it is useful to know the resilience of the spring—that is, the energy that can be stored up in the spring per unit volume.

For a helical spring of round wire subjected to axial loads the resilience is equal to $\frac{1}{4}\frac{S^2}{G}$, and for a beam as used in carriage springs where the maximum stress is reached in every section and the section is rectangular the resilience is equal to $\frac{1}{6}\frac{S^2}{E}$. The writer would like to know if the authors can give a formula similar to this for the radially tapered disk spring.

It would appear that the radially tapered disk spring is not as efficient as the helical spring for the following reasons:

1 In the formula we would use E (Young's modulus of elasticity) which is about $2^1/_2$ times greater than G (torsional modulus of rigidity).

2 In the case of the round helical spring the most of the material is situated in the region of maximum stress.

3 In the case of the radially tapered disk spring the spacers will weigh some appreciable proportion of the weight of the disks, and these spacers are so much dead weight not entering into the efficiency of the spring.

G. M. EATON.[8] The writer has followed the development of

[6] Research Department, Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa. Mem. A.S.M.E.

[7] Mechanical Engineer, Union Switch & Signal Company, Swissvale, Pa. Mem. A.S.M.E.

[8] Commercial Engineer, Molybdenum Corporation of America, Pittsburgh, Pa. Mem. A.S.M.E.

this new type of spring with a great deal of interest. Assuming that it is desirable to have a spring carry successfully the highest stresses, the writer would call attention to two ways in which the resistance of the spring to service stress can be improved. If correct in the understanding that under fatigue test the springs fail with a fatigue nucleus on the inner perimeter and on the tension corner, drop-forged blanks can never be as successful as rolled blanks.

The particular point at issue is that, in order to withstand tension most ably, it is desirable to have such structural grain distortion, as occurs during the forging operations, result in an elongation of the grains in the direction of the tension stress. This is best secured by a rolling operation such as is used in general in the production of quality rings of steel.

The second point has to do with the stresses residual in the spring after the quench and draw. It is quite obvious that, dependent on the method of quenching, the residual stress in the critical fiber noted may be either tension or compression. If the rings are quenched, with the first contact of the quenchant with the steel on the inner perimeter it is fundamental that when the ring is cold these critical fibers will be in compression. When the spring starts to pick up load, it is clear that the first increments of load will reduce the compression stress on the critical fibers. As the load increases the stress will approach zero and then pass through into tension. In this connection the severity of the quench will have to be guarded, but in quantity production on automatic quenching fixtures it is possible to control the transient and residual stresses that are set up within practical limits that will result in a superior spring.

Authors' Closure

Regarding Dr. Nadai's remarks, the authors agree that the approximate method will only hold with good accuracy where the ratio of outer to inner radius α is fairly small. For example, as mentioned in the paper, for values of α greater than 3 the approximate method will be off 10 per cent or more for deflection as compared with the more exact method, but in the case of stress, to obtain 10 per cent accuracy, the value of α must be 1.4 or less. These and Dr. Nadai's remarks make it obvious that it is necessary to exercise judgment in applying the results given by the approximate method.

Mr. Clausen remarks that the resilience of the helical spring is equal to $\frac{1}{4}\frac{S_s^2}{G}$, while that of the elliptic spring is $\frac{1}{6}\frac{S^2}{E}$. Using the shearing modulus G in the case of the helical spring, for steel it is generally agreed that $G = \frac{E}{2.6}$. This gives $G = \frac{30 \times 10^6}{2.6} = 11.5 \times 10^6$, where $E = 30 \times 10^6$ lb. per sq. in. However, it must also be remembered that recent tests have shown that in the case of pure shear the yield point is only about 0.57 times the yield point in tension. Also fatigue tests of spring steel indicate that the endurance limit in reversed torsion is only about half that in reversed flexure.[9] Therefore, for purposes of computation, we may take $S_s = 0.57\,S$. This gives for the helical spring a resilience in terms of S and E as follows:

$$U_1 = \frac{1}{4}\frac{S_s^2}{G} = \frac{1}{4}\frac{(0.57S)^2 \times 2.6}{E} = 0.21\frac{S^2}{E}$$

Comparing this with the resilience of the elliptic spring $U = 0.167\,\frac{S^2}{E}$, it is seen that the helical spring is somewhat more resilient in this case.

It should be noted that the foregoing holds only for helical springs having a *very* large index (ratio of coil diameter to wire diameter). For railway work many springs have an index of 4. For such springs the stresses are actually about 1.4 times the computed stress.[10] This fact will reduce the resilience in the ratio $\left(\frac{1}{1.4}\right)^2$, making the foregoing value for resilience of a helical spring with an index of 4

$$U_1' = \frac{0.21\,S^2}{E} \times \left(\frac{1}{1.4}\right)^2 = 0.11\frac{S^2}{E}$$

It is seen that in case of a helical spring with an index of 4, the resilience is actually less than the value $0.16\,\frac{S^2}{E}$ for an elliptic spring.

To calculate the resilience of the disk spring, one may proceed as follows: The deflection δ and load P (for small deflections) is, from Equations [6] and [7] of the paper,

$$\delta = \frac{MPa^2}{Et^3_b} \quad \ldots\ldots [1]$$

$$S = \frac{CP}{t_b^2} \text{ or } P = \frac{St^2_b}{C} \quad \ldots\ldots [2]$$

The total work done

$$W = \frac{1}{2}P\delta = \frac{1}{2}\frac{MPa^2}{Et_b^3} \times P = \frac{Ma^2}{2Et_b^3}\frac{S^2t^4_b}{C^2}$$

or

$$W = \frac{S^2Ma^2t_b}{2EC^2} \quad \ldots\ldots [3]$$

The volume of the material in a disk spring may be shown to be

$$V = \frac{2\pi}{3}a^2t_b\left(\alpha - \frac{1}{\alpha^2}\right) \quad \ldots\ldots [4]$$

The work per unit volume is therefore

$$U_2 = \frac{W}{V} = \frac{S^2}{E}\left[\frac{M}{4.18C^2\left(\alpha - \frac{1}{\alpha^2}\right)}\right] \quad \ldots\ldots [5]$$

where the factors M and C in this formula are to be taken from Figs. 5 and 6. Taking, for instance, $\alpha = 1.4$, we obtain from [5]

$$U_2 = 0.134\,\frac{S^2}{E}$$

Comparing this with the foregoing expression for resilience of an elliptic spring, it is seen that in this case the disk spring is somewhat less resilient than an elliptic spring $\left(\frac{1}{6}\frac{S^2}{E}\right)$ and somewhat more resilient than a helical spring with an index of 4. In the case of a disk spring having a ratio $\frac{a}{b} = \alpha = 2$, the resilience from [5] is $0.10\,\frac{S^2}{E}$, which makes it comparable to the helical spring having an index of 4 $\left(\text{resilience} = \frac{0.11\,S^2}{E}\right)$. From this it may be seen that the disk spring with an index of 2 has a resilience about the same as that of heavy helical springs with fairly small indices such as are used in railway work. Of

[9] Moore and Kommers, "The Fatigue of Metals," p. 147.

[10] "Stresses in Heavy Closely Coiled Helical Springs." *Trans. A.S.M.E.*, APM-51-17.

course, the resilience of the disk spring is much less than that of helical springs of very large index, but these latter are seldom used in railway work.

It is true, as Mr. Clausen points out, that the efficiency of the disk spring is somewhat reduced by the weight of the spacers.

Macro-etchings have been made of several disks that were manufactured by different methods and which failed in a fatigue test. These photographs show conclusively that the rolled disks have the best grain alignment, as Mr. Eaton predicts.

Experiments are being made with various methods of quenching to establish a method which will give the best results as regards residual stress conditions and uniformity of hardness.

APM-52-5

Performance of Oil-Ring Bearings

By G. B. KARELITZ,[1] EAST PITTSBURGH, PA.

This paper comprises notes on the performance of oil-ring-lubricated bearings. The safety of the bearing determined by the minimum oil-film thickness is discussed; a diagram for computation of this value is given. The end leakage and the amounts of oil supplied by oil rings are shown, and the mechanism of operation of oil rings is described. The friction losses and the heat dissipation in oil-ring bearings are estimated and a way to predetermine the temperature rise of a bearing is indicated.

OIL RINGS have been applied to bearings for at least 80 years. Bearings of this type exhibited in London in 1848[2] had a split ring on the shaft; the lower bearing half, however, was cut in two to make space for the ring. Designers recognized the importance of a continuous stream of oil through the bearing, apparently desiring to improve the cooling of the bearing. The present-day oil-ring bearing, with a continuous lower bearing half or with a slotted sleeve, was not introduced till much later.[3] The existence of a load-carrying oil film which requires a certain minimum supply of lubricant to compensate for end leakage from the bearing has only recently been discovered. These new ideas were the result of the work of several prominent physicists at the end of the last century. These men have also been responsible for the explanation of the mechanism of the oil film. Petroff[4] published his work in 1883; Reynolds[5] published in 1886 his explanation of the famous Tower's experiments made in England at the request of the Institution of Mechanical Engineers. However, these two papers were so difficult to read that they apparently did not make any impression in wide engineering circles. The idea of the load-carrying film of lubricant was further developed in 1904 in a paper by Sommerfeld,[6] who discussed in simpler terms the mechanism of an oil film in a very long bearing ("of infinite length") and by Michell,[7] who gave an analysis of the oil film under a plane shoe of finite dimensions. A practical application of the hydrodynamic principles of lubrication has since been made independently by Kingsbury and Michell in designing the well-known tilting-shoe type of thrust bearing.

The analytical expressions resulting from a hydrodynamical investigation of the oil film in a cylindrical bearing are rather involved. Numerical tables which allowed the presentation in graphical form of the interrelation between various elements in a bearing shell and the physical properties of the lubricant used were prepared by Harrison, Guembel, Howarth, Boswall,[8] and others. Most of this work has been prepared rather recently and is still being developed. However, sufficient information is now available to attempt a numerical analysis of the performance of oil-ring-lubricated bearings.

The oil-ring bearing is still holding an important place in the design of rotating machinery. It is true that in machines running at high speed, where the amount of heat created in the bearings requires artificial cooling, forced-feed lubrication is gradually replacing the oil rings, the practice of cooling the bearing shell proper thereby being abandoned. But the oil-ring bearing is a self-contained unit requiring very little attention or maintenance and is very desirable wherever it can be used. Efforts are therefore made, on the one hand, to raise the capacity of these bearings and, on the other hand, to be able, when designing a new machine, to predetermine closely the performance of the bearings in order to decide whether an oil-ring type will be adequate. As a result, an investigation partly reported in the present paper has been undertaken.

The paper deals with the questions of safety of a bearing and the heat balance in oil-ring types, these questions being basic to the performance of any bearing. The author realizes that many other considerations must be taken into account when designing a bearing, such as strength, oiltightness, dustproofness, convenience of inspection and maintenance, ease of manufacture, etc. Many of these properties have been considerably improved recently[9] in line with the generally stricter demands of modern industry and the serious competition offered by ball and roller bearings.

The Oil Film in Oil-Ring Bearings

The general idea of a load-carrying oil film is now well known and does not need much space here. It will be sufficient to mention that the existence of such a film is caused by the viscosity of the lubricant and by its ability to adhere strongly to the rubbing surfaces of the shell and the journal. The radial clearance provided in the bearing automatically causes the existence of a wedge-shaped film between the journal and the shell. The oil, being entrained by the journal into the clearance, tends to be compressed; due to its practical incompressibility, strong currents and countercurrents of oil are created in the film. The rate of shear in the oil is naturally very high, the gradient of velocity from the journal surface to the shell surface being of the order, say, of 500,000 ft. per min. per inch of oil film, and the viscous resistance of the oil to this motion creates high hydrostatic pressures, quite ample to carry the load on the journal.

Under these conditions, the only frictional losses in the bearing are caused by internal friction of the lubricant. This friction is only a fraction of that which would be present should the load be carried by direct contact between the rubbing surfaces, even in the case when such surfaces are covered by a good "greasy" (or "oily") film of lubricant.

It is therefore important to be in a position to evaluate the minimum thickness of the oil film when designing a bearing in order to be certain that this thickness is above the safe limit for the type of bearing under consideration. Now, this limit may vary considerably, depending on the kind of service, the finish

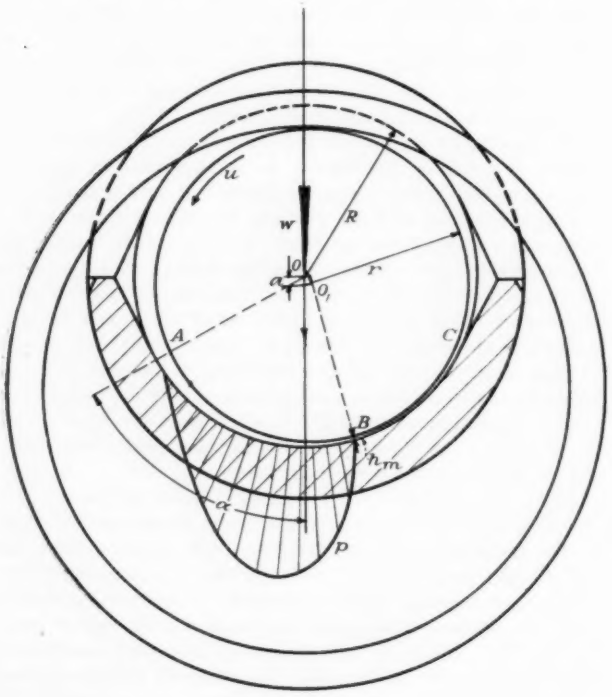

FIG. 1

of the surfaces, and probable misalignment or thermal distortion of the bearing. In finely bored small bronze bushings a film of the order of 0.0001 in. will be sufficient,[10] while for ordinary commercial bearings, with a steel shaft and a babbited shell, a thickness of oil film above 0.00075 in. should be maintained if the speeds are high, and a thickness not below 0.0004 in. in all other cases.[11] This limit was checked on several occasions and appears to be well founded. It will be shown later that the determination of the minimum thickness is a comparatively simple matter, and the safety of a bearing should be checked by a designer on this basis rather than by empirical formulas which are usually obsolete a few years after being established. For example, there is one formula giving for the safe limits of bearing design[12] $pv = 50{,}000$, where p is the pressure on the projected area in pounds per square inch and v is the peripheral speed in feet per minute. Bearings are now operating successfully where $p = 100$ and $v = 2100$, pv being above 200,000. Another formula derived by Moore[13] has been used indiscriminately; $p = 7.47\sqrt{v}$. This would give as a limiting safe load $p = 335$ lb. per sq. in., which is obviously too high. An oil-ring bearing of standard construction shown in Fig. 1 will now be considered. Let

$d = 2r$ = diameter of journal
$D = 2R$ = diameter of shell

$D - d$ = clearance (play) in shell; $R - r$ = radial clearance
$m = (D - d)/d = (R - r)/r$ = clearance ratio; $R - r = mr$
h_m = minimum oil-film thickness
a = linear eccentricity between center O of shell and center O_1 of journal in running position
$c = a/(R - r)$ = eccentricity ratio; $a = (R - r)c$
p = pressure in the oil film at any point
h = the thickness of the oil film at this point
W = total load on bearing
L = active load-carrying length of bearing between end grooves
$P = W/dL$ = pressure on projected active area
α = angle between entering edge A of oil film and direction of load W. (In case of symmetrical bearings with vertical load on the journal, the bearing angle $AOC = 2\alpha$.)
u = peripheral velocity
N = revolutions per minute of the journal
$\omega = \pi N/30$ = angular velocity in radians per second
μ = absolute viscosity of the oil in the oil film, assumed to be constant throughout the film
Z = the viscosity measured in centipoises.

Assume for the time being that the oil film is sealed at the bearing ends, i.e., that there is no end leakage, making the conditions therefore identical in each cross-section of the bearing.

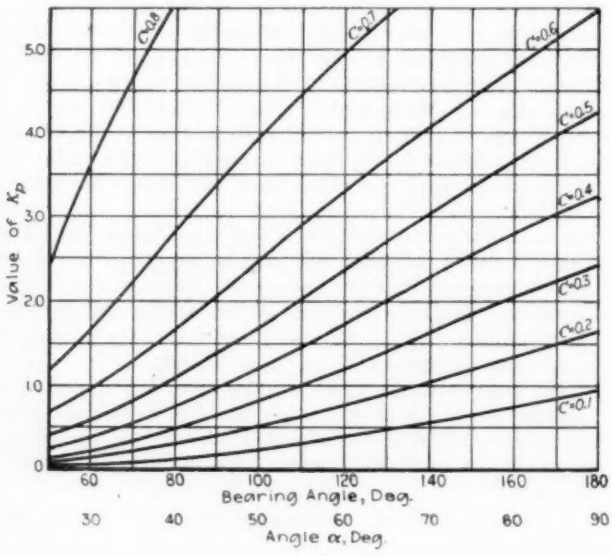

FIG. 2

The middle strip of the bearing, a unit of length (inch, centimeter) wide, carries then a load $w = W/L$. If equilibrium exists, the resultant of all oil pressures p on the journal strip is equal and opposite to w.

The center O_1 of the journal can take any position inside a small circle described around O by the radius $(R - r)$ (see Fig. 4), and the journal will automatically adjust itself to a position where this equilibrium exists.

The pressures p are, however, determined completely by the viscosity of the oil μ, the velocity u, and the shape of the clearance. These values are interconnected by the equation:[14]

[14] The derivation of this equation is given very concisely in A. Stodola's "Steam and Gas Turbines," translated by Louis C. Lowenstein. McGraw-Hill, New York.

$$\frac{dp}{dx} = -6\mu u \frac{h - h_1}{h^3}$$

where h_1 is a constant the value of which happens to be larger than h_m but smaller than h_a.

It was observed on numerous occasions that the oil pressure at B, the point of minimum oil-film thickness, is very near zero, the pressure in BC where the film is divergent being slightly negative. A vacuum up to several inches of mercury may be observed even in forced-feed bearings when the oil is supplied under a low head of, say, 10 lb. per sq. in. The assumption that the pressure p_B at B is equal to zero in oil-ring-lubricated bearings is therefore justified. On the other hand, under usual conditions of bearing construction, the pressure at A is quite low and the pressure p_A may also be taken equal to zero. It is true that pressures may be observed sometimes under the upper cap of the shell or in the relief at A, but these are usually small when compared with the pressures in the oil film proper and they do not affect appreciably the values of p.

With $p_A = p_B = 0$, the pressures p can be evaluated from the differential equation referred to for each position of O_1. Charts[15] presenting the values of p were prepared by the author in an earlier paper. The pressures p, when combined vectorially, give for each position of O_1 the value of w and its direction, i.e., the angle α between w and the entrance edge A. As a rule, the shape of the pressure curve p is such that the angle between

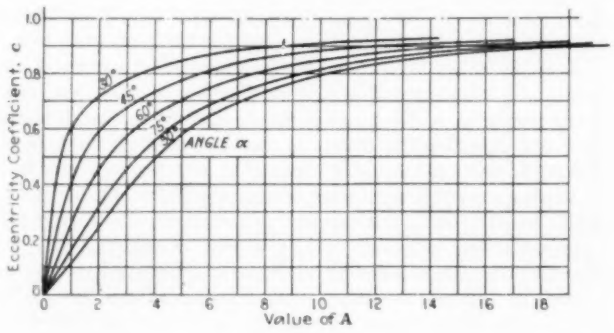

FIG. 3

w and B is smaller than α, the difference growing with the increase of the linear eccentricity a.

It will be noted from the charts that the pressures p are proportional to the value $\mu\omega/m^2$, the coefficient of proportionality being determined only by the relative position of O_1 with respect to O, while the load-carrying capacity of the strip of unit width is

$$w = K_p r \frac{\mu\omega}{m^2}$$

where K_p is also determined only by the position of the journal. By tabulating the values of w and α for a large number of positions O_1 and by graphical interpolation, the relation between K_p, α, and $c = a/(R - r)$ can be represented in a chart shown in Fig. 2.

In actual bearings, the end leakage causes a gradual decrease in oil pressure from the middle section to the ends where it is zero. Experimental data by Lasche,[16] Kingsbury, and others show that with normal ratios of length to diameter of from 1 to 3, the pressure distribution lengthwise may be taken as parabolic. The load-carrying capacity of the bearing is then:

$$W = \frac{2}{3} wL = \frac{2}{3} K_p Lr \frac{\mu\omega}{m^2}$$

Since $W = PLd = 2PLr$, $P = {}^1/_3 K_p \mu\omega/m^2$. With a given load, load direction, speed, viscosity, clearance, the coefficient $K_p = 3Pm^2/\mu\omega$ can be found, and from Fig. 2 the value of c will be determined. The linear eccentricity OO_1 is $a = c(R - r)$, and the minimum thickness of the oil film is $h_m = (R - r) - a = (1 - c)(R - r) = (1 - c)mr$.

The chart in Fig. 2 is not convenient. It has been rearranged

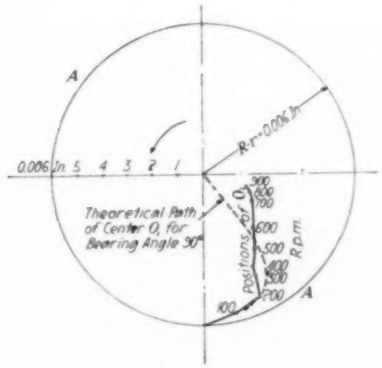

FIG. 4

and extended partly on the basis of the calculations of Guembel,[17] partly by extrapolation, and the chart in Fig. 3 was drawn. The coefficient K_p is replaced by A, allowing for the diverse units used in engineering; P is measured in pounds per square inch, and $\omega = \pi N/30$, where N is the revolutions per minute. The absolute viscosity μ should be measured in (pounds per sq. in. of rubbing area) per (inch per second per inch of film thickness) or in $\frac{\text{lb. sec.}}{\text{in.}^2}$, while it is given usually in centipoises, where 1 poise = 1 (dyne[18] per square centimeter of area) per (centimeter per second per centimeter of film thickness) $= 1 \frac{\text{dyne sec.}}{\text{cm.}^2}$; the viscosity in centipoises being Z, $\mu = 1.45 \times 10^{-7} Z$. Now

$$P = \frac{1}{3} K_p \frac{\mu\omega}{m^2}$$

$$= \frac{1}{3} A \frac{ZN}{m^2} \frac{1.45 \times 10^{-7}\pi}{30}$$

therefore

$$A = 198(1000m)^2 \frac{P}{ZN}$$

The value ZN/P, which is a non-dimensional number, may be called the characteristic number of the bearing. It not only defines the running position of the journal in the shell but determines the running friction in the bearing as well, as has been pointed out repeatedly in the literature.

As an example, a slow-speed oil-ring bearing of the following specification will be considered: diameter d = 11 in.; full length, 25 in.; end grooves occupy $1^1/_4$ in. on each end, giving an active length L = 22.5 in.; clearance on diameter s = 0.0125 in., or m = 0.0012; the relief at the split is 15 deg. on each side; load W = 35,400 lb. is directed downward; speed of

[18] 1 dyne = $^1/_{981}$ gram.

rotation $N = 187.5$ r.p.m. The oil used was machine oil having a viscosity of 320 sec. Saybolt at 30 deg. cent. and 50.5 sec. Saybolt at 100 deg. cent.; specific gravity 0.86.

The pressure on the projected area of the bearing is $P = W/dL = 141.5$ lb. per sq. in. The temperature rise in the oil film may be assumed to be 20 deg. cent. above the ambient temperature; with a possible air temperature of 40 deg. cent., the temperature in the oil film will be 60 deg. cent., or $Z = 17.0$

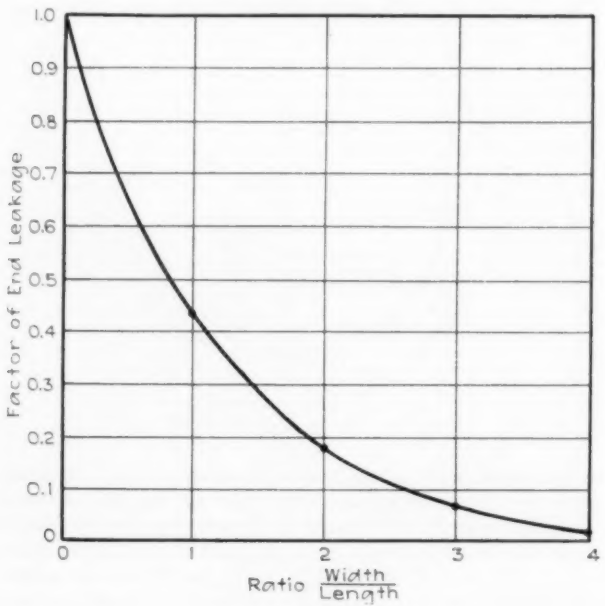

FIG. 5

centipoises (see Appendix No. 1). The coefficient $A = 198 \times 1.2^2 \times \frac{141.5}{17 \times 187.5} = 12.7$. The angle α in this case is 90 deg. — 15 deg. = 75 deg. Entering $A = 12.7$ in the chart (Fig. 3), the curve $\alpha = 75$ deg. gives $c = 0.86$. The minimum oil-film thickness is then $h_m = (1 - c)(R - r) = 0.14 \times \frac{0.0125}{2}$ = 0.0009 in. This bearing works therefore within safe limits.

Observations on actual bearings seem to confirm the accuracy of this computation of the minimum thickness of the oil film. It is true that a report to the contrary was published recently by Wolff,[19] but very accurate electromagnetic measurements of journal positions carried out on an oil-ring bearing of 9 in. diameter and 18 in. long with a 45-deg. relief at the split on each side gave an oil-film thickness very close to the precomputed values.[20] The bearing was loaded by the constant weight of the armature of a synchronous motor, while the speed was varied from 100 to 900 r.p.m. The oil-film thickness was found to be as in Table 1.

The actual path of the journal center O_1 did not coincide, however, with the theoretical path as determined on the basis of the charts for the oil pressure, mentioned above. Fig. 4 shows the discrepancy. The circle AA of radius $(R - r)$ encloses the area of all possible positions of the journal center O_1. The journal appears to be pressed to the right from its theoretical path, no doubt due to the initial pressure in the relief pocket on the "down" side of the journal. It will be appreciated that a small pressure of several pounds per square inch in the pocket produces an appreciable horizontal force on the journal.

TABLE 1

R.p.m.	Min. oil-film thickness, in. Computed	Observed
100	0.0007	0.0005
200	0.0012	0.0010
300	0.0016	0.0015
400	0.0019	0.0020
500	0.0023	0.0025
600	0.0025	0.0029
700	0.0028	0.0030
800	0.0030	0.0031
900	0.0031	0.0031

It is obvious that oil-ring-lubricated bearings work in the best conditions when the load applied to the journal is directed downward or at a small angle to the vertical. Should the load be directed upward, as may happen with an industrial motor with a belt or gear drive, the slot or slots through which the oil rings pass divide the bearing into two or more parts. In fact, the shaft may be considered as supported by several separate bearings. In a bearing of a length equal to two diameters, or longer, with one oil ring at midlength of the bearing, the top half presents two bearings each one diameter long. Such bearings work quite efficiently, and the performance of the bearing as a whole is practically identical in any direction, provided oil-distributing grooves are cut properly. In shorter bearings, the oil film will be inherently thinner with loads acting upward than when the same loads act downward upon the journal. This fact must be remembered when rating oil-ring bearings for general service.

A quantitative idea about the influence of the ratio of the length of a load-carrying oil film (in direction parallel to motion) to its width (in a direction normal to motion) can be obtained from Fig. 5, which was drawn on the basis of Michell's paper.[21] Taking as unity the carrying capacity in pounds per square inch of bearing area of a very wide bearing with a ratio of length to width equal to zero, the capacity of a square plate is only 0.4, approximately. Although the pressure distribution in the bearing clearance is different from that in the plane bearing considered by Michell, the order of the influence of end leakage on the bearing performance will be the same in both instances, and the curve in Fig. 5 is useful when necessarily short bearings are designed.

MECHANISM OF OIL-RING OPERATION

All previous considerations were made with the assumption that the oil film in the bearing is not starved, i.e., the oil supply to the bearing is quite sufficient to compensate for the loss of lubricant due to end leakage and that the design of the bearing permits free axial distribution of the oil to the load-carrying oil film. Should this not be the case, the oil film will naturally become thinner and the running position of the journal, i.e., the minimum oil-film thickness, will depend on the amount of oil supplied to the bearing. Obviously such a situation is undesirable.

The end leakage can be estimated by the formula (see Appendix No. 2)

$$Q = 0.00022\, k\, \frac{P}{Z}\, \frac{d}{L} \left(1000 s\right)^3$$

where Q = oil loss through end leakage in gal. per min.
P = pressure on the projected area in lb. per sq. in.
Z = viscosity of oil in the oil film in centipoises
d = diameter of the journal, in.
L = active length of bearing, in.
s = clearance on diameter, in.

[19] R. Wolff, "Ueber die Schmierschicht Messung durch Interferenz." Forschungsarbeiten, No. 308, V.D.I., Berlin, 1928.

[20] These tests were made by M. Stone, Power Engineering Department, Westinghouse Elec. & Mfg. Co., as a part of a bearing vibration study and will be published in detail at a later date.

[21] A. G. M. Michell, loc. cit.

The coefficient k depends on c and α, as shown in Fig. 6. In order to form a numerical idea of the oil demand, the end leakage has been computed for a series of bearings of similar dimensions, taking for all of them P = 100 lb. per sq. in.; Z = 15 centipoises; symmetrical bearings with a downward load, the relief at the split being 30 deg. on each side, i.e., the angle α = 60 deg. Under these conditions, the end leakage is estimated for various speeds of the journal. The results are given in Table 2.

The amounts of oil required for the maintenance of a perfect oil film are not large; however, in order to have a margin of safety, the oil supply should be, say, twice the oil loss through end leakage. The capacity of standard oil rings has been investigated by the author. Incidentally a number of observations have been made on the mechanism of performance of oil rings.

Preliminary tests were carried out on a disk 4 in. in diameter

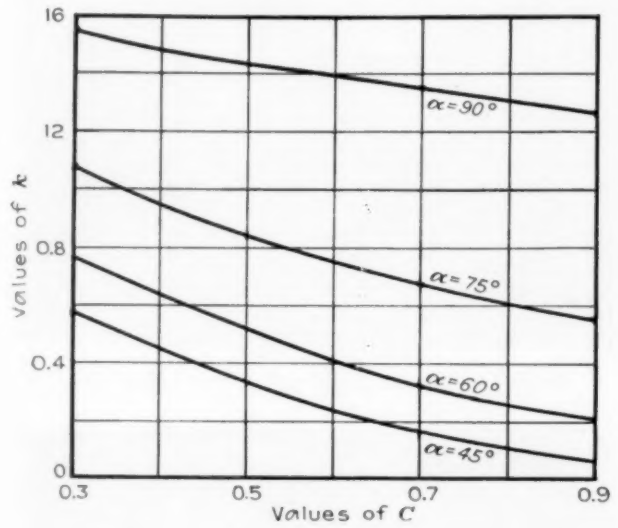

FIG. 6

carrying an oil ring used with this size of bearing. The oil ring was of 7 in. inside diameter, $^3/_8$ in. wide, and was made of brass. The arrangement is seen in Figs. 7 and 8. The ring was kept in place by a guide placed at its lower point so that nothing interfered with the transfer of oil by the ring. The speed of the motor was 1760 r.p.m. Medium machine oil was used for the test. The amount of submersion of the oil ring in the oil was varied and the corresponding speed of the oil ring measured. When the oil ring just dipped into the oil, and practically no oil was carried along, the ring raced on the journal with a metallic sound. At submersion of $^1/_8$ in. and upward an oil film was built up between the ring and the journal and no metallic sound could be heard. The breaking of the metal-to-metal contact was checked by a test light and voltmeter.

The speeds of the oil ring at different amounts of submersion, with oil at room temperature and at 53 deg. cent., are given in Fig. 9. As the temperature of the oil was raised, the oil ring slowed down, due to the fact that the viscosity of the hot oil decreased, the friction force exerted by the oil film on the oil ring decreasing correspondingly.

Figs. 7 and 8 show clearly the mechanism of operation of oil rings on high-speed journals. A heavy oil film was lifted on the "up" side of the oil ring. This film was very stable; when some solid object was put in its way, the film went around the object and did not seem to diminish in body. On the upper part of the ring, most of the oil was carried on the outer surface,

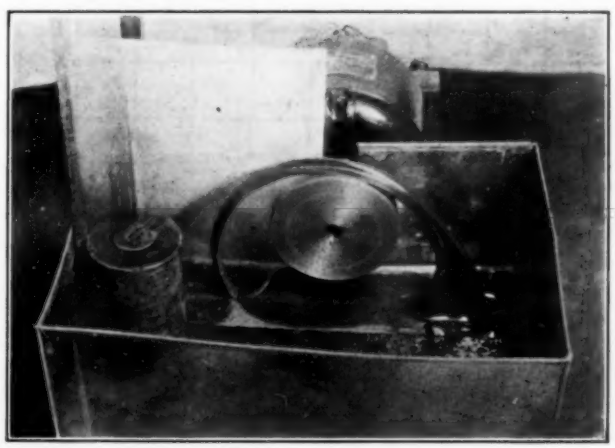

FIG. 8 OPERATION OF 7-IN. OIL RING, 2-IN. IMMERSION

forced there by the centrifugal force. The oil carried on the inner surface formed the oil film on which the oil ring was riding. The oil was squeezed out from underneath the ring by the pressure in the oil film, and coming in contact with the surface of the journal, was thrown off, so that two sprays of oil were built up on both sides of the ring. A very thin oil film was formed between the down side of the journal and the inner surface of the ring on this side. The oil from the outer surface and sides of the oil ring fell in a rainy spray from the down side of the ring into the oil bath. Fig. 7 shows the ring submerged 1 in., while the submersion in Fig. 8 is 2 in.; at submersions below 1 in. the oil film was thrown over the top of the ring. At higher

temperatures all oil films were considerably thinner, the viscosity of the oil being lower. A scoop was used to collect the oil delivered by the oil film on the down side, as shown in Fig. 10. The amount of oil collected varied with the distance from the knife edge of the scoop to the journal. It was measured at submersions of 1 in. and 1⅝ in. The amounts collected were in cubic centimeters per minute (1 gal. = 3785 cc.), as shown in Table 3.

The amount of oil delivered by the spray was obtained for the submersion of 1⅝ in., at different temperatures, by collecting the spray into a separate container. The rate of oil flow was:

Temperature of oil, deg. cent.....	23	34	43	51
Oil delivered by spray, cc. per min..	618	616	421	288

The amount of oil adhering directly to the journal was determined by applying a wiper to it and was found to be approximately 30 cc. per min. for oil at 22 deg. cent. and 60 cc. per min. for oil at 50 deg. cent.

Complete tests were made with a large oil ring and a 16-in. journal. The arrangement of the test apparatus is shown in Fig. 11. The disk 16 in. in diameter, 2 in. thick, was mounted on the shaft of a variable-speed motor. A brass oil ring of 27 in. inside diameter, 0.762 in. wide, and with a cross-section as shown in Fig. 12 was employed, the weight of the ring being 16.15 lb. The clearance between the lowest point of the oil ring and the bottom of the oil bath was 1¾ in. Three guides held the ring in position; two of these are seen in Fig. 11, while the third was at the bottom of the ring in the oil. Heaters placed in the oil allowed the temperature to be varied. Light machine oil of a viscosity approximately 300 sec. Saybolt at 30 deg. cent. was used for these tests.

In Fig. 11 the ring is shown running counterclockwise. The oil ring carried on its up side a heavy oil film in which the oil was in an eddy. The oil from the sides of the ring was shifted to the outer surface by the centrifugal force and formed a crown on the outer surface. This oil was carried over the top of the ring and back into the oil well. The oil on the inner surface formed an oil film on which the ring was riding. As in the case of the small ring the break of contact was verified by a test lamp. The oil from the inner surface was partly squeezed out by the weight of the ring forming two sprays on either side of the ring, the other part passing by the journal and forming a

FIG. 10 METHOD OF COLLECTING OIL IN OIL-RING TEST

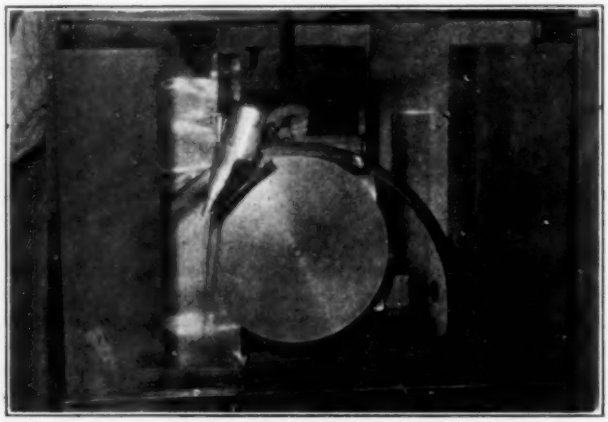

FIG. 11 TESTING OF 27-IN. OIL RING ON 16-IN. DISK

film between the journal and the ring on the down side. It must be noted that the spray appeared only after a certain speed of the journal was attained. On the other hand, the down-side film was heavy at low speed, nearly disappearing as the speed of the journal reached 300 r.p.m., when the oil was thrown off effectively from the journal surface by centrifugal force.

At low speeds, the oil ring followed the journal, their peripheral velocity being equal. The revolutions per minute of the journal and the ring were at this stage inversely proportional to their diameters, with but a slight slippage. As the revolutions of the journal increased, a transition speed was reached when the oil film between the journal and oil ring became sufficiently strong to carry the weight of the oil ring. A considerable slipping

between the journal and the ring took place and the oil ring slowed down considerably. Below the transition speed the test light connected across the ring and journal burned brightly with occasional flickering. This flickering increased when the transition speed was approached, and the light was dimmed at higher speeds. Fig. 12 shows the change of speed of the oil ring with increase in revolutions of the journal for various amounts of submersion, the oil being at room temperature. Fig. 13 gives the same data with oil heated to 50 deg. cent. The transition speed was considerably higher at the elevated temperature, corresponding to a lower viscosity of the oil.

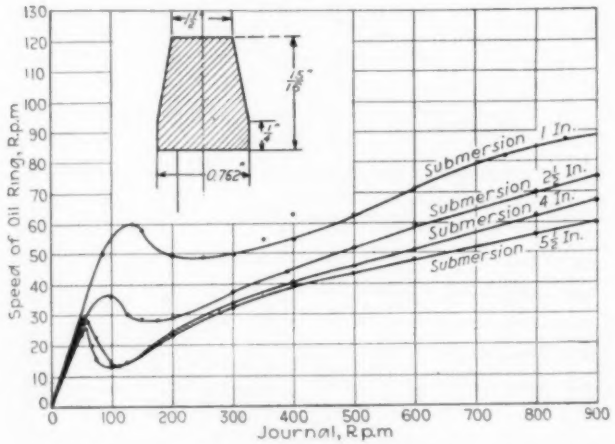

FIG. 12 CHANGE OF SPEED OF OIL RING WITH INCREASE IN REVOLUTIONS OF JOURNAL

(Diameter of journal, 16 in.; diameter of ring, 27 in.; weight of ring, 16.15 lb.; temperature of oil, 23 to 27 deg. cent.)

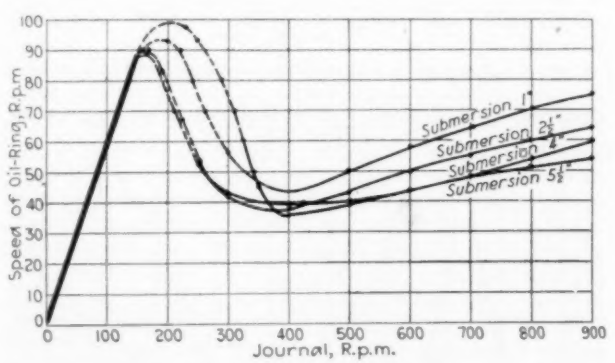

FIG. 13 CHANGE OF SPEED OF OIL RING WITH INCREASE IN REVOLUTIONS OF JOURNAL

(Diameter of journal, 16 in.; diameter of oil ring, 27 in.; width of oil ring, 0.762 in.; weight of oil ring, 16.15 lb.; temperature of oil, 48 to 55 deg. cent.)

The amounts of oil delivered by the oil ring were measured by collecting the oil from the sprays through the funnels shown in Fig. 11. A scoop, similar to the one used with the small oil ring described above, was employed to measure the amount of oil available in the oil film on the down side. It was found that in the case of the large ring this oil film thinned out very fast toward the ring; the scoop edge was therefore kept at a constant distance $^3/_4$ in. from the journal surface. Figs. 14 and 15 show the amounts of oil delivered by the sprays and oil film at various amounts of submersion for cold and hot oil, respectively.

In order to investigate the effect of weight upon the performance of an oil ring, the tests described above were repeated with oil rings of the same geometrical dimensions made of aluminum and of reinforced lead. The weights of the three rings were:

Material.....	Aluminum	Brass	Lead
Weight, lb.....	4.56	16.15	23.2

Figs. 16 and 17 show, respectively, the oil-ring speeds and amounts of oil delivered for the three rings in the case of a submersion of 4 in. and an oil temperature 55 deg. cent., this case being the closest to actual service conditions. As may be expected, the transition speeds were higher with heavier rings, and more oil was delivered in the sprays produced by these rings. It is therefore clear that light rings, sometimes advocated by designers, have no justification. Naturally, although heavier rings were shown to be better, the use of lead rings would be impractical.

The influence of the width of oil rings was studied in the same way; three brass rings of the same shape but of various widths were prepared, as shown in Fig. 18.

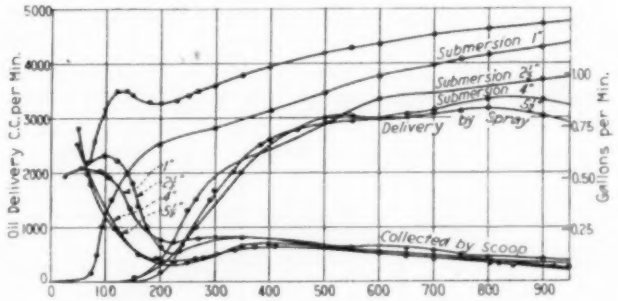

FIG. 14 AMOUNT OF OIL DELIVERED BY SPRAYS AND OIL FILM

(Diameter of journal, 16 in.; diameter of oil ring, 27 in.; weight of oil ring, 16.15 lb.; temperature of oil, 23 to 27 deg. cent.)

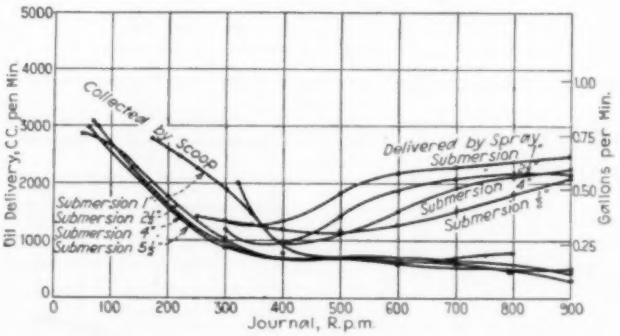

FIG. 15 AMOUNT OF OIL DELIVERED BY SPRAYS AND OIL FILM

(Diameter of journal, 16 in.; diameter of oil ring, 27 in.; weight of oil ring, 16.15 lb.; temperature of oil, 45 to 52 deg. cent.)

The ring speeds and amounts of oil delivered by the oil rings at a submersion of 4 in. and with oil heated to 55 deg. cent. are shown in Figs. 18 and 19. The speeds, at higher revolutions of the journal, are approximately the same, but the amounts of oil appear to be roughly proportional to the width of the rings. This result is important, giving a simple method to increase the oil delivery from an oil ring, if so desired.

In high-speed machines very little oil can be obtained from the oil film on the down side of the journal, most of the oil being delivered by the oil ring to the sprays. It is therefore necessary to provide means for conducting this oil into the shell and preventing it from flowing directly back into the oil well. The recent designs of larger oil-ring bearings produced by the Westinghouse Company are provided with special grooves which perform this duty.

Figs. 20 and 21 give the oil-ring speeds for an oil ring of 17 in. inside diameter mounted on a 10-in. journal. The surface of the ring was slightly rough, which was responsible for the large variation in the transition speed. Fig. 22 shows the amounts of oil carried in the oil sprays of this ring at room temperature.

FRICTIONAL LOSSES AND TEMPERATURES IN OIL-RING BEARINGS

While the running positions of the journal, i.e., the minimum oil-film thickness, can be computed with a fair amount of accuracy, the friction losses and the temperature of a bearing can be estimated only as a first approximation. The determination of the running temperature of a bearing involves the consideration of the thermal equilibrium of the bearing pedestal—the amount of heat created by the frictional losses must be equal to the heat carried away by direct dissipation through the pedestal surface and by the cooling liquid, when artificial cooling is used.

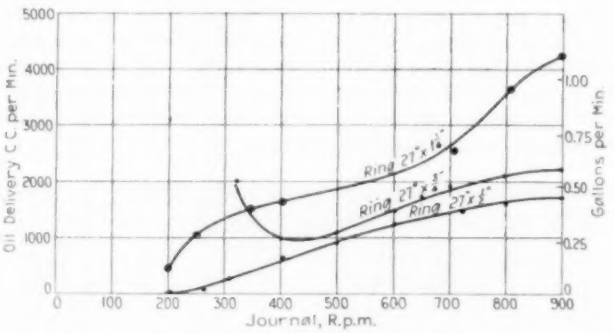

FIG. 19 AMOUNT OF OIL DELIVERED BY RINGS OF DIFFERENT WIDTHS
(See note under Fig. 18.)

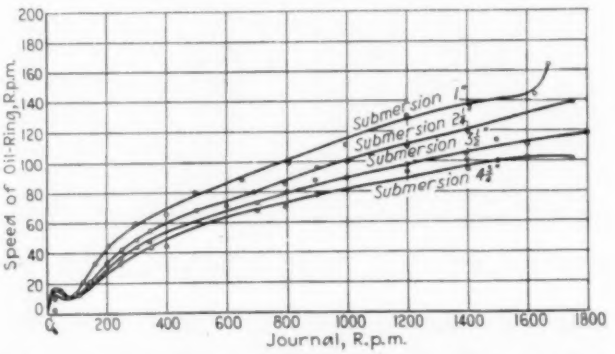

FIG. 20 OIL-RING SPEEDS WITH TEMPERATURE OF OIL AT 25 DEG. CENT.
(Diameter of journal, 10 in.; diameter of oil ring, 17 in.; weight of oil ring, 4.15 lb.)

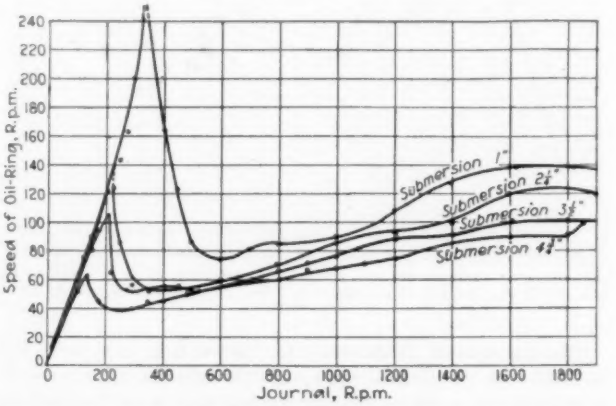

FIG. 21 OIL-RING SPEEDS WITH TEMPERATURE OF OIL AT 50 TO 55 DEG. CENT.
(See note under Fig. 20.)

It is customary to measure the frictional losses in a bearing in terms of its coefficient of friction. This is a purely fictitious conception in so far as usual bearings are concerned, since only the friction torque T of the journal can be measured. The coefficient of friction f must be defined as the ratio of the fictitious friction force $F = T/r$ acting on the journal surface to the total load W on the journal:

$$f = \frac{F}{W} = \frac{T}{rW}$$

The value of f depends on the design of the bearing, the size of side reliefs, the shape and type of the upper bearing half, the type of end seals used to prevent oil leakage from the pedestal, and on the misalignment of the shell.

Limiting the discussion to oil-ring bearings of good mechanical design with top and bottom half bored to the same diameter D, without any tight felt or other packing to prevent leakage (these at times considerably increase friction losses), it may be assumed that the coefficient of friction in such bearings is equal to the

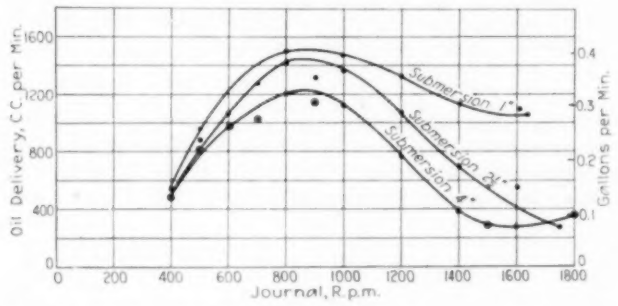

FIG. 22 AMOUNT OF OIL CARRIED IN OIL SPRAYS AT DIFFERENT DEPTHS OF SUBMERSION

(Diameter of journal, 10 in.; diameter of oil ring, 17 in.; temperature of oil, 25 deg. cent.)

coefficient of friction of a tubular bearing of the same size and clearance.

The power necessary to drive the oil rings proper is quite small. This was determined for the 27-in. × $^3/_4$-in. oil ring previously mentioned. It was found to be nearly proportional to the speed of the journal with a slight drop at the transition speed, reaching 115 watts at 900 r.p.m. The relief at the split tends to decrease the losses, but this effect is compensated by the additional friction at the ends of the bearing, in the end grooves, and on the oil throwers. It is therefore justifiable to assume that the losses in an oil-ring bearing may be computed considering it as a tubular shell of the length L, i.e., the active length of the bearing. Very little work has been done on the friction in actual oil-ring bearings, while experimental and theoretical determinations of friction in tubular bearings are available.

The theoretical values of the coefficient of friction in tubular bearings can be found in the literature. Charts for its numerical value are supplied, for instance, in the work of Howarth.[22] A recent experimental determination of the coefficient of friction in tubular bearings was made by McKee.[23] These experiments were made on four small bearings mounted simultaneously on one shaft and may therefore have the virtue of an automatic averaging of results. On the basis of these experiments, the chart in Fig. 23 gives the coefficient of friction as a function of the characteristic number of the bearing ZN/P for different clearance ratios m. The coefficient of friction is seen to increase with the speed of rotation N and with the viscosity Z and to decrease with an increase in the pressure P on the journal. The coefficient depends also considerably on the bearing clearance m.

The coefficient of friction f having been determined, the power losses in the bearings are

$$H = \frac{fWV}{33{,}000} \text{ hp.}$$

$$= \frac{fWV}{44{,}300} \text{ kw.}$$

$$= \frac{fWV}{46{,}700} \text{ B.t.u. per sec.}$$

where V is the peripheral speed of the journal in ft. per min.

The temperatures throughout the pedestal and bearing are such that when a steady state is reached in three to six hours after starting a machine, equilibrium exists between the heat generated in the bearing shell and that lost through radiation, convection, and conduction.

It can be easily shown that conduction generally plays a small part in the heat transfer. The conduction of heat through steel is 0.9 to 1.1 watts per sq. in., and for cast iron, 1.0 watt

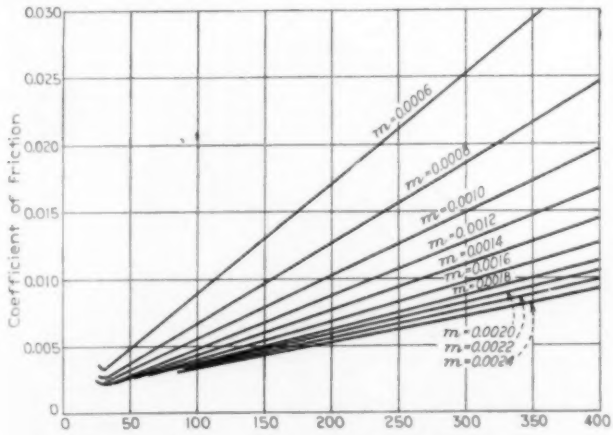

FIG. 23 JOURNAL FRICTION OF SLEEVE BEARINGS

$$\left(m = \frac{\text{clearance}}{\text{diameter}}\right)$$

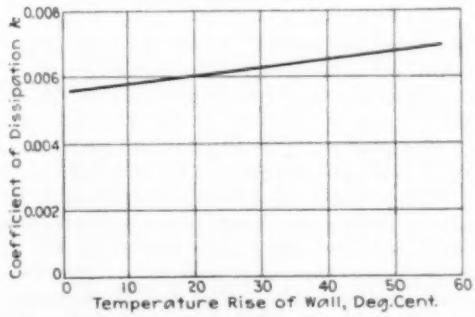

FIG. 24 VARIATION OF COEFFICIENT k WITH TEMPERATURE RISE

per sq. in., for a temperature gradient of 1 deg. cent. per in. The temperature gradient is ordinarily not large, of an order, say, of 2 deg. cent. per in. along the shaft. (It may be larger along a shaft between a bearing and a coupling rotating in open air.) The conduction of heat to the foundation depends on the height of the pedestal. It is negligible in case of a pedestal electrically insulated from the foundation. It is therefore advisable for general design purposes to neglect the heat conduction entirely, assuming that the heat is lost only through dissipation from the pedestal surface and through artificial cooling. The amount of heat dissipated from a hot surface in air depends on many factors, such as the color and finish of the surface, the temperature of the pedestal wall, the angle of the surface to the horizon, and the air currents around the surface. The velocity of the air adjacent to the surface has a remarkable influence on the heat transfer.

[22] H. A. S. Howarth, "A Graphical Analysis of Journal-Bearing Lubrication." Trans. A.S.M.E., 1923, 1924, 1925.

[23] S. A. McKee and T. R. McKee, loc. cit.

For a smooth metallic surface, such as sheet metal, the dissipation of heat in quiet air, as determined in the Westinghouse Laboratories by the late G. E. Luke, with plates and large horizontal pipes, is approximately $k = 0.006$ watt per sq. in. per 1 deg. cent. of temperature rise of the surface over the ambient temperature. This coefficient varies slightly with the temperature rise as shown in Fig. 24.

In order to determine the heat dissipation from actual bearings, a standard pedestal with a 4-in. × 8-in. bearing shown in Fig. 25 was employed. The pedestal had a dull black finish. Its outer surface was 1980 sq. in.

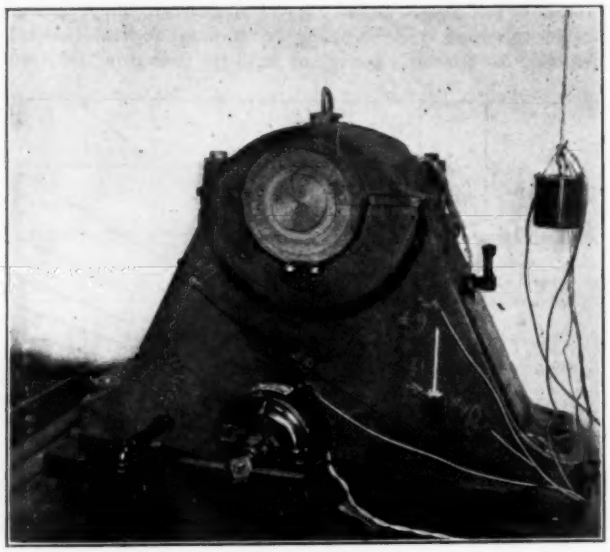

FIG. 25 APPARATUS FOR DETERMINING HEAT DISSIPATED FROM ACTUAL BEARING

A dummy shaft was placed in the bearing shell. The oil well was filled with oil. Two electric heaters were placed in the oil and a third cartridge heater was mounted in the shaft in order to produce temperature gradients in the pedestal comparable to those met in practice. The temperatures were measured by means of thermocouples welded to the surface of the pedestal. As may be seen from Fig. 25, the thermocouple leads were held flat against this surface for a length of one inch, approximately, in order to be sure that the temperatures of the hot junctions were equal to the temperatures of the surface. The temperature of the dummy shaft was also recorded by a thermocouple placed in a hole drilled through the bottom half of the shell. The observations of the temperature rise in the pedestal for various inputs into the heaters were carried out in quiet air and under the blast of two 16-in. electric fans. The average velocity of the air near the pedestal walls was approximately 500 ft. per min. Figs. 26 and 27 show the temperature rise and the coefficients of radiation observed with various inputs of power into the heaters. The coefficient of heat dissipation $k = W/St$, where W = the input in watts, S = the area of the pedestal in square inches, and t = the average temperature rise of the pedestal wall in degrees centigrade, was found to be

$k = 0.0075$ in quiet air
$k = 0.0210$ in a draft of velocity of 500 ft. per min.

The computation of power losses using the coefficients of friction from Fig. 23 was applied to a number of actual machines tested in the Westinghouse Works. The bearings of these were of the oil-ring type, without artificial cooling, i.e., the heat created by bearing losses was carried off by direct dissipation through the pedestals. The temperature rise of the walls was measured. The coefficients of dissipation computed are shown in Fig. 28. They fall well in line with the values determined in the laboratory.

It must be noted that the power losses in the oil film depend on the viscosity, hence on the temperature of the oil film, while the heat dissipation is determined by the temperature of the wall. The temperature of the oil film is naturally higher than that of the wall, since heat flows from the oil film to the wall. Observations on numerous bearings allow the compilation of the following approximate values:

Temperature rise of the pedestal wall, deg. cent	12	18	24	30
Average temperature of oil film above temperature of wall, deg. cent	18	25	32	40

With these data, an estimate of the temperature of a self-cooled bearing can be made when a new machine is designed. The procedure is as follows:

Assume a reasonable temperature rise of the pedestal wall.

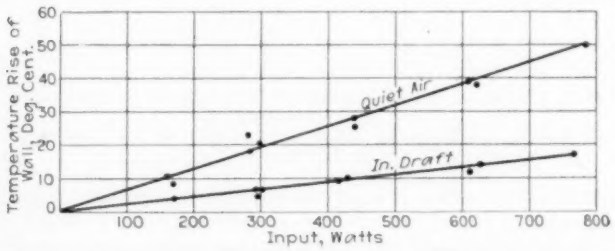

FIG. 26 TEMPERATURE RISE IN 4-IN. × 8-IN. BEARING PEDESTAL WITH 1980 SQ. IN. OF SURFACE

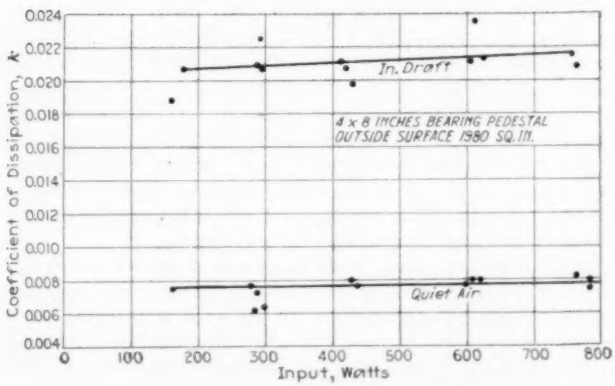

FIG. 27 VARIATION OF COEFFICIENT OF DISSIPATION k
(4-in. × 8-in. bearing pedestal, 1980 sq. ft. of surface.)

Take the lowest possible ambient temperature, since the losses and consequently the temperature rise will be the highest when the temperatures are lower and the viscosity of the oil higher. Find the temperature of the wall, then the probable average oil-film temperature, and the corresponding value of viscosity Z. Find ZN/P and the value of f. Find the losses H in watts. Knowing the radiating area of the pedestal S, take a suitable value of k, and find the temperature rise of the pedestal wall $t = H/kS$. Compare with the assumed value. If the values do not check within sufficient accuracy, make another trial. Two or three trials generally will be sufficient.

It should be noted that the radiating area S of the pedestal is rather indeterminate. In tall pedestals, it is convenient to assume the radiating area extending, say, 4 in. below the bottom

of the oil well. In short pedestals with electric insulation, the total area above the bedplate must be taken. A designer must use his judgment in all instances.

Conclusion

The author realizes that the discussion brought forth in the above notes may be criticized because of a number of assumptions and rough approximations. Unfortunately, all mechanical engineering consists, when applied to actual designing, in an approximate application of "exact science." Exact analysis is a powerful tool, but its application must always be controlled by sound judgment of the designer. This personal element may be eliminated only by an accumulation of facts and observations which will gradually narrow the range of the correction coefficients employed in the reported computations.

Appendix No. 1

COMMERCIALLY, the viscosity of an oil is given in this country in "seconds Saybolt," this being the time necessary for 60 cc. of the oil at a given temperature to flow out of a standard Saybolt viscosimeter.[24] An empirical chart with logarithmic coordinates, prepared by the Texas Company, makes it possible to plot the temperature-viscosity curve as a straight line for usual petroleum oils. Given viscosities at two temperatures, the viscosities at any other temperature are easily found by the use of this chart. To the right, a scale for kinematic viscosity is plotted. The absolute viscosity is the kinematic viscosity times the specific gravity of the oil.

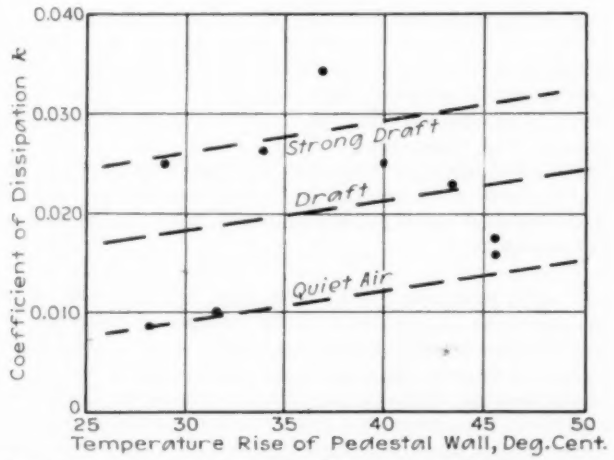

FIG. 28 VARIATION OF COMPUTED COEFFICIENT OF DISSIPATION FOR ACTUAL MACHINES

For the machine oil mentioned in this paper, at 60 deg. cent. the viscosity is found to be 102 sec. Saybolt, or a kinematic viscosity of 19.8; the absolute viscosity is 19.8 × 0.86 = 17.0 centipoises.

Appendix No. 2—End Leakage in Oil-Ring Bearings

AN EXACT determination of the oil flow on basis of the hydrodynamical theory would be quite difficult. A rough estimate of this quantity can be made, however, as follows. In so far as the axial flow is concerned, the surfaces of the journal and shell are at rest. In this case, the volume of viscous liquid passing through both ends of the bearing in a unit of time is:

$$Q = 2\,\frac{b}{12}\,\frac{dp}{dZ}\,\frac{h_0^3}{\mu}$$

where b = the width of the oil stream
$\frac{dp}{dZ}$ = the average pressure gradient at the bearing end
h_0 = the average oil-film thickness
μ = the absolute viscosity.

This equation is obtained easily from the corresponding equation given by Stodola[25] when $\mu = 0$. The value of b depends on the values of the angle of α and coefficient c. The angle of the pressure zone varies between 1.5α and 2α;[26] assume it to be 1.8α, then $b = 1.8r\alpha$. Considering the geometry of the oil film,

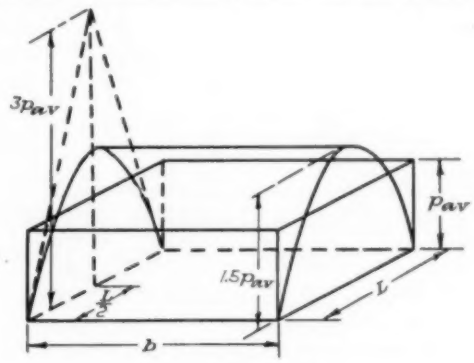

FIG. 29

$$h_0 = \frac{1}{1.8\alpha}\int h\,d\theta = \frac{1}{1.8\alpha}\int_0^{1.8\alpha} mr(1-\cos\theta)\,d\theta$$

$$= mr\left(1 - c\,\frac{\sin 1.8\alpha}{1.8\alpha}\right)$$

The average gradient of pressure at the bearing end may be estimated as in Fig. 29

$$\frac{dp}{dZ} = 6\,\frac{p_{av}}{L}$$

where p_{av} is the mean pressure in the oil film and L is the active length of the bearing. Collecting,

$$Q = \frac{1.8r\alpha}{6\mu}\,6\,\frac{p_{av}}{L}\,m^3r^3\left(1 - c\,\frac{\sin 1.8\alpha}{1.8\alpha}\right)^3$$

$$= \frac{0.9\,d}{\mu\,L}\,p_{av}\,(R-r)^3\,\alpha\left(1 - c\,\frac{\sin 1.8\alpha}{1.8\alpha}\right)^3$$

$$= k_1\,\frac{p_{av}}{\mu}\,\frac{d}{L}\,(R-r)^3,$$

where $k_1 = 0.9\,\alpha\left(1 - c\,\frac{\sin 1.8\alpha}{1.8\alpha}\right)^3$

The values of k_1 are as follows:

	$c = 0.3$	$c = 0.5$	$c = 0.7$	$c = 0.9$
45 deg.....	0.34	0.20	0.09	0.035
60 deg.....	0.58	0.40	0.25	0.16
75 deg.....	0.90	0.70	0.59	0.46
90 deg.....	1.28	1.21	1.13	1.05

[24] W. H. Herschel, "Viscosity and Friction." Jour. S.A.E., 1922.

[25] Loc. cit., p. 470, et seq.

[26] G. B. Karelitz, loc. cit.

Assuming the values of p_{av} to be:

α, deg.....	45	60	75	90
p_{av}.....	1.7 P	1.3 P	1.2 P	1.2 P

in order to take into account the difference between the area of the pressure zone and the projected area

$$Q = k \frac{P}{\mu} \frac{d}{L} (R - r)^3$$

where P is the pressure on the projected area and k is a coefficient equal to

	$c = 0.3$	$c = 0.5$	$c = 0.7$	$c = 0.9$
45 deg.....	0.58	0.34	0.15	0.06
60 deg.....	0.75	0.52	0.32	0.21
75 deg.....	1.08	0.84	0.71	0.55
90 deg.....	1.54	1.45	1.35	1.26

If Q_{gal} is expressed in gallons per minute, pressure P in pounds per square inch, viscosity Z in centipoises, the clearance $s = D - d = m(R - r)$ in inches, $Q_{gal} = 0.00022\, k \frac{P}{Z} \frac{d}{L} (1000\, s)^3$.

It should be noted that the influence of each element of the bearing on the oil leakage is not apparent directly from the expression derived, since the change of each element affects the value of c, hence the coefficient k.

Discussion

L. J. Bradford.[27] During the last year considerable work has been done at the Pennsylvania State College on a machine designed to permit accurate determination of the pressure distribution within the oil film in a complete bearing, lubricated from one end. In no case has the pressure been found to be zero at the point of minimum film thickness. For the cases investigated the pressure has varied from 55 per cent to 93 per cent of the maximum pressure. Positive pressure was found to extend for 20 to 25 deg. beyond the point of minimum film thickness. The point at which the pressure becomes zero seems to be affected by all the variables that enter into a bearing, but there has not as yet been done enough work to enable one to say just how it is affected by each. This discrepancy between the assumed and actual pressure distribution probably accounts for the deviation of the observed path of the shaft center from that predicted by the author.

The author's equation for shaft displacement, however, gives results in remarkable agreement with the values actually observed. Comparison between calculated and observed shaft displacements for load ranging from 100 to 400 lb. per sq. in. showed discrepancies that at no time exceeded 0.0003 in. This was about 10 per cent of the displacement and about the limit of accuracy of observation.

S. A. McKee.[28] The author has presented an interesting and valuable paper relating to bearing design. Its value as a practical working guide, however, depends chiefly upon the correctness of certain assumptions that have been made. Possibly the place where the uncertainty of the correctness of the assumptions has its greatest significance is in the evaluation of the minimum film thickness for a given bearing under given conditions, and in deciding from this value whether or not the bearing will operate in a satisfactory manner. Unfortunately this is a point where the lack of sufficient reliable and systematic experimental evidence causes a considerable degree of uncertainty. The foregoing is intended not to especially criticize the particular methods or values chosen by the author, but to emphasize the need for research on this phase of the problem.

There is one factor in the determination of the minimum film thickness that possibly might have been given greater emphasis by the author. This is the question of the effect of the deflection of the journal and bearing under the load imposed. This question in many cases may be neglected when the loads are relatively light, as compared to the rigidity of the parts involved. However, the writer would like to ask the author to what extent the deflection of the journal will affect the value of the minimum film thickness of 0.0009 in. as given in the example of the slow-speed oil-ring bearing. In this case a journal 11 in. in diameter with a working length of 22.5 in. has a total load of 35,400 lb., and even if the bearing is so constructed that it may align itself properly, the deviation of the journal axis from a straight line may be such that in some parts of the bearing the minimum film thickness is much smaller than the computed value. This is suggested not to imply that this particular bearing will not operate successfully under the given conditions, but to point out that there are cases where serious difficulty may be encountered unless journal deflection is considered.

A. E. Flowers.[29] The Society and the author are to be congratulated upon this paper, which is the first contribution to the subject of oil-ring bearings since the classical work of Lasche in Germany many years ago.

It is to be hoped that if the author has not already carried out similar studies on the lubrication of vertical bearings, he will find an opportunity to do so and will present his results to our Society for publication.

H. A. S. Howarth.[30] The writer was glad to see Fig. 5 in this paper which gives a factor for end leakage, showing how it depends upon the width-length ratio. Although this was derived for slightly inclined flat surfaces and does not apply exactly to journal bearings of any ordinary kind, it gives a fair idea of the magnitude of the influence of leakage. Charts of journal-bearing characteristics, based on the hydrodynamic theory, but neglecting leakage, may be corrected by means of this curve. The "factor for end leakage" should be represented by some letter, such as S. Then, when studying the bearing by means of a chart neglecting side leakage, if we find that an oil film of a given form and dimensions would appear to carry a unit pressure w, we must multiply this by S in order to determine the actual unit pressure w_1 that would be supported by this film when leakage is taken into account. Thus, we have $w = w_1/S$. w and the width-length ratio would be found from the problem data; but w would be a fictitious value of the unit pressure that should be used for entering the scale of a chart, such as contained in the pamphlet entitled "A Graphical Analysis of Journal-Bearing Lubrication."

A chart somewhat like that offered by the author, but not so generally useful, was published in London *Engineering* in a discussion of the Michell bearing, February 20, 1920. The author has, however, used the opposite names for the same bearing dimensions. He uses "width" for what *Engineering* calls "length," and vice versa. It seems more logical to use the word "length" for the dimension in the direction of motion and "width" for that at right angles thereto or along the axis of the shaft. The term "end leakage" means the same as what others, including the writer, have called "side leakage." In view of this confusion in bearing nomenclature it would seem to be high time that some

[29] De Laval Separator Company, Poughkeepsie, N. Y.

[30] Vice-President and General Manager, Kingsbury Machine Works, Philadelphia, Pa. Mem. A.S.M.E.

committee should endeavor to coordinate the work of various investigators and to have them use similar names and symbols, thereby avoiding confusion in the minds of engineering designers.

The leakage factor may be expressed in different ways. The writer made a study of Mr. Michell's theory on leakage for flat bearing surfaces many years ago and drew a chart. This was published as Fig. 2 in a letter entitled "A Graphical Study of Journal Lubrication," April, 1927, *Mechanical Engineering*. This shows a correction factor k to be applied for determining the relation of the friction to be expected in a bearing when leakage is taken into account to the friction that would exist in the bearing if it could carry the same load without leakage. It indicates that when the bearing surface extends three times as far in the direction of motion as it does at right angles thereto, the friction would be about three times as great as could be expected for the same load if the influence of leakage could be neglected. The approximate relation between this curve and that of the author is that the ordinates are the square root of the reciprocals of his. For a further study of the influence of film leakage upon friction, the writer would refer those interested to the letter above mentioned.

Film leakage as influencing the carrying capacity and the friction in journal bearings is now being intensively investigated with a view to determining more reliable factors for application to the study of journal bearings. It is hoped that the work along this line that is being done by Mr. Kingsbury will be completed within the following year. When this is available the whole field of journal-bearing film investigation can profitably be reviewed, theoretical considerations coordinated, and the various charts made more available for general use.

The author suggests as an alternative to the use of oil rings the employment of forced-feed lubrication. It seems, however, that there is another alternative that is very important indeed—the field of disk oiling or oiling by means of viscosity pumps. Disk oiling has been used in one form or another for many years, but it is being further developed by Kingsbury Machine Works, Inc., as a direct result of its employment for oiling thrust bearings. In this use, disk oiling requires a minimum of the upper shell to be cut away. Suitable oil channels may therefore be employed and the bearing made to carry a load in any radial direction. This is important for journal bearings of the film type when used in such machines as electric motors. Disks need not slip as rings do.

The author refers back to pressure curves that he presented several years ago. Although based upon certain assumptions that he was satisfied to use, they are not rigorously correct, so far as the Reynolds hydrodynamic theory is concerned. Hence, as previously pointed out, they do not quite agree with the charts in "A Graphical Analysis of Journal-Bearing Lubrication." An extension of the Reynolds theory indicates clearly that it is not necessary for the pressure to be zero at B, the point of closest approach, in Fig. 1. It seems, therefore, that these differences are worthy of further study and that the results of experiments by various investigators should be published so far as relevant thereto.

HAROLD C. CLAUSEN.[21] The author is to be congratulated on presenting a valuable paper which will be of use to all engineers interested in the bearing problem. Two and one-half years ago the writer had occasion to discuss with Mr. Karelitz some questions in connection with the bearing problem, and on the question of heat dissipation sent him the following note:

The writer has used the figures of 2–5 and even 10 B.t.u. per hour per sq. ft. per deg. fahr. for the calculation of the rate of heat transmission from a solid surface where a liquid is being cooled on one side and a gas being warmed on the other side. These figures are taken from "Engineering Thermodynamics" by C. Lucke and are based on experiments on hot-water radiators. The figures are equivalent to 0.0073 to 0.01825 and 0.0365 watts per sq. in. per deg. cent. and depend on the character of the liquid surface and the air velocity, the lower figure corresponding to still-air conditions and the top figure to where there is considerable turbulence of the air.

It is pleasing to note that the foregoing figures are in general agreement with the results shown in Fig. 28 of the paper entitled "Variation of Computed Coefficient of Dissipation for Actual Machines."

The question of friction and temperature was also discussed, and the writer noted to Mr. Karelitz that—

The formula used by the writer for estimating the friction loss in high-speed bearing is: B.t.u. lost in journal friction per hour $= \frac{190\, l\, d\, v}{t\text{-}32}$ where l = journal length and d the diameter, both in inches, v the velocity in feet per second, and t the temperature in degrees fahrenheit. This formula is based on the shearing resistance of the oil of the order of 0.45 lb. per sq. in. These figures are taken from a paper on "High Speed Bearings," by G. Stoney, *Engineering*, London, Aug. 7, 1914. Also see *Engineering*, London, March, 1922.

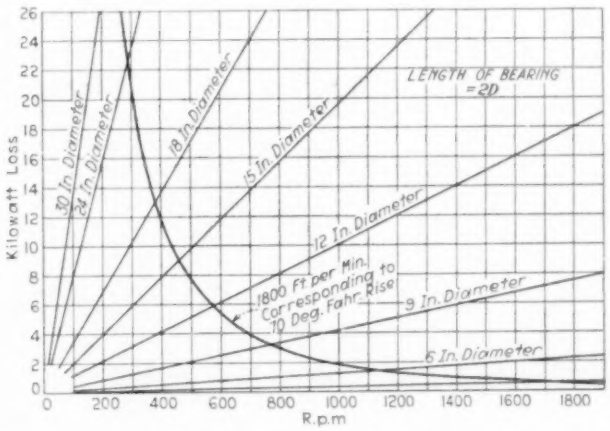

FIG. 30 FRICTION LOSS IN DIFFERENT BEARINGS FOR DIFFERENT R.P.M.

Using the information contained in the foregoing, a curve was made (see Fig. 30) showing the friction loss in different bearings for different r.p.m., and also indicating the limiting speed at which the bearing can be air-cooled. This corresponds to a circumferential velocity of the shaft of about 1800 ft. per min. for the 70 deg. fahr. rise of bearing temperature. Similar curves can be made up for Kingsbury thrust bearings, and the velocity of 1800 ft. per min. for the mean diameter of the shoe will give 70 deg. fahr. rise in bearing temperature. In both cases it is assumed that the air is kept in motion by some nearby revolving element—that is, we have some draft of air on the bearings. These results appear to agree fairly well with practice.

The writer would like to draw attention to three valuable references on the general bearing problem, and they are as follows:

1 "Reibung and Schmierung in Machinenbau" ("Friction and Lubrication in Machine Construction"), by Gumbel and Everling, 1925.

2 "Grungzüge der Schmiertechnik" ("Fundamentals of Lubrication Technic"), by E. Falz, 1926.

3 "Bedeutung der Hydrodynamischen Lagerreibungstheorie für die Praxis" ("The Practical Application of the Hydrodynamic Theory of Bearing Friction"), by Dr. Ing S. Kaisskalt, Berlin, *V.D.I.*, band 71, no. 7, Feb. 12, 1927.

In these references the value of the coefficient of friction

[21] Mechanical Engineer, Union Switch and Signal Company, Swissvale, Pa. Mem. A.S.M.E.

$\mu = \text{constant}\sqrt{\frac{ZN}{P}}$, and this does not agree with $\mu = \text{const.}\frac{ZN}{P}$ as shown in Fig. 23, "Journal Friction of Sleeve Bearings." The writer would like to know if the author can give any explanation of the different formulas for the coefficient of friction.

Author's Closure

The author agrees with Professor Bradford and Mr. Howarth that the location of the zero pressure point in a bearing must be studied further. It is significant, though, that on many occasions a vacuum has been observed in the "up part" of partial bearings.

Vertical bearings are being considered at present, together with the question of bearings under rotating loads.

Disk lubrication, as suggested by Mr. Howarth, is used, indeed, in some application such as marine bearings. But the arrangement is rather expensive and could not be conveniently embodied in, say, electric motors in face of the strong competition in this field.

The feasibility of such a device should certainly not be overlooked.

In addition to the remarks of Mr. Clausen, it is probably worth while to point to the bibliography on lubrication given in the Progress Report of the A.S.M.E. Special Committee on Lubrication, Trans., 1928, paper APM-50-4, where the authors indicated by Mr. Clausen in his discussion are mentioned among the references.

Power Application to Oscillating Axles

By ALAIN MADLÉ,[1] LIMA, OHIO

In this paper a type of axle is described in which the load is not carried by the wheel center but is suspended at the end of an arm which is permitted to swing like a pendulum about the wheel center. This mechanism is called a differential drive, and its application to motor-driven vehicles is described. The forces acting in the mechanism and the conditions necessary for an equilibrium of forces are worked out mathematically, and a comparison is given of starting motor trucks by two systems: first, when equipped with an oscillating axle with differential drive, and second, with the usual method of drive.

By means of the differential drive it is claimed that torque can be applied momentarily to the wheel without turning it, and that an elastic connection is provided between the power line and the wheel which cushions torsional impacts. Whenever there are changes in the running conditions of the vehicle, fluctuations of energy between the wheel assembly and the vehicle body take place. The reaction forces of these fluctuations provide an increased pressure against the ground, an additional accelerating force, and a greater retarding force.

WITH a view toward cushioning the horizontal road shocks and improving the general riding qualities of vehicles, a type of axle has been developed in which the load is not carried by the wheel center but is suspended at the end of an arm which is permitted to swing like a pendulum about the wheel center. The influence of this suspension on the ability of the axle to absorb road shocks is outside the scope of this paper.

Here will be discussed only the peculiar qualities of such an axle which appear when a power drive is applied. The principle of such an axle is illustrated in Fig. 1.

Since a certain movement is possible on the part of the wheel center in relation to the frame, the logical point to enter the wheel with the power line is the point *C*, Fig. 1, which is common to both the frame and the wheel. The drive which lends itself best to this arrangemnt is a planetary-gear drive in which the sun wheel is connected to the road wheel and the planet is carried to the end of the swinging arm as indicated in Fig. 2.

[1] Relay Motors Corporation. Mr. Madlé was graduated from the School of Electrical Engineering of the University of Vienna in Austria-Hungary. His practical engineering experience started with the English-owned Whitehead Torpedo factory located in Fiume, now a part of Italy. During the World War he served with the Imperial Austrian Navy, first in torpedo and submarine developments, and later in acoustical research for submarine detection and location. Since the war his electrical-engineering experience has been with the Siemens-Schuckert Company, of Berlin and Vienna, and The Neufeldt and Kuhnke Company, of Kiel, Germany. He has also been employed in the mechanical-engineering department of Brown-Boveri Company of Vienna. In automotive engineering he has been employed by the Graf and Stift Company, of Vienna, and the Peugeot Automobile Company, of Paris. Since coming to the United States, he has been employed by the Relay Motors Corporation.

Contributed by the Applied Mechanics Division and presented at the Semi-Annual Meeting, Detroit, Mich., June 9 to 12, 1930, of The American Society of Mechanical Engineers, 29 West 39th St., New York, N. Y.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

The Planetary Drive

This planetary or epicylic mechanism consists of three members—the sun wheel or track gear, the planet or track pinion, and the arm or pinion carrier. For the movement of these three members, the fact is typical that the relative velocity between the circumference of the track gear and pinion is constant, or, in other words, that the velocity of the carrier at the radius of the pinion center equals the difference between the circumferential velocity of the track gear and the circumferential velocity of the pinion.

Any one of the three members can be driving the other two members. From the relation of forces as shown in Fig. 3, it readily can be seen that the mechanism is able to transmit torque from the driving member to one of the driven members only when the second driven member is retained or supported by a circumferential force equal to the circumferential force of the output torque.

It is of course possible for the supported member to be at rest.

Fig. 1 Axle in Which Load Is Suspended at End of an Arm Which Swings Pendulum-Like About Wheel Center

Then the total transmitted energy flows from the driving member to the driven member and the three-member drive becomes a normal gear drive. It is also possible for both driven members to be rotating—then the input energy is distributed between them. Because of its peculiar conditions, the mechanism characterizes itself as a so-called differential drive.

A mechanism of this kind is sometimes used as a clutch, in which case a brake is provided to retard the movement of the part which is to be held stationary when the drive is fully engaged. The sliding engagement of the brake allows the gradual application of torque to the driven shaft, even before it turns.

Application of the Differential Drive to Vehicle Propulsion

As previously pointed out, an epicylic-gear mechanism can be used to advantage as driving mechanism for oscillating

vehicle axles. When so used the track gear of the epicylic drive is fastened to the road wheel of the vehicle, which itself is mounted rotably about a dead axle or stub shaft. The power line is enclosed in an axle housing which, by means of the spring, carries the weight of the vehicle. The swinging arm carries on its one end the dead axle, and on the other end a trunnion bearing for the axle housing and a bearing for the track pinion which is in mesh with the track gear. (Fig. 5.)

Forces Acting on the Vehicle

In order to analyze the dynamics of this application, the diagram shown in Fig. 6 will be used. The point O signifies the wheel center, and the point C the center of the pinion or the trunnion bearing. The radius of the wheel will be called R', the pitch radius of the track gear R, and of the pinion r. The length of the pinion carrier will be indicated as ρ.

According to the assumptions previously made concerning the design of the axle, the weight of the vehicle is always carried at the point C. Therefore when no other forces are applied the carrier will stand vertically.

It will be assumed for the moment that the carrier is held in this vertical position by some mechanical means. If now a torque T through the drive shaft, pinion, and track gear is applied to the wheel, a propelling force P_w will act at the wheel center. As reaction, this force is of equal amount and opposite in direction to the tractive effort acting at the contact point of tire and ground. At the same time the arm exerts a pressure P_c against its support, which is equal in amount and opposite in direction to the circumferential component of the tooth pressure in the track-gear drive.

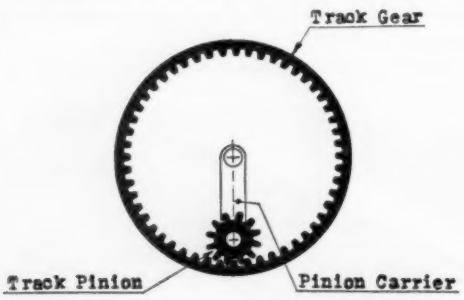

Fig. 2 Planetary-Gear Drive

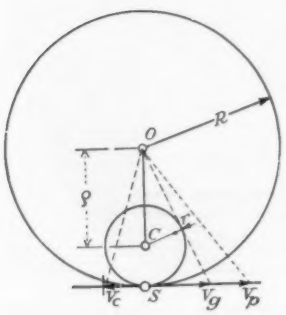

Fig. 3

ω_c = angular velocity of carrier
ω_p = angular velocity of pinion
ω_g = angular velocity of track gear
V_c = circumferential velocity of carrier (at C)
V_p = circumferential velocity of pinion at pitch line
V_g = circumferential velocity of track gear at pitch line
$V_p = V_g + V_c$; $\omega_p r = \omega_g R = \omega_c \rho$

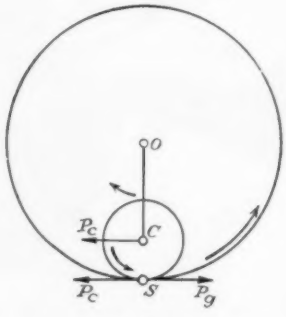

Fig. 4

P_g = circumferential force at pitch line of track gear
P_p = circumferential force at pitch line of pinion
P_c = circumferential force at pinion center
$P_p = P_g = P_c$

The propelling force can be represented as:

$$P_w = T/R'$$

and the pressure against the support of the swinging arm as:

$$P_c = T/R$$

The force P_c—the pressure of the swinging arm on its support—is therefore greater in the proportion of the radii R'/R than the propelling force P_w.

Conditions for an Equilibrium of Forces

If now the support of the point C is removed, the force P_c must be sustained by a force of equal amount in order that the torque T can be applied to the wheel.

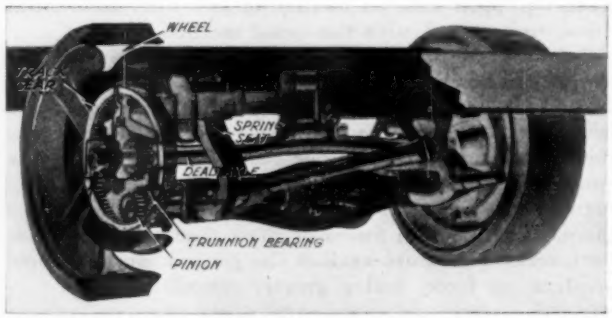

Fig. 5 Epicyclic-Gear Driving Mechanism for Oscillating Vehicle Axle

It can be seen readily from Fig. 7 that the weight supported at point C will, with increasing angle φ—the angle between the carrier and the vertical direction—develop an increasing component in the direction of the force P_c. This component can be expressed as $W \sin \varphi$.

Because of the fact that by the incorporation of the oscillating axle the vehicle practically consists of two parts, each of which may move with relation to one another, it appears to be appropriate to consider the resistances of these possible movements for both portions separately. It therefore becomes necessary to distinguish between the front-end resistance R_c, consisting of the rolling resistance of the front wheel and the air resistance of the vehicle, and the rear-wheel resistance R_w, the rolling resistance retarding a movement of the rear wheels.

The front-end resistance R_c can be assumed to be acting at the point C in a horizontal direction, and the rear-wheel resistance at the contact point of the rear wheels and the ground. The sum of these two resistances is the total resistance of the vehicle which must be overcome by the propelling force.

Assuming both resistances and the applied torque to be constant and the velocity unchanging, then the resultant of all forces and of all the turning moments about the wheel center, respectively, must be zero. To fulfil these conditions the carrier must assume a certain angular position. These conditions can be expressed as:

$$P_w = R_w + R_c \quad \ldots\ldots\ldots\ldots\ldots\ldots [1]$$

$$P_c = Mg \sin \varphi + R_c \cos \varphi \quad \ldots\ldots\ldots\ldots\ldots [2]$$

Here the force P_c is still sustained by concrete forces—the dynamics of the mechanism are not different than they would be if the carrier would be held in a fixed position by mechanical means.

The angle between the carrier and the vertical position is a function of the engine torque, the weight of the load, and the

resistance against the front portion of the vehicle, and is determined by the second of the equations just presented.

Transition Between Two Stages of Equilibrium

It is evident that each change in the acting forces will demand another angle between the carrier and the vertical position to bring the system again into a state of equilibrium. Any change in the condition will accordingly necessitate a movement of the carrier.

Whenever the carrier moves, the mass of the weight which is supported on the rear axle or at the end of the carrier must be accelerated in the path of a circle about the wheel center. The accelerating force of this movement will sustain the force P_c, and the constant flow of torque to the wheel will not be interrupted.

In order to study the process of transitions between two stages of equilibrium, the vehicle with the oscillating driving axle can be reduced to a system as shown in Fig. 8. The mass of the weight which is supported by the rear axle M_1 is assumed to be concentrated at the point C, and the mass of the weight of the wheel assembly m is concentrated at the point O, the rear-wheel center; furthermore the mass of the weight supported on the front axle M_2 is concentrated at the front wheel center. The movement of the masses m and M_2 is held to a horizontal straight-line path.

Whenever the equilibrium of such a system is disturbed by the variation of the outer forces, oscillations of the masses with relation to each other will result. This case has been treated

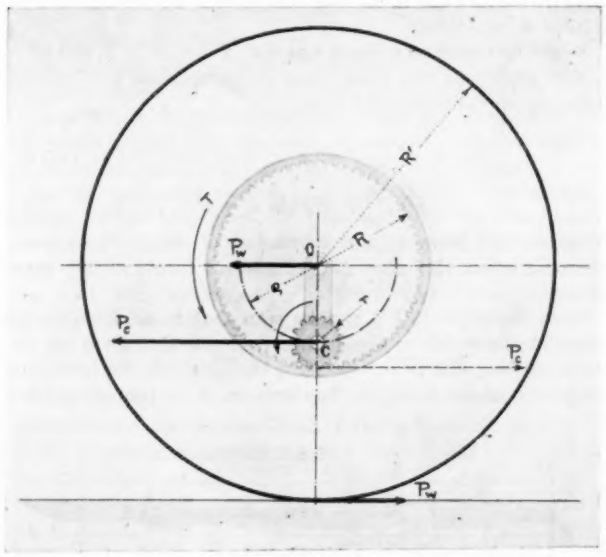

Fig. 6

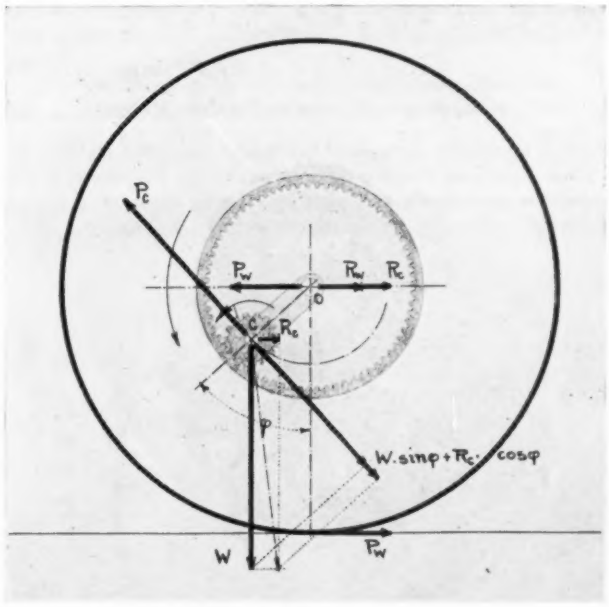

Fig. 7

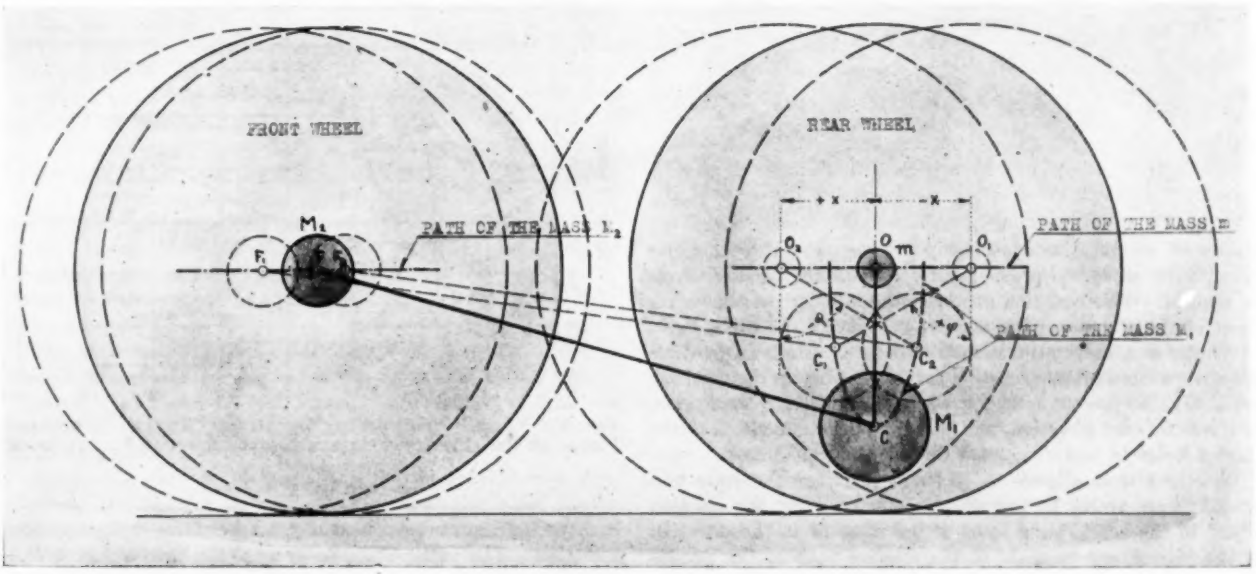

Fig. 8 Diagrammatic Representation of Vehicle With Oscillating Driving Axle

mathematically in the Appendix, and through the introduction of two independent coordinates, x for the translatory, and the angle φ for the rotary motion and neglecting M_2, the equations of the movement of this system have been established as

$$\frac{R}{R'}P_c - R_w - R_c = (m + M)x'' + M\rho\varphi''\cos\varphi - M\rho(\varphi')^2\sin\varphi \quad [3']$$

$$P_c - Mg\sin\varphi - R_c\cos\varphi = M\rho\varphi'' + Mx''\cos\varphi \quad [4']$$

where M stands for the mass of the weight supported on the axle.

These equations describe quite generally the movement of the system in transitions, the equations being those of a forced oscillation, influenced by the outer forces P_c, R_w, and R_c. As a

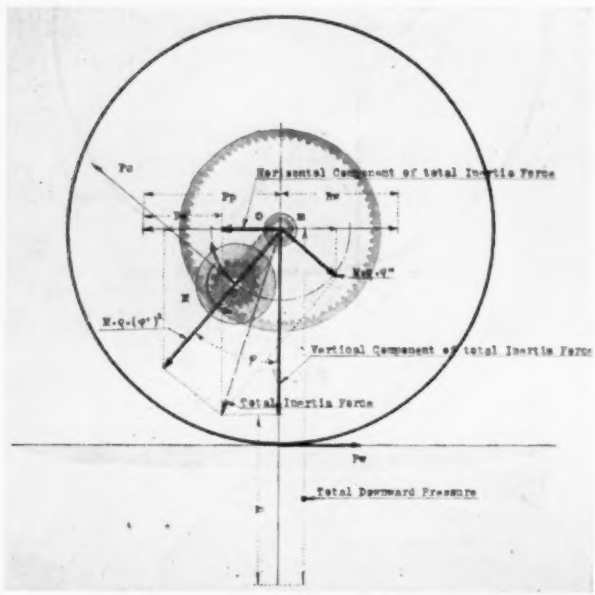

FIG. 9

matter of course, the relationship between the three angular velocities as described previously for the differential drive must be applied. This equation expresses the influence of the movement of the system on the angular velocity of the drive shaft.

Whenever a movement is restricted to a certain path, there are always inertia forces reacting perpendicularly to the resulting path. In the present case the wheel is supporting the system in the downward direction, and therefore the components of the inertia forces in this downward direction are of interest.

It follows from Equations [3'] and [4'] that there are two inertia forces acting at the wheel center, namely, the reaction $M\rho\varphi''$ to the accelerating force of the mass M in the direction of the momentary tangents of the relative path of the pendulum, and the centrifugal force $M\rho(\varphi')^2$ in the direction of the radius vector. The total vertical force at the support is the sum of their vertical components. This total pressure is in practically all cases positive, directed downward, and thus contributes to the weight supported on the wheel.

The conclusion can be drawn that *whenever there are changes in the constant running conditions of a vehicle equipped with an oscillating axle, there will be a downwardly directed force exerted on the wheel.*

Special cases of the movement of an oscillating system can be discussed on the basis of the general equations if certain assumptions as to the time change of the outer forces are made.

SPECIAL CASE OF TRANSITION WITH VEHICLE AT REST

Among the special cases of transitions is one of particular interest where the translatory movement of the wheel center is blocked—as for instance when there is extraordinary resistance R_w preventing the movement of the wheel. Then the vehicle can be represented by a reduced system as shown in Fig. 9. In this case also the horizontal components of the inertia force become of importance.

Assuming the wheel to be at rest with $x = 0$, $x' = 0$, and $x'' = 0$, and neglecting the front-wheel resistance, the fundamental equations appear then in the form

$$\frac{R}{R'}P_c + M\rho(\varphi')^2\sin\varphi - M\rho\varphi''\cos\varphi = P_p \quad [5']$$

$$M\rho\varphi'' + Mg\sin\rho = P_c \quad [6']$$

Equation [6'] refers to the movement of the carrier system, while Equation [5'] gives the relation of forces at the wheel center.

From Equation [5'] it can be seen that in addition to the propelling force due to the applied engine torque there are two forces existing due to the swinging carrier mass, the horizontal component of one acting in the direction of the propelling force,

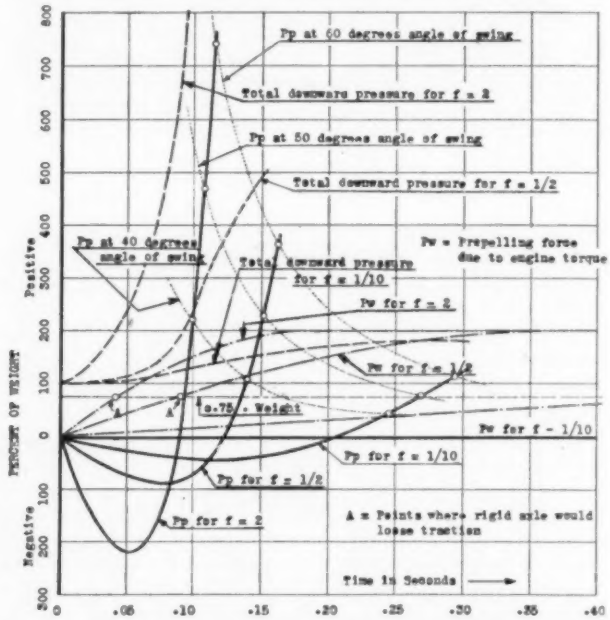

FIG. 10 TOTAL PROPELLING FORCE AND TOTAL DOWNWARD PRESSURE FOR DIFFERENT CLUTCH ENGAGEMENTS AS FUNCTIONS OF TIME

($P_c = 5Mg$; $f = a/a_m$.)

and the horizontal component of the other force in the opposite direction. The vertical components of the inertia forces $M\rho(\varphi')^2\cos\varphi$ and $M\rho\varphi''\sin\varphi$ are again downwardly directed, thus increasing the pressure on the ground due to the weight supported by the wheel.

The left-hand member of Equation [5'] determines the resultant propelling force. It is evident that a movement of the entire system cannot start before the resultant propelling force exceeds the resistance.

In order to determine the actual resultant propelling force, a time-change relation for the force P_c must be assumed. This is carried through in detail in the Appendix. The time change of the force P_c can be considered as representing the engagement of the clutch.

On this basis and for definite dimensions of the axle the total propelling force can be represented as a function of the time as is indicated in Fig. 10. This diagram shows that the resultant propelling force at the wheel center is negative at first and then increases through zero to positive values, which beyond a certain angle of swing becomes greater than the normal propelling force of the rigid axle. It shows further that the total downward pressure is greater than the weight at all times and, compared with the force P_w, which must be supported by the tire, will assure traction even for abnormally small coefficients of friction. The data appearing in this diagram invite an analysis of the various factors which influence the magnitude of the forces at the wheel center, but although interesting, such an analysis would extend this paper beyond its necessary limits.

For the preceding analysis it is assumed that the necessary relation of the planetary drive, as expressed by the formula $\omega_p r = \omega_c \rho$, is fulfilled, which will be true in practically all cases. Only in the event of an extremely great reduction in the power line would the relation of the angular velocities influence the forces at the wheel center.

Limitations of the Movement

Thus far the movement of the carrier has been considered unlimited, and in certain instances it would result in a rotary motion of the carrier with a periodically fluctuating angular velocity. Such an unlimited rotary motion would of course create inertia forces, of which the vertical as well as the horizontal components would be subjected to a periodical change. Since the vertical and horizontal components of the inertia forces must be positive in order to create favorable effects, the swinging movement of the carrier must be limited to approximately the first quadrant.

Practical reasons require a further limiting of the carrier swing, but since the additional propelling force, especially in starting, reaches greater values at greater angles, the angular limits for the movement should be extended as far as the construction permits.

It is unavoidable that under certain conditions the carrier encounters the limiting end stops. In order to keep the resulting impact force small, the elastic qualities of the end stops must be given full consideration. To obtain greatest flexibility the end stops are made of thick-walled rubber tubing and are supported in properly designed pockets. (Fig. 11.)

Starting

The previously detailed analysis makes it possible to discuss the process of starting an automotive vehicle equipped with an oscillating axle and differential drive, as compared with the starting of the same vehicle equipped with a conventional type of driving axle.

In order to start the movement of a vehicle, the circumferential force at the tire (or the propelling force at the wheel center) must be greater than the sum of all the resisting forces there. In a conventional type of vehicle with a positive connection between the power line and wheel, the required torque must be transmitted by the sliding clutch because of the fact that the engine delivers torque only above a certain minimum speed. In other words, the vehicle has to be started before the clutch can be fully engaged. If the torque required to start the movement of the vehicle is greater than the torque which can be transmitted by the sliding clutch, the engine will stall when the clutch is fully engaged.

It is a practice to start vehicles under difficult conditions by racing the engine and dropping in the clutch suddenly. Due to the inertia of the moving parts it is possible to exert momentarily more torque than the engine would provide continuously.

The torque that can be applied to the wheel is determined by the traction conditions. It is always possible, and in case of the "flywheel" start it is almost inevitable, that the applied torque exceeds the traction torque and causes wheel slippage.

On a vehicle with oscillating axle it is not necessary to slide the clutch and bring the vehicle to a start before fully engaging it. The entire starting process can be here subdivided into three periods.

The first of these periods has already been discussed. The torque, if the carrier stands in a vertical position, does not encounter any static resistance other than that of the front wheels, which because of the small load supported on the front

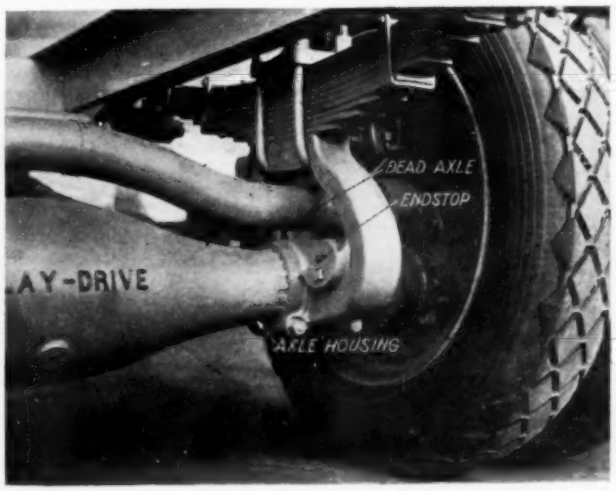

Fig. 11 Showing Axle Housing and End Stop

axle is negligible. The excess torque is consumed in accelerating the carrier (and with it the front portion of the vehicle), while the resisting weight component increases with the angle. It has been shown furthermore that while the carrier is swinging upward, inertia forces are built up, the vertical components of which press the wheel against the ground, while the horizontal components apply additional propelling forces to the wheel.

The second period of the starting begins when the sum of all the propelling forces overcomes the static resistances. The wheel begins to move—the carrier decelerates relatively to the wheel center and finally reverses its movement, and the vehicle and the wheel system then perform horizontal oscillations about the common center of gravity. These fluctuations of energy from one member to the other will, by virtue of the damping in the mechanism, die out after some time, and the third period, the constant running position, will begin.

The most important feature in the starting of a vehicle of this type is the fact that wheel slippage is practically eliminated. Because of the vertical components of the inertia forces caused by the up-swinging mass the weight utilized for traction is considerably increased, and only in exceptional cases will the applied torque exceed the available traction. Because of the additional propelling force, the vehicle with the oscillating axle can be started with a smaller amount of engine torque, and accordingly with less circumferential force on the tire.

To illustrate the difference between the two systems in starting, the following test was made. A motor truck equipped with an oscillating axle with differential drive was started on a soft sand bed. Then the oscillating action of the axle was blocked (thus making the differential drive a positive internal-gear drive) and the truck was started on the same ground. In both cases there was just enough power applied to put the vehicle in motion.

The tracks as photographed are shown in Fig. 12. The difference between these two tracks is obvious and substantiates the results previously deduced.

Encountering an Obstruction While Running

Any wheel when encountering an obstruction has a tendency to leave the ground, or at least to reduce its pressure on the ground to some extent, and in such a case the applied engine torque may not develop sufficient traction, thus causing the wheel to speed up while slipping or spinning freely. When this wheel regains traction after the impact, it will have a circumferential velocity which is different from the vehicle speed. This difference in speed imposes a torsional impact on the wheel, which in most cases causes the tire to slip.

If the wheel of a vehicle with an oscillating axle strikes an obstruction in the road the two systems—carrier and wheel—will begin to oscillate about the oscillation center. Since such an oscillation always accelerates the common center of gravity of both systems in the vertical direction, it is evident that the reaction of the accelerating force will press the wheel with an increased force against the ground. The increased pressure forcing the wheel downward counteracts the uplifting impact force. In practically all cases, therefore, the wheel of an oscillating axle will not lose traction in going over an obstruction, and thus will prevent the spinning of the tire on the road.

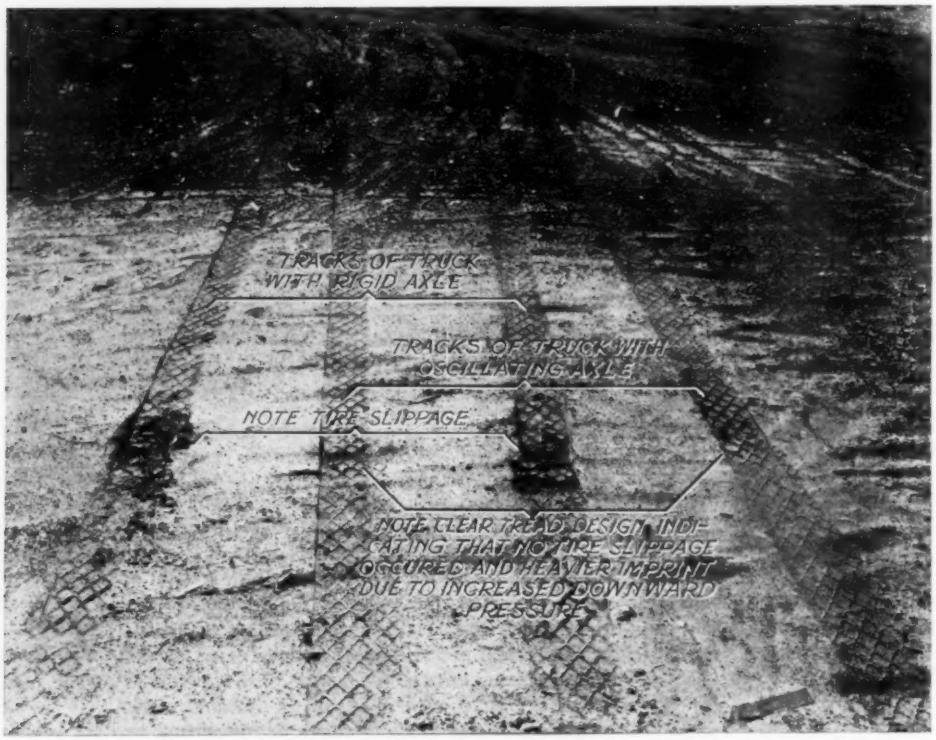

Fig. 12 Tracks Made by Tires of Truck With Rigid Axle and Truck With Oscillating Axle

Effects of Braking Upon an Oscillating Axle

When the brakes are applied to an oscillating axle, the effect is as though the carrier had been momentarily clamped to the wheel with an adhesion proportional to the braking force. This momentary fixed connection between carrier and wheel will become a sliding contact when either the weight component overcomes the brake adhesion or, as is more often the case, when the end stop is encountered.

Since the wheel is forced to follow the road, the common movement of wheel and carrier will result in an elevation of the center of gravity. In addition, the wheel is accelerated and the front portion decelerated during this period.

It is true that in this first period of braking no energy is consumed by the brakes, but the elevation of the center of gravity transforms a part of the kinetic energy of the vehicle into potential energy before the action of the brake begins. The amount of kinetic energy transformed into potential energy depends on the height to which the center of gravity is lifted, and for this reason it is desirable to extend the arc of the pendulum swing as far as the construction will permit.

It may therefore be stated that application of the brake to the oscillating axle will reduce the vehicle speed to a certain extent before the sliding action between brake shoe and drum takes place.

Summary

In recapitulation, it may be stated that the following definite effects have been determined as the result of the application of a differential drive to an oscillating axle:

1 By means of the differential drive, torque can be momentarily applied to the wheel without turning it, this gives the effect of a second clutch in the power line in which no energy is destroyed

2 The oscillating axle, by providing an elastic connection between the power line and rear wheel, cushions the torsional impacts that would be encountered with a rigid axle

3 Whenever there are changes in the running conditions of the vehicle, fluctuations of energy between the rear-wheel assembly and vehicle body take place; the reaction forces of these fluctuations provide an increased pressure against the ground

4 By virtue of the fluctuation between the rear-wheel assembly and the vehicle body, an additional accelerating force as well as an additional downward pressure is applied to the driving wheels in starting

5 Due to the transformation of part of the kinetic energy of the moving vehicle into potential energy, an additional retarding force is provided when the brakes are applied.

Appendix

THE OSCILLATING AXLE SYSTEM

THE vehicle with an oscillating rear axle has been reduced to the system shown in Fig. 13. For the calculation two independent coordinates are introduced, one linear, in the horizontal direction, called x and the other the angle φ the arm OC makes with the vertical direction.

In the system shown the mass m represents the mass of the parts of the rear axle which can swing relatively to the vehicle, while the mass M_1 represents the mass of the weight supported on the rear axle and M_2 the mass of the weight on the front axle. The mass m is assumed to be concentrated at the center O of the rear wheel, M_1 at the end of the arm in point C, and M_2 at the center of the front wheel. It is in the nature of the problem that the movement of m and M_2 is restricted to a horizontal path.

To deduce the equations of the movement of this system it is necessary to employ Lagrange's equations.

$$F_z = \frac{d}{dt}\left(\frac{\partial L}{\partial x'}\right) - \frac{\partial L}{\partial z}$$

The derivatives of the coordinates are to be represented as follows:

$$\frac{dx}{dt} = x'; \quad \frac{d^2x}{dt^2} = x''; \quad \frac{d\varphi}{dt} = \varphi' = \omega; \quad \frac{d^2\varphi}{dt^2} = \varphi'' = \epsilon$$

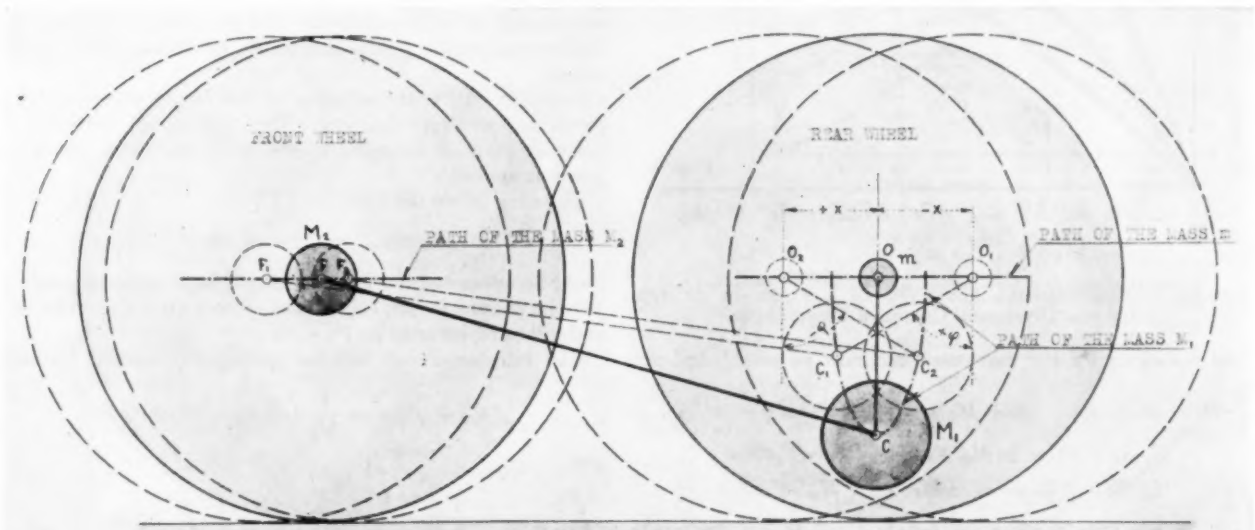

FIG. 13 DIAGRAMMATIC REPRESENTATION OF VEHICLE WITH OSCILLATING DRIVING AXLE

To make use of Lagrange's equations, however, an expression for the kinetic energy of the system must be first established.

The kinetic energy belonging to x can be expressed as

$$L_x = \frac{1}{2}m(x')^2$$

For the kinetic energy belonging to φ, both the velocity of the translatory motion x' and the circumferential velocity of the rotary motion $\rho\varphi'$ must be considered. These two components give a resultant velocity

$$V_\varphi^2 = (x')^2 + \rho^2(\varphi')^2 + 2\rho\varphi' x' \cos\varphi$$

Due to the fact that the mass M_2 is forced to travel in a horizontal path and the mass M_1 in a circular path, the kinetic energy belonging to φ will consist of two components, one in horizontal direction, namely,

$$L_{\varphi h} = \frac{1}{2}(M_1 + M_2)V_\varphi^2 \cos^2\varphi$$

and one in vertical direction,

$$L_{\varphi v} = \frac{1}{2}M_1 V_\varphi^2 \sin^2\varphi$$

The total kinetic energy of the system will therefore be

$$L = L_x + L_{\varphi h} + L_{\varphi v}$$

$$= \frac{1}{2}m(x')^2 + \frac{1}{2}(M_1 + M_2\cos^2\varphi)V_\varphi^2$$

or

$$L = \frac{1}{2}m(x')^2 + \frac{1}{2}M_1(x')^2 + \frac{1}{2}M_2\cos^2\varphi(x')^2 + \frac{1}{2}(M_1 + M_2\cos^2\varphi)\rho^2(\varphi')^2 + (M_1 + M_2\cos^2\varphi)\rho x'\varphi'\cos\varphi$$

If finally M_φ is substituted for $(M_1 + M_2\cos^2\varphi)$, the total kinetic energy of the system will be represented by:

$$L = \frac{1}{2}(m + M_\varphi)(x')^2 + \frac{1}{2}M_\varphi\rho^2(\varphi')^2 + M_\varphi\rho\varphi' x'\cos\varphi$$

For Lagrange's equations the following differential quotients are required:

$$\frac{\partial L}{\partial x'}; \quad \frac{d}{dL}\left(\frac{\partial L}{\partial x'}\right); \quad \frac{\partial L}{\partial x}$$

$$\frac{\partial L}{\partial \varphi'}; \quad \frac{d}{dt}\left(\frac{\partial L}{\partial \varphi'}\right); \quad \frac{\partial L}{\partial \varphi}$$

These as developed from the equation for L are:

$$\frac{\partial L}{\partial x'} = (m + M_\varphi)(x') + M_\varphi\rho\varphi'\cos\varphi$$

$$\frac{d}{dt}\left(\frac{\partial L}{\partial x'}\right) = (m + M_\varphi)(x'') + M_\varphi'\varphi' x' + M_\varphi\rho\varphi''\cos\varphi + M_\varphi'\rho(\varphi')^2\cos\varphi - M_\varphi\rho(\varphi')^2\sin\varphi$$

$$\frac{\partial L}{\partial x} = 0$$

$$\frac{\partial L}{\partial \varphi'} = M_\varphi\rho^2\varphi' + M_\varphi\rho x'\cos\varphi$$

$$\frac{d}{dt}\left(\frac{\partial L}{\partial \dot{L}}\right) = M_\varphi \rho^2 \varphi'' + M_\varphi' \rho^2 (\varphi')^2 + M_\varphi \rho x'' \cos\varphi + M_\varphi' \rho \varphi' x' \cos\varphi - M_\varphi \rho \varphi' x' \sin\varphi$$

$$\frac{\partial L}{\partial \varphi} = \frac{1}{2}(x')^2 M_\varphi' + {}^1/_2 M_\varphi' \rho^2 (\varphi')^2 + M_\varphi' \rho \varphi' x' \cos\varphi - M_\varphi \rho \varphi' x' \sin\varphi$$

The outer forces to be introduced in Lagrange's Equations are according to Equations [1] and [2] of the paper are

$$F_x = \frac{R}{R'} P_c - R_w - R_c \quad \ldots\ldots\ldots\ldots\ldots [1]$$

and

$$F_\varphi = (P_c - Mg \sin\varphi - R_c \cos\varphi)\rho \quad \ldots\ldots\ldots [2]$$

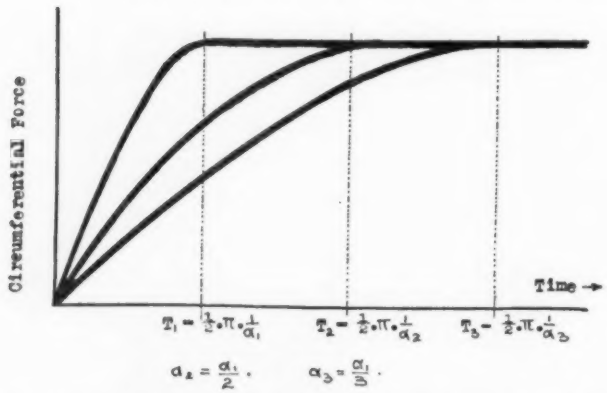

FIG. 14 CIRCUMFERENTIAL FORCE P_c AS A FUNCTION OF THE TIME FOR DIFFERENT CIRCULAR FREQUENCIES

The equations for the movement can now be established as:

$$\frac{R}{R'} P_c - R_w - R_c = (m + M_\varphi)x'' + M_\varphi \rho \varphi'' \cos\varphi - M_\varphi \rho (\varphi')^2 \sin\varphi + M_\varphi' x' \varphi' + M_\varphi' \rho (\varphi')^2 \cos\varphi \quad \ldots\ldots [3]$$

$$\rho(P_c - M_1 g \sin\varphi - R_c \cos\varphi) = M_\varphi \rho^2 \varphi'' + M_\varphi' \rho x'' \cos\varphi + M_\varphi' (\rho')^2 \rho^2 - \frac{1}{2}(x')^2 M_\varphi' - \frac{1}{2} M_\varphi' \rho^2 (\varphi')^2 \quad \ldots\ldots [4]$$

For a simpler discussion of these general equations of the movement of the system the front-wheel mass may be neglected. The equations then appear in the form:

$$\frac{R}{R'} P_c - R_w - R_c = (m + M)x'' + M_\rho \varphi'' \cos\varphi - M_\rho (\varphi')^2 \sin\varphi \quad \ldots\ldots [3']$$

$$P_c - Mg \sin\varphi - R_c \cos\varphi = M_\rho \varphi'' + Mx'' \cos\varphi \quad \ldots\ldots [4']$$

Here M stands for the mass of the weight which is supported on the axle. The equations describe the oscillations of the two-mass system, consisting of the masses m and M, where m is forced to follow a horizontal path while M is forced to keep at a constant distance from m under the influence of variable outer forces P_c, R_w, R_c, and Mg.

For the wheel at rest with $x = 0$, $x' = 0$, and $x'' = 0$, Equations [3] and [4] take the following forms:

$$\frac{R'}{R} P_c + M_\varphi \rho (\varphi')^2 \sin\varphi - M_\varphi \rho \varphi'' \cos\varphi + M_\varphi' \rho (\varphi')^2 \cos\varphi = P_p \quad \ldots\ldots [5]$$

$$M_\varphi \rho \varphi'' + M_\varphi' (\varphi')^2 \rho - \frac{1}{2\rho} M_\varphi' \rho (\varphi')^2 + M_1 g \sin\varphi = P_c - R_c \cos\varphi \quad \ldots\ldots [3]$$

To facilitate the discussion of Equations [5] and [6] the factor R_c, representing the front-end resistance, may be neglected in view of the magnitude of the other factors. Furthermore the front mass M_2 may be neglected also, which, introducing M as the mass which is supported on the axle, brings [5] and [6] to the forms:

$$\frac{R}{R'} P_c + M\rho(\varphi')^2 \sin\varphi - M\rho\varphi'' \cos\varphi = P\rho \quad \ldots\ldots [5']$$

$$M\rho\varphi'' + Mg \sin\varphi = P_c \quad \ldots\ldots [6']$$

Equation [6'], referring to the carrier system, describes a forced oscillation of a pendulum, while Equation [5'] gives the relation of the forces at the wheel center.

From Equation [5'] it can be seen that in addition to the propelling force due to the applied engine torque there are two forces existing due to the swinging carrier mass; the horizontal component of one of these acts, for starting conditions, in the direction of the propelling force, while the horizontal component of the other force is in the opposite direction. The vertical components of both forces are directed downward, thus increasing the pressure on the ground due to the weight supported by the wheel.

Equation [6'] is the equation of the forced movement of a pendulum without damping. The disturbing function P_c must be assumed according to the conditions under which the power is applied.

Equation [6'] in the form

$$M\rho\varphi'' = P_c - Mg \sin\varphi$$

could be integrated if P_c were a known function of the angle φ. For the present P_c will be assumed to be a known function of φ and will be represented by $P_c = f(\varphi)$.

The integration can now be symbolically carried through:

$$\varphi'' d\varphi = \varphi' d\varphi' = \frac{1}{M\rho}[f(\varphi)d\varphi - Mg \sin\varphi \, d\varphi]$$

and

$$\int_{\varphi_0'}^{\varphi'} \varphi' d\varphi' = \frac{1}{2}[(\varphi')^2 - (\varphi_0')^2] = \frac{1}{M\rho}\left[\int_{\varphi_0}^{\varphi} f(\varphi)d\varphi - Mg(\cos\varphi_0 - \cos\varphi)\right]$$

For $\varphi_0 = 0$ and $\varphi_0' = 0$ this equation reduces to

$$(\varphi')^2 = \frac{2}{M\rho}\left[\int_0^{\varphi} f(\varphi)d\varphi - Mg(1 - \cos\varphi)\right]$$

The left-hand member of Equation [5'] represents the total horizontal or propelling force P_p:

$$P_p = \frac{R}{R'} P_c + M\rho(\varphi')^2 \sin\varphi - M\rho\varphi'' \cos\varphi$$

Introducing the values for φ'', $(\varphi')^2$ and P_c into this equation gives the following expression for the total propelling force:

$$P_p = \frac{R}{R'} f(\varphi) + 2\left\{\int_0^{\varphi} f(\varphi)d\varphi - Mg(1 - \cos\varphi)\right\}\sin\varphi - \left\{f(\varphi) - Mg \sin\varphi\right\}\cos\varphi \quad \ldots\ldots [8]$$

In order to determine the unknown function $P_c = f(\varphi)$, it is necessary to assume a time relation of the circumferential force

TABLE 1

$\varphi = \frac{P_0}{M \cdot g \cdot (1-f^2)} \cdot [\sin(f \cdot \alpha_n \cdot t) - f \cdot \sin\alpha_n \cdot t] = 6.667 \cdot I$:

$P_0 = 5 \cdot M \cdot g$: $\alpha_n = 8.72$: $f = 1/2$: $(1-f^2) = 0.750$:

t	0.04	0.06	0.08	0.10	0.12	0.14	0.16	0.18	0.20

P_c. This relation, which for the practical case on which the problem is based, represents the torque-time relation of the clutch engagement, can be described closely enough by a quarter of a sine curve, or

$$P_c = P_0 \sin(\alpha t)$$

where α represents the circular frequency and t the time.

For the following calculation the further assumption will be

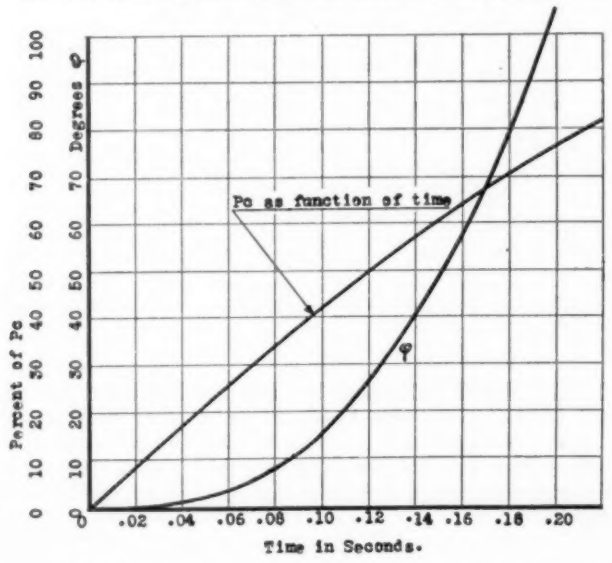

FIG. 15 P_c AND ANGLE φ AS FUNCTIONS OF TIME

made that no impact torque shall result from the clutch engagement.

Fig. 14 shows diagrammatically the different force-time relations for variable circular frequency. It is further necessary to establish a time relation for the angle φ. For this purpose Equation [6'] can be put into the following form:

$$M \frac{d^2\varphi}{dt^2} - M\varphi \frac{g}{\zeta} = \frac{P_0}{\rho} \sin(\alpha t) \ldots\ldots\ldots\ldots [9]$$

This equation is an approximation, since $\sin \varphi$ is replaced by the angle φ. This is the equation of a forced oscillation, the solution of which is given by

$$\varphi = \frac{P_0/\rho}{M(\alpha_n^2 - \alpha^2)} [\sin(\alpha t) - \frac{\alpha}{\alpha_n} \sin(\alpha_n t)] \ldots\ldots [10]^2$$

where $\alpha_n = \sqrt{g/\rho}$ = natural circular frequency. Introducing this equivalence into [10] gives:

[2] Dr. L. Geiger in "Mechanische Schwingungen."

$$\varphi = \frac{P_0}{Mg\left[1 - \left(\frac{\alpha}{\alpha_n}\right)^2\right]} \left[\sin(\alpha t) - \frac{\alpha}{\alpha_n} \sin(\alpha_n t)\right]$$

or, substituting f for α/α_n,

$$\varphi = \frac{P_0}{Mg(1-f^2)} [\sin(f\alpha_n t) - f \sin(\alpha_n t)] \ldots\ldots [11]$$

To carry the calculations further it may be best to deal with a special case, for which definite assumptions as to the dimensions and the factor f must be made. This factor represents

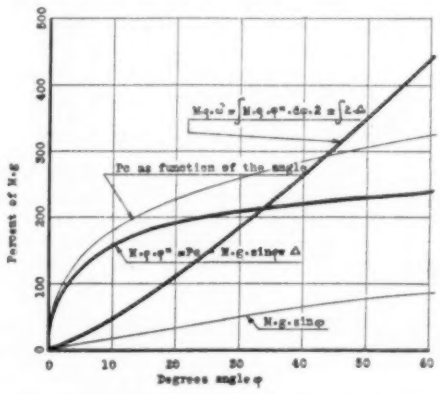

FIG. 16 DETERMINATION OF THE INERTIA FORCES ($f = 0.5 = \alpha/\alpha_n$.)

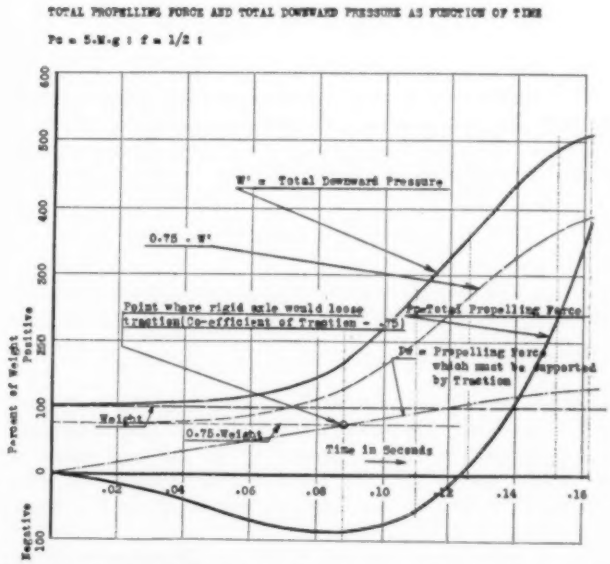

FIG. 17 TOTAL PROPELLING FORCE AND TOTAL DOWNWARD PRESSURE AS FUNCTIONS OF TIME ($P_c = 5Mg$; $f = 0.5$.)

the ratio of the imposed circular frequency to the natural circular frequency.

In the following calculations f is given the value 0.5, i.e., the harmonic application of torque to the mechanism is one-half the natural period of the pendulum. It is further assumed that $\rho = 5.18$ in. and $P_0 = 5\,Mg$. With these assumptions different values for the angle φ in relation to the time have been calculated and are given in Table 1.

The values of the angle φ as a function of time are plotted in Fig. 15, as well as the corresponding values of P_c. With the re-

sults obtained thus far it is possible to represent the circumferential force P_c as function of the angle. This is done graphically in Fig. 16.

With P_c as a known function of the angle φ it is possible to solve the integral in Equation [8]. The two inertia forces acting at the wheel center can be expressed as:

$$I_1 = M\rho(\varphi')^2; \quad I_2 = M\rho\varphi''$$

The calculation of these inertia forces under the previously stated assumption is carried through graphically, Fig. 16 being also used for this purpose. The total propelling force P_p is made up of the propelling force due to the engine torque and the horizontal components of the inertia forces:

$$P_p = \frac{R}{R'} P_c + M\rho(\varphi')^2 \sin\varphi - M\rho\varphi''\cos\varphi$$

The total downward pressure also comprises three members: the weight and the vertical components of the inertia forces; or

$$W' = Mg + M\rho(\varphi')^2 \cos\varphi + M\rho\varphi'' \sin\varphi$$

Under the assumption that R/R', the ratio of the track-gear pitch radius to the wheel radius, is 0.4, the total propelling force P_p and the total downward pressure W' for different values of the angle ρ are as given in Table 2. In figuring the total downward pressure in this table the weight Mg of the wheel assembly has been neglected.

Fig. 17 presents the values in Table 2 in diagrammatic form, and discloses fully the effect of the oscillating axle with power drive for the conditions previously assumed. The force P_w must be supported by the traction of the wheel. Assuming a tractor coefficient of 0.75, it is apparent from the diagram that in the case of the rigid axle, where only the full weight is available for traction, the force P_w becomes greater than the traction long before the full torque is applied and therefore the wheel will slide. In the case of the oscillating axle, however, where the total downward pressure W' is available for traction, the force P_w never reaches the limiting value and the wheel will not slide.

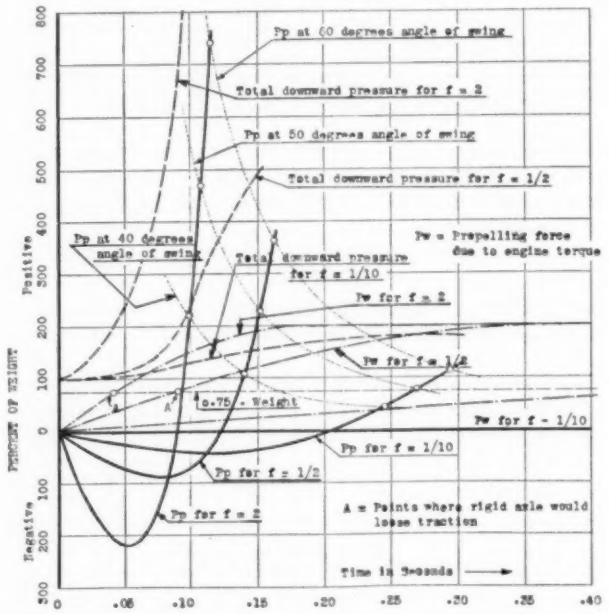

FIG. 18 TOTAL PROPELLING FORCE AND TOTAL DOWNWARD PRESSURE FOR DIFFERENT CLUTCH ENGAGEMENTS AS FUNCTIONS OF TIME

($P_c = 5Mg$; $f = a/\alpha_n$.)

Fig. 17 reveals furthermore the interesting fact that while at first the propelling force is negative, with an increased angle it later has positive values. The inclusion of the normal propelling force, i.e., the propelling force of a vehicle with rigid axle and drive, makes apparent the increased propelling force in starting.

Fig. 18 shows the total propelling force and total downward pressure for the same assumed vehicle based on different values of the factor f, and therefore for different clutch engagements.

For the preceding analysis it has been assumed that the necessary relation of the planetary drive, as expressed by the formula

$$\omega_p r = \omega_c \rho$$

is fulfilled, which will be true in practically all cases. Only in the event of extremely great reductions in the power line would the relation of the angular velocities influence the inertia forces at the wheel center.

APM-52-7

Crankless Reciprocating Machines

By ANTHONY G. M. MICHELL,[1] NEW YORK, N. Y.

The general features and properties of the crankless type of reciprocating machine, as compared with the crank-connecting-rod type, are described and illustrated. A few varieties of the crankless type are briefly described, including the author's slant-slipper form of the mechanism. The limitations of the crank type are pointed out and it is suggested that mechanical science is due to supply a type of machine for various present and probable future applications not efficiently served by either purely rotary machines or reciprocating machines of the crank type. A case is presented for the crankless type as satisfying this need.

WHILE the name "Crankless Reciprocating Machines" is not a quite accurate title for the subject matter of this paper, it has to be used in the absence of a better. It is intended to cover both prime movers and driven machines in which the reciprocating motion of pistons is interconverted with the rotary motion of a shaft without the use of cranks. But according to common and convenient usage the term is restricted to machines in which the motion of the pistons is parallel to the axis of the shaft.

The Crank and Crankless Types of Engines

The most fundamental distinction between a crankless engine, so defined, and a crank engine of the familiar type, is that the crank engine has a two-dimensional mechanism, while the crankless engine has a three-dimensional mechanism. That is to say, the essential parts of the crank engine move only in one or more planes at right angles to the axis of the engine shaft. In the crankless engine, on the contrary, motions of essential parts take place in all three of the coordinate directions of space. Another broad and significant difference in the two types of mechanism is seen when we compare multicylinder machines of each class. The typical crankless engine is an essentially symmetrical construction. Each cylinder, or piston, is geometrically indistinguishable from its fellows as regards its relation to them and to the mechanism. For this reason, crankless engines are sometimes referred to as "round engines" or "barrel engines." The crank-connecting-rod engine on the contrary is essentially a linear, or serial, arrangement, and has at most a bilateral symmetry. These differences are immediately apparent on comparison of Figs. 1 and 2, which show respectively the essential moving parts of a typical multicylinder crank-connecting-rod engine and of a crankless engine with the same number of pistons, namely, eight in each case.

We can, and often do, speak in the case of the crank-connecting-rod engine (Fig. 1) of the first, second, or third piston, or the nth piston from the front or rear end. The motion of any such piston is independent of that of each of the others in so far as it may be given any desired phase relation to those of the others by setting the crank corresponding to that particular piston at an appropriate angle.

In the typical crankless engine, on the contrary (Fig. 2), the several pistons are as truly indistinguishable from each other as the several blades of a turbine wheel, and the sequence and phases of the motions of the several pistons are unalterably determined.

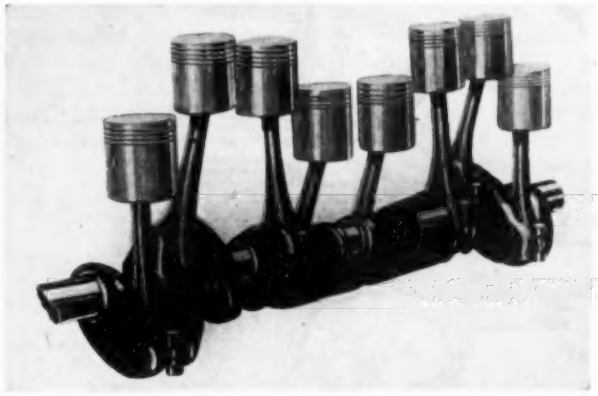

Fig. 1 Essential Moving Parts of a Typical Multicylinder Crank-Connecting-Rod Engine

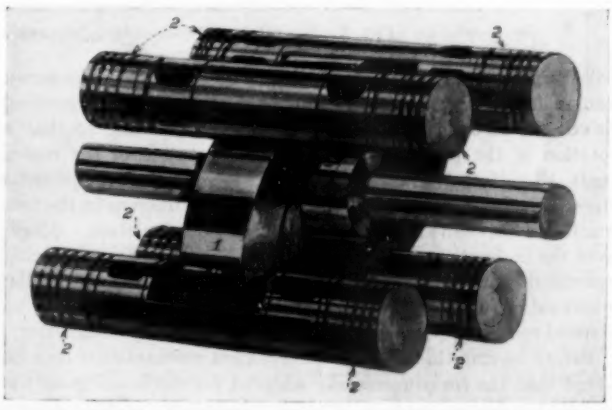

Fig. 2 Essential Moving Parts of a Crankless Engine Having the Same Number of Pistons as the Engine Shown in Fig. 1

Figs. 3, 4, and 5 show respectively three crankless machines, and illustrate three typical forms of crankless construction.

Numerous as are the forms of the crankless mechanism which have been proposed, designed, and patented, many of them extremely ingenious and interesting, these three illustrations cover, so far as the author knows, the only three species of crankless engines which are, or have been, in successful use.

The Ball-Race Type of Crankless Mechanism

Fig. 3 was the first design of the three to be perfected. It represents the well-known "Janney," "Williams," or "Waterbury" transmission mechanism.

[1] Michell Crankless Engines Corporation. Mr. Michell is an Australian engineer, whose academic training was commenced at Cambridge and completed at Melbourne. His engineering work has consisted chiefly in designing and superintending water-supply, irrigation, and hydroelectric power undertakings in Australia and in developing new types of machine elements depending on the Reynolds principle of lubrication. He is the author of several papers published in various European journals in which hydrodynamics and the theory of elasticity are applied to engineering problems.

Presented at a meeting of the Metropolitan Section of the A.S.M.E., New York, April 19, 1929.

Substantially the same machine serves either as a pump or as a prime mover. Regarded as a pump, the rotating shaft 12 carries with it the ring 20, and the stationary inclined ball race 21, upon which the ring 20 rotates, compels the ring to travel in an inclined plane relatively to the shaft. Thus the outer ends of the connecting rods 19 are brought alternately in each revolution nearer to and farther away from the cylinder barrel 15, which comprises an annular series of cylinders such as 15a, containing corresponding pistons such as 18, each attached to the upper end of a rod 19. During one half of the rotation around the race 21, the pistons move outward and draw liquid into the cylinders, while during the other half they move inward and discharge the liquid under pressure, suitable valve action being assumed.

An almost exactly similar mechanism, which indeed may form a twin and attached counterpart of the pump, as at 11 in Fig. 3,

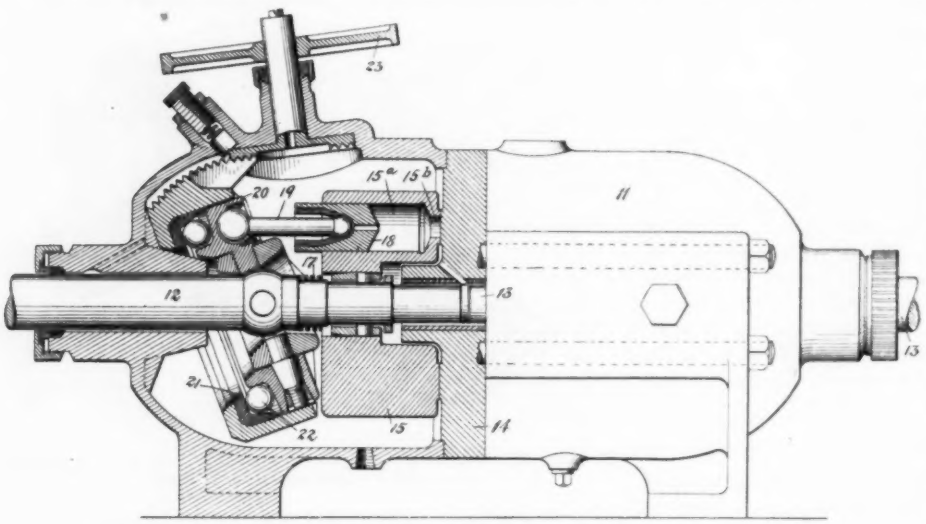

FIG. 3 BALL-RACE TYPE OF CRANKLESS MECHANISM

will function as a motor. The delivery and intakes of the pump and motor being reciprocally interconnected, the first machine drives the second through the medium of the fluid, so that a rotation of the pump shaft 12 causes a rotation of the motor shaft 13. If the pump and motor cylinders are of different sizes, or if the inclinations of the races 21 are different in the two machines, the shafts may have any desired speed relation. Moreover the inclination of the race 21 may be changed, even during operation, with an instantaneous corresponding change of the speed ratio, so that the combined machine serves not merely as a speed-reducing, but as a variable speed-reducing, transmitter.

Before leaving this form of the crankless mechanism it may be noted that the form necessarily adopted for the bearings at the ends of the connecting rods 19, while excellent for exerting a compression in the rod to resist the pressure in the fluid, would be quite unsuitable if there were considerable tension in the rods, such as would arise from inertia effects if the speed were high. The ball race 21, which is necessarily of a considerable diameter, is also only suitable for comparatively low speeds of rotation. This form of mechanism is therefore only suitable for machines operating at relatively low speeds.

THE WABBLE-PLATE TYPE OF CRANKLESS MECHANISM

Another practical form of the crankless mechanism is that shown in Fig. 4, the machine illustrated being the "Ali" two-stroke gasoline engine in use as an "outboard" boat engine. Allied forms go under the name of "Arvad engine" and other names. The cylinders 1, which contain the pistons 2 reciprocating in the vertical direction, are in this case stationary while the shaft 3, also vertical, revolves. Each piston is rigidly connected with a scavenge-air piston 4, working in the cylinder 5. Between the power cylinders and the pump cylinders lies the plate 6, which merely "wabbles" or nutates but does not rotate. A ball member 7, fixed to the plate, is socketed in the block 8 which is mounted in the piston unit and is capable of a small extent of transverse motion with respect to it. Thus the nutating motion of the plate corresponds with reciprocating motions of the various pistons in successive phases. Now the plate 6 is mounted by means of a pair of ball bearings, of the combined thrust and journal type, on a flanged collar mounted obliquely on the shaft. Thus as the shaft rotates, the plate, which is prevented from rotating by the ball-and-socket attachments to the pistons, is compelled to execute its nutating motion and so causes the pistons to reciprocate. Conversely, reciprocation of the pistons, compelled to take place in due sequence by their engagement with the plate, causes the latter to nutate and the shaft to revolve. The somewhat unfamiliar type of motion of the nutating plate can be readily followed and calculated when it is observed that its instantaneous motion at every instant is a rotation about an axis which is radially at right angles to the axis of the shaft, and in the same radial plane as the line of greatest inclination of the plate.

The angular velocity of rotation about this axis is, in fact, $\omega \tan \alpha$, where ω is the angular speed of the engine shaft, and α the inclination of the plate.

This nutating motion of the plate with respect to the pistons and frame of the engine may be called a uniform conical nutation, and is of course a three-dimensional motion. Relatively to the shaft, however, it is merely a pure rotation about an axis inclined to the shaft.

It is clear that the point of intersection of the axis of each piston with the central plane of the nutating plate reciprocates with a pure sinusoidal or harmonic motion. The piston itself, however, does not reciprocate in unison with this point of intersection, but with the axial coordinate of the center of the ball 7, which has an arcual and not a linear motion. The motion of the piston therefore deviates somewhat from a true harmonic motion.

Similarly in the Waterbury mechanism, since the radial distance from the shaft axis to the center of the outer ball ends of the connecting rods 19 varies as they traverse their inclined path, the rods 19 take up progressively varying inclinations to the shaft, and the reciprocating motion of the pistons differs somewhat from the true harmonic.

It will be noticed that in both the Ali and the Janney mechanisms there are three relatively moving parts interposed between the shaft and each piston: namely, in the Ali mechanism the ball race, the nutating plate, and the sliding block; and in the Janney mechanism, the ball race, the oblique plate, and the connecting rod. In the Ali engine the ball race is relatively of much smaller diameter than in the Janney gear, and the Ali sliding block, unlike the Janney connecting rod, is equally adapted to carry loads in both directions. The Ali engine is therefore better adapted to run at the high speeds of a multicylinder internal combustion engine than is the Janney mechanism. The load

limitations of the ball bearing in the Ali mechanism, however, seem to limit its use to engines of comparatively small size. Within its limits of application its mechanical efficiency should be very high.

The Slant-Slipper Type of Crankless Engine

The third of the three types of crankless engines which have been mentioned as having reached the stage of actual application is that which the author's own associates have developed.

Fig. 2, as already shown, illustrates one example of it. An outline view of the mechanism is shown in Fig. 5. From this

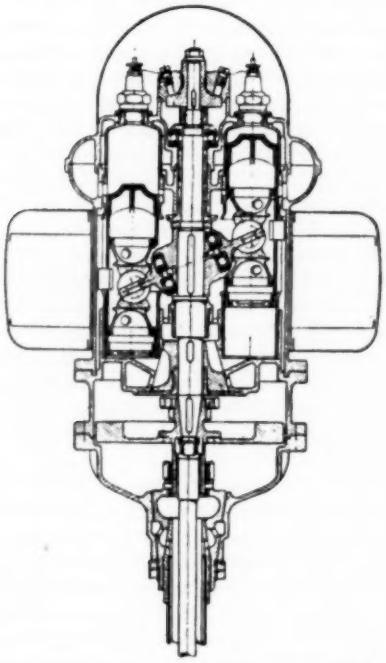

Fig. 4 "Wabble"-Plate Type of Crankless Mechanism

view it will be seen that the shaft has rigidly and permanently mounted upon it an oblique, plane-sided plate 1, which is called the "slant." It has been given this distinctive name since it is not a nutating plate, or "wabble" plate, like the oblique plates in the other two types. It has no other motion than a rotation in common with the shaft. From the slant, motion is transmitted to each of the pistons 2 by a slipper element 3, which serves the purposes of all three of the intermediate elements in the Ali, or in the Janney, mechanism.

Three views of a typical slipper are shown in Fig. 6. It has two bearing faces: a spherical face on one side and a flat face on the other. The spherical face fits into a socket formed in the piston. The flat face makes sliding contact with the flat face of the slant. By means of its spherical support in the piston, the slipper is enabled to follow the continually varying aspects of the inclined face of the slant as the latter revolves; the plane face of the slipper effecting, in fact, a uniform nutating motion of exactly the same kind as the motion of the nutating plate of the Ali engine. During its motion the center of the ball joint remains at a fixed point in the axis of the piston, and at a constant axial distance from the plane surface of the slant. The reciprocating motion of the piston is consequently truly sinusoidal or harmonic.

When in a multicylinder engine several such piston elements are arranged at equal angular intervals around the slant, there is a constant difference of phase between the motion of each piston and that of each of its neighbors.

Usually the piston elements are double, as seen in Fig. 7, pistons on each side of the slant having a common axis and being rigidly connected together by means of a bridge piece 4. A slipper 3 is socketed in each piston so as to effect both strokes of the complete reciprocating unit.

The success of such a mechanism evidently depends on the possibility of the relative sliding motion of the slant and slippers taking place with a minimum amount of friction. Particularly, if the pistons are to drive the shaft, the mechanism being employed as a motor, one recognizes instinctively that the machine would fail to run, or run very inefficiently, if the coefficient of friction of the slipper and plate had ordinary, every-day values.

The solution of the problem lies in the application of the Reynolds theory of lubrication, and the ball-socketed form of slipper which already has been described effects the application. As shown in Fig. 6, the ball is located unsymmetrically with respect to the flat face, to the extent of about one-tenth of the length of the slipper in the direction of the relative sliding motion of the slant. The effective point of application of the load on the slipper is of course the center of the ball. The slipper is thus enabled to function in the same way as the pads of the pivoted type of thrust bearings, which are well known in this country as Kingsbury bearings and which bear the name of the author in Europe. The coacting surfaces require of course an ample supply of lubricant of a viscosity suitable for the

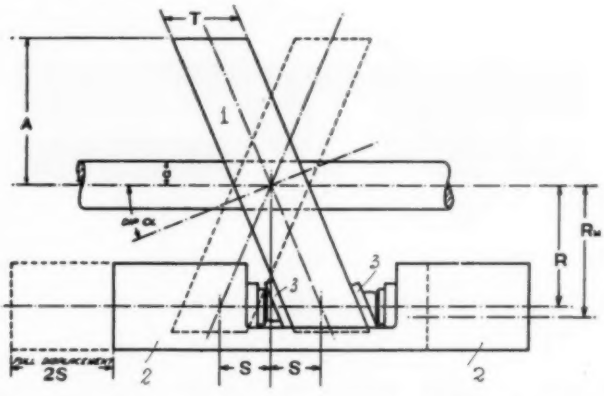

Fig. 5 Slant-Slipper Type of Crankless Mechanism Shown in Outline

ruling conditions of load and speed. With such provision, experience confirms calculation as showing that the coefficient of sliding friction can be extremely low, 0.0015 or 0.002 being usual values. As a result, the mechanism is enabled to operate with quite high efficiency and with practically the same efficiency, whether utilized as a motor or as a pump. The mechanism is regarded as operating as a motor when power applied to the pistons is transmitted through the slant-and-slipper mechanism to rotate the shaft, and as operating as a pump when power applied to rotate the shaft is transmitted through it to cause reciprocating motion of the pistons. Whichever is the direction of power transmission, some energy is of course lost in the frictional resistances of the mechanism; but if the angle of inclination of the slant to the shaft is not too nearly a right angle, such loss of energy in the crankless mechanism is small, and nearly the same in both cases. The crankless mechanism thus conforms to the rule that an efficient mechanism is reversible or, rather, is interconvertible, as motor or "movend;" and conversely, the practical demonstration that one of these machines is in this sense readily reversible is proof that it is mechanically efficient.

To illustrate by symbols: If μ is the coefficient of friction, and θ the inclination of an element of the slant over which sliding is

momentarily taking place, the efficiency operating as a motor is readily shown to be $E_M = 1 - \mu (\tan \theta + \operatorname{ctn} \theta)$; while the efficiency as a pump is

$$E_p = \frac{1}{1 + \mu (\tan \theta + \operatorname{ctn} \theta)}$$

Expanding the latter expression as

$$E_p = 1 - \mu (\tan \theta + \operatorname{ctn} \theta) + \mu^2 (\tan \theta + \operatorname{ctn} \theta)^2 - \mu^3 (\tan \theta + \operatorname{ctn} \theta)^3$$

we see that the efficiency as a motor is less than that as a pump by no more than the fraction

$$[\mu(\tan \theta + \operatorname{ctn} \theta)]^2$$

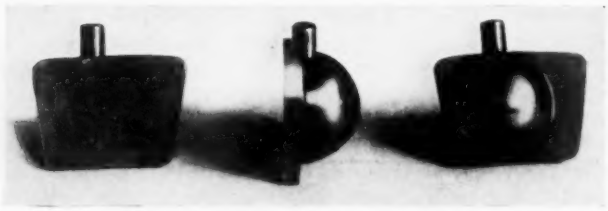

FIG. 6 THREE VIEWS OF A TYPICAL SLIPPER

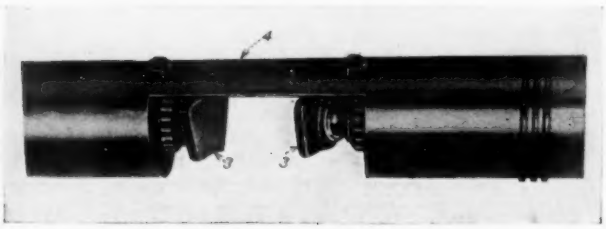

FIG. 7 DOUBLE PISTON ELEMENT OF SLANT-SLIPPER MECHANISM

If, for instance, $\tan \theta$ has the quite usual average value $^1/_4$,

$$\tan \theta + \operatorname{ctn} \theta = 4.25$$

$$(\tan \theta + \operatorname{ctn} \theta)^2 = 18$$

and if $\mu = 0.002$,

$$[\mu(\tan \theta + \operatorname{ctn} \theta)]^2 = (0.0085)^2 = 0.000072$$

or less than $^1/_{100}$ of 1 per cent, as the difference of the efficiencies in favor of the pump.

NEED OF THE CRANKLESS TYPE OF MACHINE

With such high efficiency, which has been amply realized in practice, and with the simplicity and compactness of its construction, it is to be supposed that the crankless type may be usefully applicable to a wide range of purposes. Clearly its merits will be most apparent in the case of multicylinder machines, which internal-combustion engines tend more and more to become. What actual advantages it possesses over the types of engines which at present practically hold the field, and in what applications those advantages may be most likely to secure its adoption, the author proposes to set forth by reviewing some special features of the crank engine.

DEFECTS OF THE CRANK TYPE OF ENGINE

Our familiarity with the crank type, the author believes, is apt to make us oblivious of the real nature of some of its characteristics, and perhaps unduly tolerant of some of its limitations.

In the first place, being essentially a two-dimension machine, the crank engine does not make efficient use of our space of three dimensions. Being neither symmetrical nor compact, it is apt to be unduly extensive, at least in some of its dimensions.

Furthermore, the inherent characteristics of the typical crank engine, namely, that it has no circumferential symmetry and that the motion of its pistons is not harmonic, render it impossible to make it free from vibration by giving it complete dynamic balance; and balance is surely an elementary virtue which the modern engineer, brought up on turbines and electric machines and demanding ever higher rotative speeds, very properly expects every rightly constituted machine to have.

Proceeding to the concrete, and to questions of construction, let us take the essential and characteristic organ of the crank engine, namely, the crankshaft. In an 8-cylinder crankshaft, as shown in Fig. 1, we have a member which is bent at right angles in 32 places. It has 8 crankpin bearings and, in this instance, 5 main bearings. Quite commonly it would have 9 main bearings, or 17 separate bearings in all. Such a shaft in a typical case requires about 160 distinct dimensions to describe it, all of which have to be adhered to with accuracy in all the operations of manufacture. If each of the journals is 3 in. in diameter and 3 in. wide, there will be about 500 sq. in. of bearing surfaces to be machined on these 17 journals, and an equal area of surface to be machined and fitted on the 17 corresponding bearings. This is more than three times the area that has to be machined on the parts performing the corresponding functions in the Michell crankless engine; namely, the slant's two faces, two journals, a thrust collar, and the corresponding bearings and slippers, 18 surfaces in all as compared with 34.

Regarded elastically, the elongated 8-cylinder crankshaft is obviously incapable without the support of its intermediate bearing of supporting the inertia forces of the reciprocating and revolving parts which load it transversely. These forces have therefore to be balanced individually as far as possible (which is to the extent of about 50 per cent), by adding adventitious masses to each crank; and the forces remaining unbalanced in each unit are transmitted through the bearings to the engine frame, to equilibrate as nearly as possible the resultants of corresponding stresses arising from the other units. In so doing, heavy stresses and vibrations are necessarily set up throughout the unit.

While it is true, therefore, that a 6- or 8-cylinder crank engine can be very approximately balanced as a whole, it is only at the cost of much added weight in balance weights, bearings, and frame, and complications to the design, which are entirely unnecessary in the typical crankless engine. What has been said as to the multicylinder crankshaft might be repeated, *mutatis mutandis*, with regard to the connecting rods, to the accommodation of which, by the way, the crank engine usually owes about one-third of its bulk.

Let us proceed, however, to a more vital element, the piston. It is for the sake of the piston, of course, and its unique capacity, with its sealing rings, for compressing in a cylinder a volume of fluid under pressure, that we have reciprocating engines. Turbine rotors will utilize the energy of expanding or falling fluid, with all desirable efficiency and with admirable convenience; but no efficient rotary or other substitute has been found, or seems likely to be found, for the cylindrical piston and its sealing rings, as a compressing agent. Efficient compression is an essential condition of successful operation of the internal-combustion engine, and it is the failure of the gas turbine in this respect which preserves the internal-combustion field for the reciprocating engine. One of the worst of the defects of the crank type is that it does not deal fairly with, or develop the full potentialities of, the piston, especially the piston of the internal-combustion engine.

The secret of the success of the cylindrical piston is, of course, its cylindricality, or the complete symmetry of the piston and the cylinder around their common axis; but in its two-dimensional motion transverse to the crankshaft, the connecting rods apply forces in one diametral plane only of the piston, and this to large extent destroys its symmetry. Contact of piston and cylinder takes place only along the two generating lines in the plane of the connecting rod, from which follows wear of piston and cylinder; while on other portions of the circumference the relatively considerable interspace remains filled with oil or gas, which effectually prevents the conduction of heat from piston to cylinder wall which is an essential function in the internal-combustion engine. An overheated and an unsymmetrically heated and consequently deformed piston is the result, unless the troublesome expedient—almost impracticable except in large engines—of fluid circulation for cooling the piston is resorted to.

In the typical crankless engine, on the contrary, as shown in Fig. 2, since the obliquity of the slant is turned in succession to all azimuths around the axis, every generating line of the piston makes contact at some phase of the cycle with the corresponding generating line of the cylinder. Fig. 8 shows the sequence of the directions of these contact pressures in a particular 4-stroke, 8-cylinder crankless engine, the radial distances to the curves at each azimuth being proportional to the radial pressure between piston and cylinder. This action makes the lubricant in the cylinders effective for reduction of friction, and it also effects symmetrical cooling of the whole piston wall.

In case it may be suggested that the mere "line contact," as it may be called, would not be effective for transmission of the heat, it may be pointed out that in the case of a piston having $^{5}/_{1000}$ in. diametral clearance in its cylinder, the clearance space is less than $^{1}/_{10,000}$ in. wide throughout an arc of more than 30 deg., and that the resistance of a film of oil of that thickness is no greater than that of $^{1}/_{8}$ in. of metal.

Thus while it is generally agreed that in the conventional internal-combustion engine only the gas rings of the piston are effective for conducting heat from the piston to the cylinder walls, in the crankless engine the whole piston barrel is effective for the purpose. In thus fully utilizing the virtues of the piston, the crankless type admits of higher compression pressures and temperatures, and higher piston speeds, just as its perfect balance admits of higher rotative speeds than the crank type.

Fields of Application of the Crankless Type of Engine

It is believed, therefore, that we can confidently expect a future, especially in the field of the internal-combustion engine, for the crankless type in whichever of its present or future forms may prove to be the best. Its success will come first where the defect and limitations of the crank type hinder its further progress. And the author ventures to suggest that there are clear indications, in several directions, of important new fields which the crank type cannot satisfactorily fill.

Diesel Locomotive. First, there is the oil-engine locomotive for main-line service. Very many attempts have been made with the crank type for the past 15 or 20 years. In the most recent examples 1200 to 1500 hp. has been reached, but the crank engine of this power attains the limit of height of most railway loading gages, and the weight and cost of the structure prevent economic competition with the steam locomotive.

The author visualizes the oil-engine locomotive of the future, of any required power, with a crankless engine of approximately the same size and shape and in much the same location on the locomotive as the present steam boiler, coupled to an electric generator in roughly the same location as the present firebox. The higher speeds which are acceptable for the crankless type will enable the weight and cost to be kept within reasonable limits.

Diesel Aero-Engine. Another field of even greater importance which he sees marked off for the crankless engine of the future is that of the heavy-oil engine for flying machines. The disabilities of the crank type of engine for this application are its inadaptability to the two-stroke cycle—at least without a second crankshaft—its excessive height or other dimension transverse to the shaft, its relatively great frontal area in all its lighter forms, and its deterrent weight. It is true that remarkable progress has lately been made in the reduction of weight of crank engines for this purpose, but whatever success is achieved in that direction will enable crankless engines to be constructed by the same methods at least 30 per cent lighter, and in this field the demand for the lightest possible engine will always be insistent.

Twelve-Cylinder Automobile Engine. Looking in another less lofty direction, if the fashion in automobilism should trend to a demand for an engine with twelve or more cylinders, as seems very probable in view of the diminution of torque fluctuation—which is now the most serious cause of vibration and unsteady running in automobiles of the best class—the crankless type must apparently be adopted. A 12-crank shaft can scarcely be contemplated with equanimity, and no other crank type than the straight-line type seems to be acceptable. A 12- or even a 16-cylinder crankless engine presents no difficulties, and would be no longer than an 8-cylinder engine.

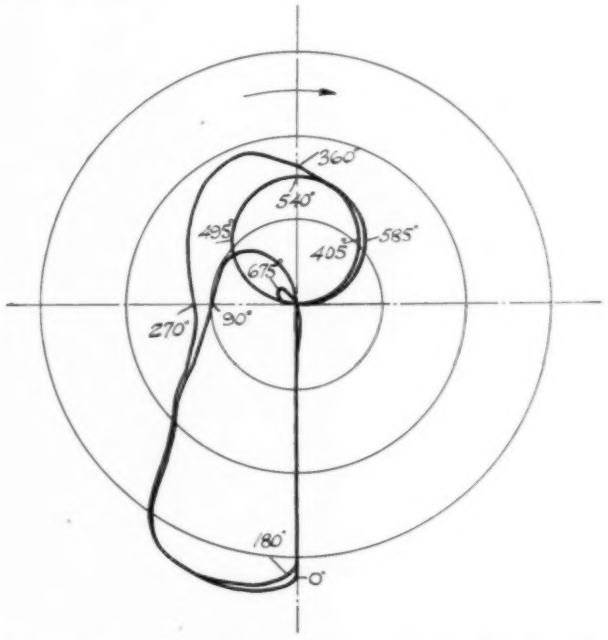

Fig. 8 Showing Sequence of Directions of Contact Pressures in a Particular 4-Stroke 8-Cylinder Crankless Engine

Compressors for Large Volumes. There are, the author thinks, numerous other fields in which the progress of internal-combustion engineering depends upon the adoption of an engine mechanism different from the crank and connecting-rod, but of those he will mention only one more. It is the field of compressors for very large volumes of air and gas required to be delivered at moderate or high pressures; that is, pressures from 5 lb. per sq. in. upward and volumes of several or many thousands of cubic feet per minute. Considerations of space occupied and the convenience of direct-electric driving demand that the machine shall have a high rotational speed.

The turbine and centrifugal types are negatived not only by their poor efficiency at any but low pressures, but by their inflexible control characteristics.

APM-52-8

Engineering Computations for Air and Gases

By SANFORD A. MOSS[1] and CHESTER W. SMITH,[2] LYNN, MASS.

In this paper the authors give methods of making the usual engineering computations for adiabatic compression, expansion, flow through measuring nozzles, and similar work concerned with the thermodynamic properties of air and gases, in the minimum amount of time and with the greatest accuracy possible with engineering methods. The theoretical formulas needed are included, together with extensive tables for use in computation.

THE object of this paper is to give methods of making the usual engineering computations for adiabatic compression, expansion, flow through measuring nozzles, and similar work concerned with the thermodynamic properties of air and gases, in the minimum amount of time and with the greatest accuracy possible with engineering methods.

In making such computations it is amply sufficient for engineering purposes to use the perfect-gas laws. This gives a well-known set of engineering formulas involving various constants, such as c_p and standard density. The values of these constants for air and other gases as given by different experimenters vary somewhat, and are usually thermodynamically inconsistent. Furthermore the constants as usually given apply to theoretically dry air or gas, which seldom exists for the engineer. It is of course just as easy to carry out computations with one set of constants as another. There is no good reason why a reputable, self-consistent set of constants should not be selected and used universally for ordinary humidity. The present common practice is the use by every engineer of a different set of constants, often mutually inconsistent, selected from an old edition of an engineering handbook which he happens to have in his desk. Blind faith in a set of constants which may have no justification except that an engineer is accustomed to them, will probably be the principal objection to adoption of the constants selected as reputable in the present paper.

The humidity of air in a compressor or flowing through a measuring nozzle varies from day to day with atmospheric conditions. Furthermore the specific heat and other properties of air vary slightly with temperature and with the amount of CO_2. However, most engineering work does not warrant exact measurement of humidity, or variation in the fundamental constants to take account of the change in the humidity from day to day, the change of specific heat with temperature, or the CO_2 content. A reputable set of constants is therefore selected for air with average temperature and CO_2 and with a usual humidity, which is here called "Normal Air." This "Normal Air" of the present paper is much more nearly representative of the air actually passing through a compressor or measuring nozzle than the dry air without CO_2 at 0 deg. cent., whose properties as obtained 60 years ago are often used by engineers.

Computations for the compression and flow of a perfect gas make a great deal of use of various exponential functions of pressure and temperature ratios, which are difficult to handle numerically. The theoretical formulas have therefore been recast by various authorities, and tables suited to these systems used for computations. The present paper selects what is believed to be the best system of the kind. This uses, as the most convenient function,

$$Y = \left(\frac{p_1}{p_2}\right)^{\frac{k-1}{k}} - 1$$

where $k = c_p/c_v$.

The paper gives a complete set of the commonly used thermodynamic expressions for air and gases, in terms of Y. An extensive numerical table is then given so that Y may be found for any case, on the basis of the selected reputable constants for Normal Air or perfect diatomic gases. This gives a complete system for computations in a convenient way which yields results somewhat more accurate on the average than is otherwise possible. No deductions are given for the various thermodynamic formulas, as these may be found in most thermodynamic textbooks.

The tables and values of constants are given with enough places to insure mathematical accuracy, so that checks with different forms of formula will agree, and so that the only uncertainties in computed values will be due to original observations, none being introduced by the computation work. For a great deal of engineering work, some of the last places in the constants and tables may be omitted.

Selection of Fundamental Constants. The fundamental constants often used for thermodynamic computations of air are based on values of c_p/c_v or k, obtained by direct experiments, which vary between 1.40 to 1.41. The corresponding values of $(k-1)/k$ vary from 0.286 to 0.291. These values are presumably for theoretically dry air. Such values and good experimental values of density do not exactly satisfy the fundamental relation for perfect gas, namely, $c_p - c_v = R/J$. This gives a discrepancy in the consequent relations,

$$Jc_pT(k-1)/k = 144\,pv$$

or

$$c_p = \frac{144\,p_0}{JT_0\rho_0(k-1)/k}$$

where ρ_0 is the density at p_0 and T_0. It follows that numerical results obtained from various combinations of thermodynamic equations, some of which have been transformed by means of the above relations, will not be self-consistent. A complete system for the selection of constants for Normal Air which avoided all such disabilities was used in a paper by one of the authors, "Measurement of Flow of Air and Gas With Nozzles,"[3] to which reference must be made for details. A brief résumé of this paper is as follows:

The start is made with a value of the density of atmospheric air at standard conditions with usual moisture, here called "Normal Air," which has been found satisfactory in ventilating work. This is 0.075 lb. per cu. ft., at 14.7 lb. per sq. in. and 68 deg. fahr. It is shown in the paper referred to that if there are used the best values of the densities of the various constituents of air, including the rare ones, or the values of the density of pure air (including the rare gases) with correction for the usual CO_2 content, the above figure for the density of Normal Air gives a humidity of about 36 per cent. This is a reasonable figure, so that the value of 0.075 lb. cu. ft. at 14.7 lb. and 68

Presented at the Annual Meeting, New York, N. Y., December 2 to 6, 1929, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

[3] S. A. Moss, Trans. A.S.M.E., vol. 50 (1928), no. 2, paper no. APM-3.

deg. fairly represents air with usual humidity and usual CO_2 content, which we call Normal Air. It is further shown in the paper referred to that a reputable experimental value for c_p for Normal Air, which as shown has 36 per cent humidity, is 0.243. This is higher than old values, because of Swann's experimental work by the "continuous flow" method (which here as usual, shows slightly higher values than by other methods, but which must be given due weight), because of the moisture content, and because of allowance for the slight increase of c_p with the temperatures at which air usually occurs in engineering work. Fig. 1 shows the various values, the data being obtained from "The Specific Heats of Gases," by Partington and Shilling. The authors of course take the responsibility for the weight given to the work of the various experimenters in selecting the value here used. As mentioned, the thermodynamic relations given above must be exactly satisfied by the fundamental constants used in order that numerical results obtained by equivalent thermodynamic formulas shall be consistent. Using the selected reputable values of c_p and density for Normal Air in these relations gives a value

$$(k-1)/k = 0.283$$

The exact value corresponding to the value $c_p = 0.243$ has more decimal places (0.28296), but one is not justified by the accuracy of the other work in using more than three places. The value 0.283 is therefore selected as being the exact fundamental basis of all of the work and the tables for Y computed from it. (This makes it necessary, in order to have exact consistency in any numerical work which demands it, to use a value of $c_p = 0.242967$. It is of course absurd to use so many places unless it is sought to show exact numerical identity of values computed by different methods.) A value of $(k-1)/k$ of 0.29 is often used, but the value here given of 0.283 is better for Normal Air. It leads to a value of $k = 1.3947$, which is better for Normal Air than the values 1.40 to 1.41 already referred to.

The use of 0.283 instead of 0.29 gives a difference in computed values of power for compression, etc., which, however, is completely justified by the data given herein.

The values of k and $(k-1)/k$ thus computed for Normal Air should also be practically correct for any perfect diatomic gas, and comparison with experimental values given in Partington and Shilling's work indicates that this is the case. The actual values by different experimenters differ appreciably, but reputable results are obtained by maintaining the fundamental values of the present paper for all nearly perfect diatomic gases with the assumption that the perfect-gas laws hold exactly.

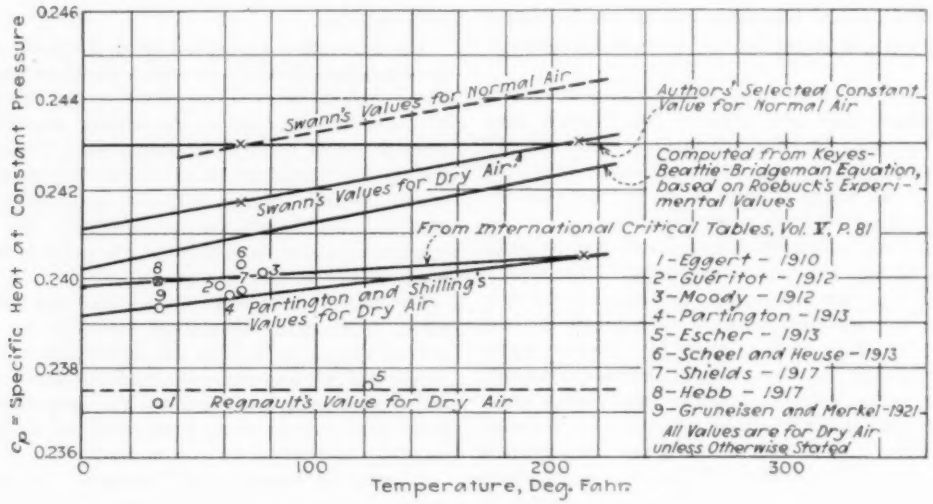

FIG. 1

NOTATION

p_1 = absolute value, lb. per sq. in., of the greater pressure
p_2 = absolute value, lb. per sq. in., of the lesser pressure
T_1, T_2 = corresponding values of absolute temperature, deg. fahr.
v_1, v_2 = corresponding values of volume, cu. ft. of a given weight, which may be any weight, but is usually 1 lb.
p_0 = 14.7 lb. per sq. in. = standard atmospheric pressure. This is almost exactly 760 mm. Hg, the usual physicists' standard. It is equal to 29.92 in. Hg at 32 deg. fahr.
T_0 = 527.6 deg. fahr. abs. = standard atmospheric absolute fahrenheit temperature. This is 68 deg. fahr. or 20 deg. cent., and is a convenient and commonly used value of standard temperature
M = molecular weight
ρ_{a0} = 0.075 lb. per cu. ft. = density of Normal Air at standard conditions, 14.7 lb. and 68 deg. fahr.
ρ_0 = density of any gas at p_0 and T_0

$$\rho_0 = G\rho_{a0} = M\rho_{a0}/28.896$$

G = specific gravity of any gas referred to normal air as 1.00

$$G = M/28.896 = \rho_0/\rho_{a0}$$

c = coefficient of discharge for a nozzle. For a nozzle with well-rounded approach, this may be taken as 0.97 for nozzles with diameters less than 1 in., 0.98 for diameters 1 in. to $2^1/_2$ in., 0.985 up to 4 in., 0.99 up to 12 in., and 0.995 for greater diameters
A = nozzle area, sq. ft.
V = velocity, ft. per sec.
p_m = mean effective pressure, lb. per sq. in.
P = horsepower
w = energy, ft-lb.
w = weight flow, lb. per sec.
q_s = volume, cu. ft. per min. at conditions p_s, T_s
J = 778 = mechanical equivalent of heat, ft-lb. per B.t.u.

c_p = specific heat at constant pressure, B.t.u. per lb. per deg. fahr.
= 0.243 for Normal Air with usual moisture
c_v = specific heat at constant volume
k = c_p/c_v. This is 1.3947 for normal air and perfect diatomic gases such as air, oxygen, nitrogen, etc., k is said to be about 1.67 for monatomic gases such as mercury vapor or helium, and 1.33 for triatomic gases such as CO_2 and for some gases with a greater number of atoms. The table for Y and most of the numerical values apply only for $k = 1.3947$.
Y = $(p_1/p_2)^{(k-1)/k} - 1$
R = perfect-gas constant in the relation $pv = RT$
= $p_0/\rho_0 T_0$

II—PARTICULAR VALUES FOR ALL PERFECT DIATOMIC GASES

Gas		Molecular weight	c_p	c_v	v_0 (Volume, cu. ft. per lb. at 14.7 lb. per sq. in., 68 deg. fahr.)	ρ_0 (Density, lb. per cu. ft. at 14.7 lb. per sq. in., 68 deg.)	G (Specific gravity referred to normal air)	R (R in $pv = RT$ with p in lb. per sq. in.)

I—GENERAL VALUES FOR PERFECT DIATOMIC GASES

$$\frac{k-1}{k} = 1 - \frac{1}{k} = 0.283$$

Volume in liters of 1 gram of any perfect gas at 0 deg. cent. and 760 mm. of mercury

$$= 22.4115/M$$

Density of normal air (carrying usual moisture) at 14.7 lb. per sq. in. and 68 deg. fahr.

= 0.075 lb. per cu. ft.

These exact values and the perfect-gas laws are the entire basis of the present paper. The resultant numerical values are given throughout to a greater number of decimal places than usually needed in engineering work, for use in checks with different forms of formula, or in especially precise computations.

$$k = c_p/c_v = 1.3947;\quad \frac{2}{k+1} = 0.83518;\quad \frac{k}{k-1} = 3.53357$$

Critical-Pressure Ratio for Flow

$$= \left(\frac{2}{k+1}\right)^{\frac{k}{k-1}} = 0.52918$$

Volumetric Specific Heat, B.t.u. per deg. for 1 cu. ft. of any perfect diatomic gas

$$= 0.075 \times 0.243 = 0.0182$$

The properties of hydrogen do not quite fall in line with the constants of Table II. Diatomic gases other than those given depart appreciably from the perfect-gas laws. It is to be noted that the distinguishing characteristic of a particular gas may be given either by the value of R the gas constant, c_p specific heat, ρ_0 standard density, v_0 specific volume, M molecular weight, or G specific gravity, and that any one of these quantities may be given in terms of any of these quantities, but may be changed to terms of any others by the relations of the first two lines of Table II.

III—GENERAL FORMULAS

The term "adiabatic change" is used for the process of perfect compression or expansion, without loss of energy or addition of heat. It is sometimes called "Isentropic Change."

Pressure, Volume, and Temperature Relations for Adiabatic Change for Any Perfect Gas

$$\frac{\rho_1}{\rho_2} = \frac{v_2}{v_1} = \frac{p_1/p_2}{Y+1} \quad \text{..... [1]}$$

$$\frac{T_1}{T_2} = (Y + 1) \quad [2]$$

$$T_1 - T_2 = \left(\frac{Y}{Y+1}\right) T_1 = YT_2 \quad [3]$$

$$(p_1/p_2)^{(k-1)/k} = Y + 1 \quad [4]$$

$$\left(\frac{p_2}{p_1}\right)^{2/k} = \left(\frac{Y+1}{p_1/p_2}\right)^2; \quad \left(\frac{p_2}{p_1}\right)^{1+1/k} = \frac{Y+1}{(p_1/p_2)^2};$$

$$\left(\frac{p_2}{p_1}\right)^{2/k} - \left(\frac{p_2}{p_1}\right)^{1+1/k} = \frac{Y(Y+1)}{(p_1/p_2)^2} \quad [5]$$

IV—MEAN EFFECTIVE PRESSURE, ENERGY OF COMPRESSION AND EXPANSION, ETC., FOR ADIABATIC CHANGE OF NORMAL AIR AND PERFECT DIATOMIC GASES

Mean Effective Pressure, Lb. per Sq. In.:

(*a*) Under the adiabatic curve pv^k = constant, during compression or expansion only,

$$p_m = \frac{2.534\ p_1 Y}{p_1/p_2 - 1 - Y} = \frac{2.534\ p_2 Y}{1 - (p_2/p_1)(Y+1)};$$

$$2.534 = 1/(k-1) \quad [6]$$

(*b*) During a complete cycle or indicator card, and including work of delivery,

$$p_m = 3.534\ p_2 Y; \qquad 3.534 = k/(k-1) \quad [7]$$

Energy of Compression or Expansion, Ft-Lb. per Lb. of Gas:

(*c*) Under the adiabatic curve pv^k = constant, during compression or expansion only,

$$w = 364.8\ p_1 v_1 \frac{Y}{Y+1} = 364.8\ p_2 v_2 Y = 364.8R\ T_2 Y \quad [8]$$

$$364.8 = 144/(k-1);$$

(*d*) During a complete cycle or indicator card, and including work of delivery,

$$w = 508.8\ p_1 v_1 \frac{Y}{Y+1} = 508.8\ p_2 v_2 Y = 508.8R\ T_2 Y \quad [9]$$

$$508.8 = 144k/(k-1)$$

Energy of Compression or Expansion, Ft-Lb., for Gas Occupying a Volume of 1 Cu. Ft. at Low-Pressure Conditions p_2:

(*e*) Under the adiabatic curve pv^k = constant, during compression or expansion only,

$$w = 364.8\ p_2 Y; \qquad 364.8 = 144/(k-1) \quad [10]$$

(*f*) During a complete cycle or indicator card and including work of delivery,

$$w = 508.8\ p_2 Y; \qquad 508.8 = 144k/(k-1) \quad [11]$$

Power of Compression or Expansion, Horsepower During a Complete Cycle or Indicator Card and Including Work of Delivery:

$$P = 0.9252\ p_2 v_2 Y; \qquad 0.9252 = \frac{144}{550}\frac{k}{k-1} \quad [12]$$

For small pressure ratios,

$$P = 0.2618\ v_2(p_1 - p_2); \qquad 0.2618 = 144/550 \quad [13]$$

These are the horsepowers for any flow v_2 in cu. ft. per sec., at the low-pressure conditions, or the horsepowers for a flow of 1 lb. per sec. if v_2 is the specific volume, cu. ft. per lb.

The horsepower for a flow of 1 Lb. per Sec. of Normal Air is

$$P = 0.3437\ T_2 Y = 0.3437\ T_1 Y/(Y+1) \quad [14]$$

$$0.3437 = \frac{144Rk}{550\ (k-1)}$$

For small pressure ratios, for 1 Lb. per Sec. of Normal Air,

$$P = 0.0973\ T_2(p_1 - p_2)/p_2; \qquad 0.0973 = 144R/550 \quad [15]$$

Formulas for Compression in s Stages With Complete Intercooling to Initial Temperature Between, and With Equal Pressure Ratio in Each Stage (this theoretically gives minimum power):

There is first found the value Y_s for each stage. This is the value of Y corresponding to the sth root of the overall pressure ratio, or it is given by

$$Y_s = \sqrt[s]{Y+1} - 1$$

where Y corresponds to the overall pressure ratio. Then P_s the power for one stage is found from [12] or [14]. The overall power is

$$P = s\ P_s \quad [16]$$

The Equivalent Mean Effective Pressure for a multi-stage compressor based on the initial volume of the first stage is

$$p_m = 3.534\ s p_2 Y_s; \qquad 3.534 = k/(k-1) \quad [17]$$

V—FLOW OF GAS THROUGH A NOZZLE

If the greater pressure p_1 is taken with an impact tube, the formulas are to be used as given. If the greater pressure p_1 is taken as static pressure, all of the expressions for velocity and flow are to have included as a divisor the value

$$\sqrt{1 - \left(\frac{D}{D_p}\right)^4 \left(\frac{Y+1}{p_1/p_2}\right)^2} \quad [18]$$

Here D/D_p is the ratio of the diameter of the minimum section of the nozzle to the diameter of the pipe where the static pressure p_1 is taken. If D/D_p is small, the divisor becomes practically 1.00 and need not be used.

Velocity of Discharge Through a Nozzle With Well-Rounded Approach, Ft. per Sec, (see next paragraph):

(*a*) For any perfect gas,

$$V = 223.75\ c\ \sqrt{c_p}\ \sqrt{\left(\frac{Y}{Y+1}\right) T_1} = 223.75\ c\ \sqrt{c_p}\ \sqrt{T_2 Y} \quad [19]$$

$$223.75 = \sqrt{2gJ}$$

(*b*) For normal air

$$V = 110.30\ c\ \sqrt{\left(\frac{Y}{Y+1}\right) T_1} = 110.30c\ \sqrt{T_2 Y} \quad [20]$$

$$110.30 = \sqrt{2gJc_p}$$

Critical Pressure. For flow of a compressible fluid through a nozzle, there is a "Critical Pressure" which is about half of

VALUES OF Y FOR NORMAL AIR AND PERFECT DIATOMIC GASES [$Y = (p_1/p_2)^{0.283} - 1$]

the greater pressure p_1. The exact ratio of critical pressure to p_1 for any perfect gas is

$$\left(\frac{2}{k+1}\right)^{k/(k-1)} \quad \text{.....[21]}$$

The value is 0.52918 for Normal Air and other perfect diatomic gases.

Affected Flow. If the lesser pressure p_2, or the pressure of the region into which the nozzle discharges, is above the Critical Pressure, so that the differential pressure $(p_1 - p_2)$ is less than half of p_1, the nozzle theoretically required has a well-rounded approach, ending in a parallel portion with the minimum section, and the above formulas for velocity and the succeeding formulas for flow apply directly. The pressure at the nozzle end is exactly the pressure p_2 of the region into which the nozzle discharges. This pressure, therefore affects the flow.

Unaffected Flow. If the lesser pressure p_2, or the pressure of the region into which the nozzle discharges, is below the "Critical Pressure," the nozzle theoretically required has a well-rounded approach, *succeeded by a divergent portion.* The theoretically required ratio of the area at the nozzle end to the area at minimum section for any perfect gas is

$$\frac{p_1}{p_2}\frac{\left(\frac{2}{k+1}\right)^{1/(k-1)}\sqrt{\frac{k-1}{k+1}}}{\sqrt{Y(Y+1)}} \quad \text{.....[22]}$$

For normal air or perfect diatomic gases, this becomes

$$\frac{p_1}{p_2}\frac{0.2572}{\sqrt{Y(Y+1)}}; \quad 0.2572 = \left(\frac{2}{k+1}\right)^{1/(k-1)}\sqrt{\frac{k-1}{k+1}} \quad [23]$$

If the divergent portion is properly supplied, the formulas for velocity above given apply directly, but if the divergent portion is not supplied, they do not hold.

If the lesser pressure p_2, or the pressure of the region into which the nozzle discharges, is less than the "Critical Pressure," this pressure does not affect the flow, and the formulas for flow below do not apply, whether or not the nozzle has the divergent portion. The pressure at the minimum section, if there is a divergent portion, or the pressure at the nozzle end, if there is no divergent portion, is the critical pressure.

Flow With Small Differential Pressure. If the differential pressure $(p_1 - p_2)$ is less than 10 per cent of the greater pressure p_1 the formulas below are unduly cumbersome, and while they are correct, they should not be used. For this case, and for the case of flow where the lesser pressure p_2 is less than half of the greater pressure, proper formulas for flow are given in the paper "Measurement of Flow of Air and Gases With Nozzles" (S. A. Moss, Trans. A.S.M.E., vol. 50 (1928), no. 2, paper no. APM-3). The formulas for flow below therefore only apply to the case where the differential pressure $(p_1 - p_2)$ is between 10 per cent and 50 per cent of the greater pressure p_1. Even in this region, the use of the formulas below is *merely optional*, and they may be replaced by a set of formulas not using Y, given in the paper mentioned above.

Any of the expressions for velocity or flow for any gas may be expressed in terms of the value for the gas in question of any one of the quantities R, c_p, p_0, v_0, M, or G. The relations between these are given in the first two lines of Table II.

Weight Flow Through Nozzle, Lb. per Sec.:

(*a*) For perfect diatomic gases,

$$w = 296.88\frac{cAp_2}{\sqrt{T_1}}\sqrt{G}\sqrt{Y(Y+1)} \quad \text{.....[24]}$$

$$296.88 = \sqrt{\frac{144\ 2gT_0\rho_{a0}}{p_0(k-1)/k}}$$

(*b*) For normal air,

$$w = 296.88\frac{cAp_2}{\sqrt{T_1}}\sqrt{Y(Y+1)} \quad \text{.....[25]}$$

$$296.88 = \sqrt{\frac{144\ 2gT_0\rho_{a0}}{p_0(k-1)/k}}$$

Volume Flow Through Nozzle, Cu. Ft. per Min., expressed in terms of volume at given conditions p_3, T_3:

(*a*) For perfect diatomic gases,

$$q_3 = 6618\frac{T_3}{p_3}\frac{cAp_2}{\sqrt{G}\sqrt{T_1}}\sqrt{Y(Y+1)} \quad \text{.....[26]}$$

$$6618 = 60\sqrt{2gJGc_p}$$

(*b*) For normal air,

$$q_3 = 6618\frac{T_3}{p_3}\frac{cAp_2}{\sqrt{T_1}}\sqrt{Y(Y+1)} \quad \text{.....[27]}$$

$$6618 = 60\sqrt{2gJc_p}$$

Outline of Tables for Y

Seven-place Vega logarithm tables were used in computing the tabular values. These are given for every pressure ratio p_1/p_2 from 1.000 to 3.000 in steps of 0.001, with some proportional parts to enable interpolation to 0.0001. For ratios from 3.00 to 12.00, steps of 0.01 are used. It is to be noted that if values of $(p_1 - p_2)/p_2$ are known, the corresponding values of p_1/p_2 for use of the table are given by

$$\frac{p_1}{p_2} = \frac{p_1 - p_2}{p_2} + 1$$

The values of the adiabatic factor Y are given to five decimal places for pressure ratios from 1.000 to 3.000, and to four places for ratios from 3.0 to 12.0. It is to be noted that the Y-table applies only to air and perfect diatomic gases.

Errata. In the previously mentioned paper "Measurement of Flow of Air and Gases With Nozzles" [S. A. Moss, Trans. A.S.M.E., vol. 50 (1928)], there is a typographical error in the formula immediately preceding the section headed "Temperature Corrections for Mercury Columns." In the denominator of the last fraction in the formula, p_2 should be p_1.

Discussion

Barton H. Coffey.[4] The authors' 1927 and 1929 papers are really one, and the writer therefore experienced double pleasure in going over them for two reasons: first, the broadminded and liberal spirit of public service exhibited by one of our great corporations in giving to the profession this extremely valuable experience and original research; second, the clear and thorough manner in which the authors have presented the data.

The writer believes the method of choosing the mathematical constants so as to harmonize the links in the chain of perfect-gas relations leads without doubt to maximum overall accuracy, as the Y-function and its elaborate table of values most certainly lead to important labor savings in computation. The writer believes that dry air plus the normal or annual average quantity of water vapor is the proper and scientific basis for rating capacity of compressed-air apparatus as advocated by the author under the caption "Normal Air." The chosen psychrometric state is 68 deg. dry-bulb and 36 per cent relative humidity, which appears somewhat low for a mean value based upon population affected. On a population basis the sparsely settled country east of the Cascade and Sierra Nevada Ranges and west of the Rockies averaging 50 per cent mean annual relative humidity comes out leaving a rough average for the rest of the country of 75 per cent relative humidity at 56 deg. mean average temperature and about 50 grains of water vapor per pound of dry air.[5] At 68 deg. air temperature, identical water vapor would call for 50 per cent relative humidity, or an increase of 14 per cent over the authors' figure, a trifling difference in affecting the constants.

Thomas E. Butterfield.[6] The table contained in this paper will be valuable in the computation of the work, horsepower, and mean effective pressure for adiabatic compression of air.

For the maximum pressure ratio of 12, the assumption of constant specific heat is justified for engineering computations. The maximum variation of specific heat for the corresponding temperature range is less than 2 per cent.

For expansions with the same maximum pressure ratio, the approximation involves a considerably greater error. This is because the specific heat for the corresponding temperature range is considerably lower than that assumed by the authors, and also because the air composition constantly varies due to separation of moisture. For nozzle work the effect of supersaturation will diminish the error.

Though the usual methods of interpolation were presumably used in computing the table, the work must have taken much time. Nevertheless, the question arises whether the computation of additional tables for compressions other than adiabatic would not yield results valuable enough to compensate for the labor involved.

The writer feels that the great value of the table is ease in finding the temperature ratio, which is $Y + 1$. This gives the final temperature. The work of the compression cycle, discussed under IV (*d*), is then readily found as $w = 778 \times 0.243\ (T_1 - T_2) = 189\ (T_1 - T_2)$ in ft-lb. per lb. air. The work of compression alone is $778 \times 0.174\ (T_1 - T_2) = 135.37\ (T_1 - T_2)$.

In calculating the mean effective pressure of compression, the most convenient procedure is to find the volume ratio v_2/v_1 as the quotient of the pressure ratio p_1/p_2, which is the argument, divided by the temperature ratio, equal to $(Y + 1)$.

Dividing the work of compression by the reduction in volume $v_2 - v_1$, the mean effective pressure is obtained, or

$$\text{m.e.p.} = \frac{135.37\ (T_1 - T_2)}{144\ (v_2 - v_1)} = 0.940\frac{T_1 - T_2}{v_2 - v_1}\ \text{lb. per sq. in.}$$

$$\text{The m.e.p. for the compression cycle is} = \frac{189(T_1 - T_2)}{144\ v_2} = 1.312\frac{(T_1 - T_2)}{v_2}$$

M. G. Robinson.[7] This paper gives a clearly stated set of formulas for use in the thermodynamic computations dealing with compression, expansion, and flow of "normal" air, as defined by the authors. The pains taken in framing the formulas to make them mutually consistent, easy to work with on an ordinary slide rule, and yet capable of yielding numerical accuracy, as well as the care exercised in stating the basis for selecting the fundamental constants involved, should make this paper helpful, within the scope of its application. Although the paper contains frequent references to other "perfect" diatomic gases, the remarks following will be confined to air.

The graphical summary of the available data for c_p of air,

[4] Consulting Engineer, Elizabeth, N. J. Mem. A.S.M.E.

[5] Bulletin Q, 1916, p. 61, U. S. Weather Bureau, Washington, D. C.

[6] Professor of Heat Power Engineering, Lehigh University, Bethlehem, Pa. Mem. A.S.M.E.

[7] Centrifugal Compressor Department, General Electric Company, Lynn, Mass. Assoc-Mem. A.S.M.E.

as given on the second page, is of particular interest. Several years ago, in connection with heat-balance testing of centrifugal compressors (Paper No. 1991, Trans. A.S.M.E., 1925), the speaker went to considerable trouble in an effort to select the most satisfactory value for c_p of air near atmospheric pressure and temperature. The number of textbooks and handbooks still quoting Regnault's value of 0.2375 B.t.u. per lb. per deg. fahr. was amazing. The study pointed to a value of 0.240–0.243 as more proper for average conditions. The well-known work of W. F. G. Swann (1909) was adopted at that time as fully trustworthy, and, if anything, somewhat on the conservative side for the application in question. Referring to the graph on the second page of the paper, it might be well to add the value 0.2415 given by J. R. Roebuck ("The Joule-Thomson Effect in Air," Proc. American Academy of Arts and Sciences, 1925).

It should be definitely understood that the fundamental constants recommended by the paper are for ordinary engineering work with air at or near atmospheric pressure and temperature. For special engineering problems involving the use of very high or very low temperatures, or high pressure, or demanding extreme accuracy, these constants are considerably modified. Excellent data are now available. Probably the equation of state as developed by Dr. Keyes and reported recently in the *Journal of the American Chemical Society*, would furnish satisfactory data for most cases.

The paper applies to air with an average humidity of about 36 per cent. There are cases when the effect of the actual humidity contents of air must be taken into account. Although there are no great theoretical difficulties in estimating this effect, experience shows that the average test engineer, particularly one who is sent to witness an acceptance test, is quite hazy about it, inclined either toward overestimating or underestimating. The title and contents of this paper make the writer feel justified in the following remarks.

At the same pressure and temperature, water vapor is about five-eighths as heavy as air. On the other hand, the c_p of water vapor is approximately double that of air. The adiabatic exponent for water vapor is less than that for air. Hence, in general, it follows that as the relative humidity of air increases, its density (or specific gravity referred to dry air) and adiabatic exponent decrease and its specific heat at constant pressure increases. Applying these observations to flow measurements, it is noted that for a given pressure differential, the weight flow of moist air will be less, it being almost exactly proportional to the square root of specific gravity of the air. On the other hand, the energy required for compressing a given weight of air from a given pressure and temperature to a specified pressure will be greater the greater the relative humidity, it being very nearly inversely proportional to the specific gravity only. In both cases the effect of the exponent variation is practically negligible, and correct results will be obtained by allowing for the specific-gravity change only.

At low relative humidity, and particularly at low temperatures, say, below 75 deg. fahr., the magnitude of the effects mentioned is not great. With high humidity and high temperatures, and especially in case of exhauster or low-pressure air operation, the effects may be quite serious. For instance, air at normal atmospheric pressure, at 100 deg. fahr. and 100 per cent relative humidity, will require almost $2^1/_2$ per cent more energy for compression and will have a c_p value almost $3^1/_2$ per cent greater than dry air under the same conditions of pressure and temperature; while air at one-half atmospheric pressure at 100 deg. fahr. and 100 per cent relative humidity will require nearly 5 per cent more energy for compression to a given pressure and will have a c_p value some 7 per cent greater than dry air at the same pressure and temperature.

A. PETERSON.[8] The authors deserve credit for their efforts to establish uniform constants for use in calculations covering adiabatic compression and expansion of gases, and particularly for the considerable amount of painstaking work involved in calculating the Y-values for the many pressure ratios given in the table. The writer has worked up such tables and therefore knows what it means.

In reading the first part of the paper one obtains the impression that the use of constants established about 60 years ago might lead to results that are not quite reliable. The most important one of these constants is the exponent 0.29, found in many old engineering handbooks. The writer therefore proceeded to calculate what difference in results would be obtained by the use of the exponent 0.29, corresponding to $c_p/c_v = 1.4085$, and the exponent 0.283 given in the paper, and selecting a pressure ratio $p_1/p_2 = 2$ and calculating the theoretical horsepower for this ratio, found a difference of only 0.22 per cent, which is insignificant for all practical purposes.

While the difference in the value of Y is considerably greater (2.65 per cent) for the two exponents, this difference is almost entirely offset by the factor $k/(k-1)$ in the horsepower formula, which for $k = 1.4085$ is 3.448 and for $k = 1.3947$ in the paper is 3.534.

Therefore no serious errors will result by the use of the old constants. However, it would be very desirable if uniform constants as recommended in the paper be adopted in all handbooks if for no other reason than the excellent and most complete table for values of Y, which alone will save considerable time for any one who may have occasion to make calculations on adiabatic compression or expansion of gases, and who may not have available such complete tables.

The writer is a little surprised to note that air of 68 deg. fahr. is referred to as normal air. Practically all blower and compressor manufacturers use a temperature of 60 deg. fahr. for standard air, and this also applies to many users of such equipment. The writer would like to know if there was any particular reason for selecting a temperature of 68 deg. fahr.

H. A. EVERETT.[9] A paper such as this represents a large amount of repetitive computation, and all should be grateful for the authors' willingness to share with us the results of these arduous labors. Such a tabulation may be extremely helpful when used within its limitations, but these limitations must be carefully kept in mind. The authors have clearly stated the basic values on which the table was reared; yet it may not be out of place to point out in a somewhat different manner the assumptions accepted when using the tables.

That hypothetical substance the "perfect gas" is assumed to be a substance which not only conforms completely to the gas laws of Boyle, Charles, and Joule, but also one in which the specific heats remain constant. This assumption of constancy of specific heats is in addition to and independent of that of conformity with the first-mentioned gas laws. In actual gases the variation of specific heat with pressure is but trifling for wide ranges of pressure, but the variation of specific heat with temperature is pronounced, and for temperature ranges met in adiabatic compression or expansion of even moderate amounts its variation is appreciable. For example, in the very common volumetric compression of 5 to 1, with an initial pressure of 14.7 lb., the final temperature of the perfect diatomic gas figured from the customary expression, $pv^{1.40} = \text{constant}$, is equal to 1005 deg. fahr. abs. when the initial temperature is 68 deg. fahr. If,

[8] Chief Engineer, Pump & Compressor Dept., De Laval Steam Turbine Co., Trenton, N. J. Mem. A.S.M.E.

[9] Professor of Thermodynamics, Pennsylvania State College, State College, Pa. Mem. A.S.M.E.

however, the final temperature be figured taking cognizance of the variation in specific heat in accordance with Goodenough's equation $Mc_p = 6.93 + 0.1200 \times 10^{-3}T^2$, the final temperature is 999 deg. fahr. abs. There is thus a difference of $^1/_2$ per cent due to the effect of the variable character of the specific heat.

If the specific heat varies, the value of k also varies. It would of course be entirely possible to assume a value of k that would bring the results of the computation by the first method into harmony with that taking cognizance of the variable specific heat. For example, if we were to take the value of k as 1.396, we should obtain the same final temperature by the first method as was computed by using the variable-specific-heat expression. But this would be good for this particular range of temperatures, and only for this particular range of temperatures.

The kinetic theory of gases clearly shows that perfect gases having monatomic molecules should have the value of k equal to $^5/_3$, or 1.6667, since these molecules have but 3 degrees of freedom. For the diatomic molecules where the degrees of freedom are increased to 5, the value of k is $^7/_5$, or 1.4000. For the tri- or poly-atomic molecules, the degrees of freedom become 6, and the corresponding value of k should be $^8/_6 = 1.3333$. If, then, one is to discuss the performance of diatomic perfect gases, it would seem that the value of k must be 1.40. If the authors choose to select a value of k differing from this sufficiently to approximately correct for the effect of the variation in specific heat, that is their privilege, but it should be clearly understood that such an approximation has been made, and furthermore that this value is strictly correct only for that one range where the average value of the true k's as affected by specific-heat variation is equal to that assumed. The authors do not make it quite clear that this point is involved as they have accepted a value of specific heat for what is termed "normal air" and hung the rest of the structure on that value. It may be that this is a reasonable value to assume for air, but if one is to discuss really perfect diatomic gases, then such an assumption of specific heat is unwarranted, and it seems to the writer that the effect of variable specific heat should be taken account of as such, rather than included in the acceptance of an arbitrary value of k.

The writer has checked temperature rises computed both by the tables and by the rather laborious variable-specific-heat method for several of the larger ranges covered by the table and finds their agreement fairly close. He does not wish to detract in any way from the obvious merits of such a paper as the authors have given, but thinks it would be of interest to call attention to the fact that the accepted values really take into account the variation in specific heat, though in an indirect manner. He doubts, however, if the results are dependable to the number of significant figures quoted in the table.

Frank O. Ellenwood.[10] The authors have presented a paper that gives in convenient form certain quantities that are likely to be of service to those making extensive calculations for air and other gases. There are a few statements in the paper, however, that appear to the writer to be slightly misleading at least, and he will therefore call attention to them.

In the first place, considerable stress is laid upon what the authors call the "normal air," and the statement is made on the first page that "this air is much more nearly representative of the air actually passing through a compressor or measuring nozzle than dry air without CO_2 at 0 deg. cent., whose properties as obtained 60 years ago are often used by engineers." In another place on the same page reference is made to the correction for the usual CO_2 content and the "rare gases" to justify the values of density and relative humidity in the so-called "normal air." By looking up the previous paper of Dr. Moss, to which reference is made, the amount of CO_2 in the normal air is found to be 0.03 per cent by volume, and the sum of all the rare gases is much less than 0.002 per cent. Therefore these factors, it seems to the writer, are very much overemphasized in the paper because they are not the ones that are affecting the gas constants appreciably.

On the other hand, consider Fig. 1, and it will be observed that Swann's values of c_p for dry air are nearly 1 per cent higher than Partington and Shilling's and those of other recent experimenters. In this connection it should be mentioned that the Goodenough and Felbeck values of c_p for dry air would give a curve passing almost through points 6 and 8 of Fig. 1. This would be about $^3/_4$ of 1 per cent less than Swann's values for dry air. Thus a difference of nearly 1 per cent is involved in our most reliable values of c_p for dry air, whereas the effect of the CO_2 in the atmosphere on this specific heat is about $^1/_{100}$ part as great. Furthermore, a relative humidity of about 0.70 is very common for the atmosphere in various parts of this country, and when the relative humidity is changed from 0.36 to 0.70, the value of c_p is thereby increased $^1/_2$ of 1 per cent.

Considering the facts that have just been given, the writer believes that one may therefore very properly question the wisdom of defining "normal air" as has been done by the authors of this paper. Since the density of air is far more dependent upon its temperature and humidity than are c_p and k, it seems logical that these two terms should form the starting point, rather than density, from which the other gas constants of "normal air" may be found after agreement is reached on the composition of the latter.

The value of k for normal air has very commonly been used as 1.4, and with a relative humidity of either 36 or 70 per cent it is probably still closer to that figure than it is to the much longer one used in the paper. Since 1.3947 is only about $^1/_3$ of 1 per cent less than 1.4, the question naturally arises as to how much this small difference affects the values of Y given in the table. The answer is that for the pressure ratios used in the table the values of Y are about $1^1/_4$ per cent less than they would be with $k = 1.4$, so this difference is certainly not a serious one in engineering applications.

Authors' Closure

The authors are gratified that so many competent engineers have been interested enough in the paper to discuss it and to give words of commendation. In reply to Mr. Peterson, a standard temperature of 68 deg. fahr., rather than 60 deg., was selected because this is believed to be more nearly the average temperature for most engineering work, and because it corresponds exactly to the value of 20 deg. cent. commonly used.

Following the suggestion given by Mr. Robinson, there has been added to Fig. 1 a line which represents the values of specific heat computed on the basis of the work of Keyes, Beattie, and Bridgeman, with constants based on Roebuck's experimental values. This gives additional credibility to Swann's specific-heat values, as compared with the previous lower ones.

There are a number of detail criticisms regarding the exact numerical values which have been finally selected. The selected value, $(k - 1)/k = 0.283$, applies to air at 68 deg. fahr., 29.92 in. of mercury, and 36 per cent relative humidity if the value of c_p is as high as Swann's value. It applies to a relative humidity of 70 per cent, if the value of c_p is approximately as determined by the recent experiments of Roebuck (Proc. Am. Acad. Arts and Sci., vol. 60 (1925), p. 537). It applies to a higher relative humidity if the lower values of c_p shown in Fig. 1 are correct.

[10] Professor of Heat-Power Engineering, Cornell University, Ithaca, N. Y. Mem. A.S.M.E.

However, the authors feel that the set which they have selected is at least as good as any other set of values which would accord on the average with the various items of experimental data, which would be thermodynamically self-consistent, and which would give an even value to three significant figures of the quantity $(k - 1)/k$, which is the direct number used in computing the tables for Y. The rounding off of some of the other constants, with retention of thermodynamic consistency, would require more places than $(k - 1)/k = 0.283$, and this is not justified under the circumstances.

APM-52-9

Elastic and Inelastic Behavior in Spring Materials

Progress Report No. 5 of the A.S.M.E. Special Research Committee on Mechanical Springs (Technological)

By M. F. SAYRE,[1] SCHENECTADY, N. Y.

SINCE the Fourth Progress Report of the committee was published, work has been continued at Union College on fundamental studies of the elastic behavior of spring materials. The purpose of this work has been to lay a sound theoretical basis for the whole problem of spring design, taking up those underlying problems which it would be uneconomical for any one manufacturer by himself to tackle, but which are vitally necessary to a real understanding of the whole problem. During the past six months it has been possible to clarify several points which were uncertain at the time the last report was written, and to open up several new points regarding the elastic behavior of spring metals in tension. These results may prove to be of value outside as well as within the field of spring design.

1 In the phosphor-bronze and spring-steel samples tested the modulus of elasticity has been shown to be greatly affected by overstressing. Overloading in tension beyond the yield point lowers the modulus of elasticity with respect to future lighter loads. Within limits, the greater the permanent elongation, the greater the reduction in modulus. Two weeks' rest at room temperature causes only a slight recovery. Specimens are being held for future tests at longer intervals. Such overloading as this, as in surging a spring, operates in two ways to increase the energy-storing capacity of a spring, first by lowering the modulus of elasticity, and second by raising the apparent elastic limit of the material. Further tests are desirable in order to show to what extent this gain is counterbalanced in other ways.

2 For years Hooke's law, that stress is proportional to strain, has been almost a fixture in engineering practice. Numerical results obtained seem to indicate a second-order correction to this law, not great enough to be perceptible for materials commonly used at low stresses, such as structural steels, but great enough to be noticeable at customary spring stresses in phosphor bronze and spring steel. With sufficiently accurate measuring instruments, the stress-strain line appears to be continuously curved from zero load upward, not because of minute departures from elastic behavior, but because the elastic line itself is curved. The modulus of elasticity in tension decreases as the load increases, the decrease in slope of the stress-strain line being of the general order of magnitude of 2 to 4 per cent. This effect was noted in last year's work, but an attempt was made to fit successive straight lines to the stress-strain curve, so obtaining an upper and a lower proportional limit, and two different moduli of elasticity. The work done since then has emphasized this curvature as a real elastic property, and indicated that the proportional limit properly so-called is not evidence of the elastic limit of the material, but tests have not yet been made on enough specimens to show whether the rate of curvature will vary with individual specimens, and whether such variation, if any, is indicative of the character of the material.

From theoretical reasons it is expected that in compression the modulus will increase as the load increases. Work is planned on the much more difficult problem of checking this phase of the work.

The practical effect of this curvature of the stress-strain line upon the stresses in a power or cantilever spring will be to shift the neutral axis toward the compression side, to slightly decrease the maximum stresses on the tension side, and to increase them on the compression side. The magnitude of the effect will be small.

3 In last year's report, mention was made of a discrepancy in the law of variation of internal friction, or elastic hysteresis, between tension and bending specimens. Later tests have shown that this discrepancy resulted from a sharp break in the law of hysteresis in tension which occurs at about the yield point. The precision with which it was possible to work last year was such that practically all our significant results in tension were limited to the upper load ranges, near or above the break in the curve. By multiplying the precision of the extensometer by five, so that one scale division of the extensometer now represents 1 part elongation in 500,000, and working with an extensometer with almost negligible instrumental hysteresis, it has been possible to obtain results on the lower part of the curve as well. For stresses below 160,000 lb. per sq. in., the actual width of the hysteresis loop (i.e., the amount of "backlash" which was shown by the specimen on descending loads as compared to ascending loads, at half full load) increased in these tests as some power of the maximum load varying between 2.5 and 3. The energy loss in hysteresis would vary as the maximum load raised to the 3.5 or 4 power. Above 160,000 lb. per sq. in., which is a point about midway between elastic limit and yield point and not far from where appreciable permanent set first begins, and up to maximum stresses of 180,000 lb. per sq. in., the hysteresis varies more nearly as the eighteenth power of the maximum stress. In specimens in bending, the outside fibers reach the yield point only one by one as the load is increased, and consequently no such sharp change in the law of hysteresis will be evident.

4 Any overloading, to stresses which exceed this same figure of 160,000 lb. per sq. in., acted to increase the future energy loss in hysteresis, even for small load ranges. Within limits, the greater the amount of overloading, the greater was the effect on the hysteresis. Recovery from the effect of the overloading, after two weeks at room temperature, was relatively slight. Further tests are planned to study the amount of recovery after longer periods.

The fact that permanent or quasi-permanent changes in both modulus of elasticity and hysteresis begin at about the same unit stress indicates that the two are tied together.

5 The data obtained as to the actual shape and character of the hysteresis loop are not yet complete. This information is of course likely to be of academic rather than of practical interest to spring manufacturers and users, but a number of questions have been asked about it. It seems to be more nearly of string-bean shape than like an ellipse, with pointed, eccentric ends, and with often a slight in-curve on the under side. The exact shape will

[1] Supervisory Member in Charge of Research at Union College and Associate Professor of Mechanical Engineering, Union College. Mem. A.S.M.E.

Contributed by the Special Research Committee on Mechanical Springs and presented at the Annual Meeting, New York, N. Y., December 2 to 6, 1929, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

depend upon the magnitude of the stress range, upon the speed with which the readings are taken, and upon how nearly the material has reached a cyclical state.

As stated in the preceding report, the experimental problems have not been entirely simple. The elastic changes in shape of a metal, particularly in tension or compression, are themselves small. Much of the work done has required the measurements of slight discrepancies in this elastic behavior of the order of magnitude of 0.00001 in., so calling for the highest available degree of precision, with repetition of work to allow for elimination of erratic results and for use of average values. It has been necessary to work in all cases practically to the limit of accuracy of the instruments used, and to apply all practicable precautions.

Details of Work

The testing machine used was an Amsler universal machine with 50,000 lb. maximum capacity, but with seven load ranges. This was a new machine just installed by the college, calibrated in Switzerland and again calibrated here, up to a load of 4000 lb., using standard 50-lb. weights. The results of that calibration are shown in Table 1. It was installed in a large ground-floor

TABLE 1 DEAD-LOAD CALIBRATION OF TESTING MACHINE

Weight, lb.	Actual error of machine in pounds at the load indicated — Scale setting — 5,000 lb.	10,000 lb.	25,000 lb.
0	+3 lb.	−2 lb.	−28 lb.
500	−2	−4	0
1000	+1	0	−10
1500	+5	+3	− 3
2000	−3	0	0
2500	+3	+8	+15
3000	−1	0	0
3500	−1	0	0
4000	+4	0	+ 5

room, practically free from vibration. The temperature at the machine was relatively uniform during the entire period of the tests with a maximum range from 68 to 78 deg. fahr. The range during any one day did not exceed 4 deg., and was usually not over 1 deg. A cloth curtain around the specimen and extensometer shielded them from direct drafts.

The extensometer used was of the Riehlé-Sayre type, developed by the author. For this work it was adjusted for an 8-in. gage length. Each of the 500 divisions on the scale represented an elongation of 1 part in 500,000, so that the full scale range represented 1 part in 1000, or a load range (for steel specimens) of 28,000 to 30,000 lb. per sq. in. Errors in absolute calibration of the extensometer are believed to be within 0.5 per cent. The extensometer is relatively free from instrumental hysteresis. The combined sensitivity of the testing machine and extensometer was such that successive readings, taken at the same nominal load reading (about 5000 lb.) on the machine, checked within one division on the extensometer, equivalent to about 3 lb. load on the specimen. This, of course, was true only provided the load variation on the machine was kept small enough so that the internal hysteresis of the specimen itself was not a factor.

The method of operation was so planned as to eliminate experimental errors as far as possible. The accuracy of the hysteresis figures depended upon the sensitiveness only, and not upon the absolute accuracy of the testing machine and extensometer, since they came as a difference of two readings taken at the same load and at nearly the same point on the extensometer scale. Values of modulus of elasticity were based on sets of readings, each taken over practically full scale range of the extensometer. As a result, any errors of calibration of the extensometer as a whole or in individual parts of the scale affected only the absolute value of the modulus of elasticity and did not appreciably affect the difference in readings, upon which the conclusions are based. Any index error in the zero setting of the testing machine would not appreciably affect the conclusions. A consistent error in the testing machine, of the same percentage at all loads, would affect the absolute values of the modulus but not appreciably the differences in modulus. Erratic errors, varying in magnitude from point to point, remain as a possible source of error.

Most of the work was done on samples of the same $^1/_2$-in. × $^1/_8$-in. oil-tempered 0.68 per cent carbon flat steel wire used for the work of the last report. The description of this wire as given by the manufacturers was as follows:

> A tempered annealed rod 0.5 in. × 0.162 in. is rolled and straightened and then lead-annealed at 0.160 in., rolled to 0.147 in., then to 0.140 in., lead-annealed at this stage, and then rolled successively to 0.135, 0.130, and 0.125 in.
>
> In hardening and tempering this wire, the furnace for heating is at 1550 deg. fahr., and the temperature of the tempering furnace is 900 deg. fahr.

The analysis of this material is as follows:

	Per cent
Carbon	0.68
Manganese	0.67
Sulphur	0.046
Phosphorus	0.036
Silicon	0.201

The hardness numbers obtained were:

Shore	51.7
Brinell	37.4
Rockwell	C39–C40

It has a yield point of about 175,000 lb. per sq. in. and an ultimate strength of 198,000 lb. per sq. in. Tests were also made on flat spring tempered sheet and round rod of phosphor bronze, and on a bar of nickel steel, both obtained locally.

In studying hysteresis the specimen was put through a series of cycles of loading and unloading between a nominal load and the desired maximum load in tension. After the specimen had approached a cyclical state, sets of readings were taken with the extensometer for three complete cycles, or more if necessary to obtain consistent values. In the work covered by the last report readings were taken at even load intervals over the entire cycle. Since then the sensitivity of the extensometer has been multiplied by 5 and this increased sensitivity had to be paid for in the form of reduced range. On the flat-wire steel specimens an actual load of 1600 lb. gave almost a full scale reading. Consequently, when working for instance within a load range from 100 lb. to 6400 lb., after running some preliminary cycles, the extensometer was set at zero for a 2400-lb. load. Readings were taken at 2800, 3200, 3600, and 4000 lb. Leaving the extensometer in place the load was increased to 6400, then lowered and readings taken at 4000, 3600, 3200, 2800, and 2400 lb. as the load decreased. The load was then lowered to 100 lb., raised to 2400 lb., and the cycle of readings repeated. In this way the width of the loop as measured by the differences in readings, ascending and descending, was taken at five points near the middle of its height. The sides of the loop are so nearly straight at this point that the average of these five differences, or rather the mean of three sets of five differences each, could be taken as the maximum width of the loop itself.

Such measurements were made using successively increasing maximum loads and the results are given in Table 2 and are shown graphically in Fig. 1. Repeat runs, dropping back to a lower maximum load after a cycle at a higher load had been completed, gave no appreciably changed results until the maximum load had reached nearly the yield point of the material. The results of sets of test runs taken after the yield point had been reached are also given in Table 2. The results are given in millionths of an inch per inch length of specimen, and the measurements involved are so minute and so close to the limits of accuracy of the instrument used that too great consistency must not be expected in the lower load ranges. Some tests are planned

for the future using a 50-ft. gage length under carefully controlled temperature conditions, and it is hoped that it will be possible to obtain higher precision in these tests.

In all of these measurements the extensometer readings were taken over the same load range of 1600 lb. except in those few cases where the hysteresis of the specimen was so great that some of the readings came off the scale. A study of these elongation readings gave the first definite indication that the true modulus of elasticity of the material changed as the load increased. Table 3 gives a set of the readings for one bar. It will be noticed that the change in length for a 1600-lb. load range with ascending and descending load checks within a reasonable limit of error, but as the actual load itself increases, the elongation also fairly consistently increases. In the second series of runs, taken after the specimen had been loaded to the yield point, the elongation readings were consistently higher than in the first series; and in the third series, after still greater overload, the readings were still higher.

With this as a clue a program of measurements was planned with the special purpose of studying the true elastic stress-strain curve. The most obvious method was to take measurements over the complete stress-strain curve itself, from zero load to the yield point. This immediately introduced the factor of elastic hysteresis, and also made it impossible to study the elastic elongation of the bar as separated from the effect of minute plastic yield which might be simultaneously occurring. To avoid these effects, the total curve was broken up into a series of short sections, each of short enough range so that the elastic hysteresis within that range would be small. For the first run a new specimen was loaded to 100 lb. and the extensometer set at zero. A series of load cycles was then run between 100 and 1600 lb. in order to develop any permanent elongation which was likely to occur within the 1600-lb. load range and to set the extensometer firmly in place on the specimen. The load was again brought to 100 lb., the extensometer again set at zero, and readings taken at 800 and 1600 lb. on ascending and descending loads for at least three cycles. The load was next brought to 1600 lb., and the extensometer rest to an 8-in. gage length at this loading. After a series of preliminary cycles as before, readings were now taken over the load ranges from 1600 to 3200 lb., ascending and descending. In that way the true slope of the stress-strain curve was found between the 1600- and the 3200-lb. load, corresponding to unit stresses of 26,800 and 53,600 lb. per sq. in., respectively. This was followed by a similar run from 3200 to 4800 lb. In some cases intermediate runs from 800 to 2400, and from 2400 to 4000 lb., were interpolated.

The load was now dropped to 100 lb., and the runs 100–1600 lb., 1600–3200 lb., and 3200–4800 lb. were repeated, both as a check and to determine whether the cycle from 3200 to 4800 lb. had perceptibly affected future behavior at lower loads. This second series was continued with runs at 4000–5600 lb. and at 4800–6400 lb., and then a third series was started beginning at

KEY TO TABLE 3

Columns 1 and 2 give the maximum stress in the cycle, and the stress range over which readings were taken, both in thousands of pounds per square inch.

Columns 4 to 6 give the measured elongation, in parts per 500,000, resulting from a load increase or decrease of 1600 lb. or 26,746 lb. per sq. in. Each figure represents the mean of at least three results.

Column 7 gives the same figures as corrected to 68 deg. fahr. for the effect of temperature upon modulus of elasticity.

Column 8 includes also a correction for the effect of the total change in cross-section, both elastic and plastic. Poisson's ratio was assumed as 0.27.

Column 9 is corrected for temperature and for permanent, plastic change in cross-section only.

Column 10 gives moduli of elasticity in millions of lb. per sq. in. based on the results in column 9.

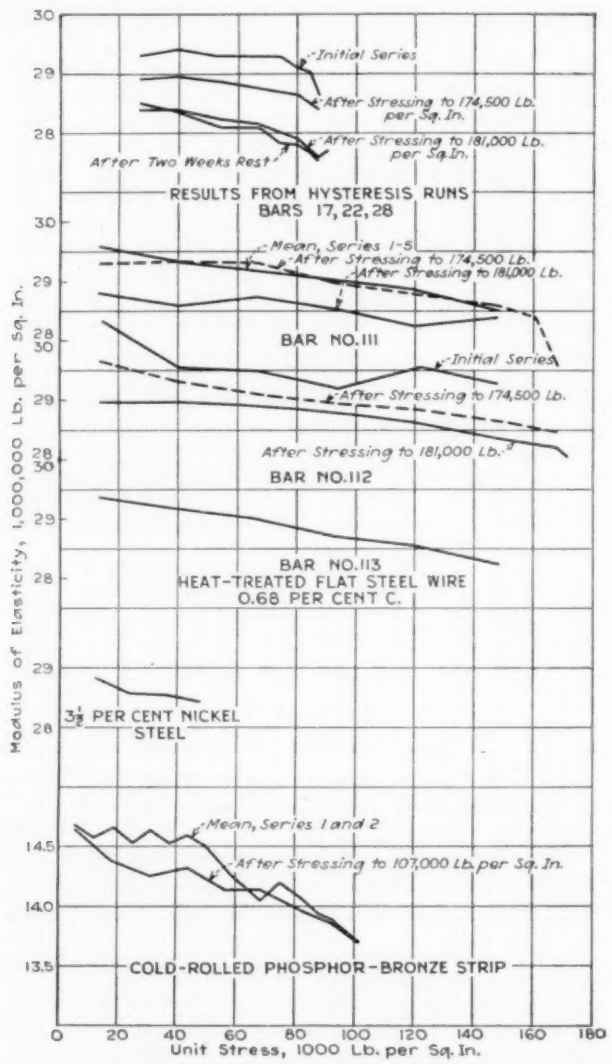

FIG. 2 RESULTS OF MODULUS-OF-ELASTICITY DETERMINATIONS

unit strain can be obtained by dividing it into the constant stress range of 26,800 lb. per sq. in.

A study of these figures reveals a relatively steady increase with increasing load in any one series of runs. This of course indicates a decreasing modulus of elasticity. From series to series, the variations are within experimental limits of error until after the fifth series. At the end of the fifth series, the load was raised to 10,400 lb., equal to 174,500 lb. per sq. in., and held there for some time. This was sufficient to cause permanent elongation of the order of magnitude of two-tenths of 1 per cent; and resulted in a slight decrease in the average values of modulus of elasticity. A further overload, to 181,000 lb. per sq. in., equivalent to an elongation of one-half per cent, resulted in a much more perceptible decrease in modulus. Summarized values are given in Table 5.

Before computing moduli of elasticity, it will be well to make certain corrections.

1 It has been known for some time that the modulus of elasticity decreases, and the flexibility increases, with increasing temperature. All readings were therefore reduced to find the equivalent reading as of 68 deg. fahr., correcting[2] 0.014 per cent per deg. fahr.

2 Any permanent elongation of the specimen results in an equivalent decrease of area of cross-section, so that larger elongations would naturally be expected as a result of a given actual load. To compensate for this, all readings made after the speci-

men had been overstrained were corrected so as to give the elongation corresponding to the original area.

3 Any elastic elongation results in an equivalent elastic decrease in cross-section, but not in the same ratio. The actual amount depends upon the value of Poisson's ratio. It is not felt that this correction properly should be made. It would in any event not be likely to exceed one-quarter of 1 per cent.

4 The extensometer was reset at an 8-in. gage length before each run, whereas ordinarily an extensometer would be set at the given gage length at zero load and left on while the gage length gradually increased with increasing load. This correction may reach a maximum of one-half per cent at the highest loads. If made, it would still further emphasize the decrease in modulus of elasticity at high load.

Values of moduli of elasticity at various loads, with the first two corrections applied, are given for various spring-steel samples in Tables 3 to 6. Moduli of elasticity for hard-rolled spring-tempered phosphor-bronze samples $^1/_8$ in. thick × $^1/_2$ in. wide are given in Table 7 The values are uncorrected for temperature or set. In these cases the first correction is uncertain in magnitude, and the correction would in any event not be large. Additional tables and full data are on file ready for inspection.

In closing, reference should again be made to the fact that a large amount of time and attention has been required for each series of tests, and that therefore only a small variety of samples have been tried. The results, as representing a general law, are consequently tentative. On the other hand, the evidence in favor of the curved stress-strain line is increased by the fact that for some time past the theories regarding the nature of atomic attraction and repulsion have called for just such curvature. This aspect of the case can well be taken up at some other time.

Acknowledgment should be made to Union College, for the use of its facilities in this investigation, and to Mr. Henry W. Sory, through whose skill and care in experimental operations these sets of readings have been made possible.

Discussion

W. J. Sweetser.[3] At the University of Maine some work has been done on soft steel of approximately 0.15 carbon and in investigating some of the properties after the steel has been stretched beyond the proportional limit and well into the plastic region. This work has been done in torsion on an Amsler testing machine of 1000 ft-lb. capacity. A troptometer has been used of such radius that 1 in. of arc on the scale was equal to 1 deg. of twist, and this arc has been divided into 0.1 deg. Great care was taken in laying out this arc and in making the divisions; 30 deg. being laid off and the chord measured to check for accuracy. The 30-deg. scale was then divided into single degrees by spacing with dividers, and each degree was subdivided into tenths. A magnifying glass was used in making the latter divisions and in marking the radial lines.

The modulus of elasticity of this steel was determined after it had been stressed to approximately 62,500 lb. per sq. in. maximum fiber stress in torsion. The load was then released to zero and the test piece allowed to rest for a week to recover its normal elasticity, as it was found that this steel will change very materially during that period, but will not make much further change after a longer rest. The data of Table 9 were taken a month and a half after the steel was first overstressed, so that it had over six weeks in which to recover. The readings were over an 8-in. gage length, and the load was applied to give equal angles of twist, then the readings of the twisting moment were taken from the machine. These latter readings are on a cylinder which is divided into divisions of 10 ft-lb., a vernier gives the unit figure, and one can estimate to one-quarter of the unit figure, due to the large divisions on the scale. This machine, however, has not been accurately calibrated. The settings on the troptometer are determined by sighting over the end of a pointer through a peep sight over 8 in. distant, and as the pointer moves close to the troptometer scale quite accurate settings for a given angle of twist can be made when the twisting force is applied. These settings of the troptometer are in error less than one-hundredth of a degree on the scale, and as the increments taken were 0.8 deg., which represented a twist on the piece of 0.1 deg. per inch of length, it is believed that the results are within the degree of accuracy which the machine will permit. The three sets of data quoted are from the same specimen and were taken over different divisions of the troptometer so that individual errors on the troptometer scale as well as errors due to the personal equation are included in the settings for equal angles of twist.

The maximum stress while taking this data was more than a 1000 lb. per sq. in. less than the maximum to which the material had been subjected, and no creep could be detected when the piece was stressed to this value. The piece was strained in increments of 0.1 deg. per inch of length up to a maximum of 0.6

[3] Professor of Mechanical Engineering, University of Maine, Orono, Maine. Mem. A.S.M.E.

deg., then released to 0 deg. This latter setting was determined by bringing the machine to zero twisting moment and then reading the troptometer. In only one of the three sets of data did the troptometer apparently fail to return to the original zero reading and then by not over 0.00125 deg. per inch of length.

As will be noted from the results given in Table 9, the modulus of elasticity in torsion decreases with the increase in stress. Over this range the specimen complies with the definition of an elastic material in that it shows no permanent set after the load is released.

R. L. Templin.[4] The author has presented some interesting data pertaining to some spring materials. The data undoubtedly have been obtained by carefully considered methods and well-designed apparatus. Unfortunately, however, some of the conclusions reached by the author are not in agreement with similar data obtained in tests of other materials.

In the laboratories of the Aluminum Company of America tests have been made of a number of different alloys of aluminum in both the wrought and cast conditions, using a Martens mirror extensometer with which unit deformations could be determined to 0.000005 in. In Table 10 are shown the observed changes in the tensile modulus after an initial test carried to the stress value indicated for a few specimens.

TABLE 10 CHANGES IN THE TENSILE MODULUS AS A RESULT OF SECOND LOADING

First loading stress, lb. per sq. in.	Proportional limit (from plotted data) lb. per sq. in.	Change in modulus,[a] per cent
8,100	2,900	— 1.9
6,100	1,900	0
7,000	1,800	0
28,000	10,000	0
22,000	6,000	0
24,000	7,000	— 10.9
13,000	3,000	— 2.7
24,000	7,000	— 0.9

[a] Second loading value compared to first loading value.

As the observed changes were of the same magnitude as the probable errors involved, it is doubtful that any changes in modulus actually occurred.

Generally speaking, one usually expects an increase in the modulus value with successive loadings, provided the material is stressed appreciably above the proportional limit or above the yield point. The initial stress-strain deformations include bending deformations, deformations due to relief of internal strains resulting from cold working or heat treatment, deformations due to misalignment of testing-machine heads and grips, non-axial application of load, etc. These non-uniform strains are largely equalized by overstressing, with the result that an increase in modulus would be anticipated.

If the conclusions of the author to the effect that cold working, which is a form of overstressing, decreases the tensile modulus by as much as 10 to 15 per cent are valid, how can the fact be explained that copper and aluminum both have the same modulus values after reductions in area, by cold drawing or rolling, of more than 90 per cent?

In view of these points it would appear unfortunate if the author attempted to draw too fundamental conclusions from his data and assume that they were generally applicable to all or even to most metals.

Dr. A. Nadai.[5] So far as the phenomenon of elastic hysteresis is concerned opinions have been expressed that such non-elastic properties of the materials of construction may be explained by certain processes which take place in the atomic structure of the crystal grains. A mechanical model which had been proposed some years ago in a paper published in England seems to account for a number of observations which are known under the heading mentioned as the phenomena of elastic hysteresis (loops in stress-strain diagram). In this mechanical model, ordinary friction was an essential part. It is well known that such materials as cast iron or sandstone show a pronounced elastic hysteresis. This type of material must be imagined as consisting either of grains with loose connections or of grains of two materials with very different properties of strength. A well known example is cast iron which has the soft and weak graphite particles imbedded in a more solid metallic mass. In a piece of such a material under compressive stress many grains will be constrained to slide a little under the pressure. For example, in a cast-iron piece the soft graphite inclusions will permit small tangential movements of the grains. Hence, ordinary friction will be present between the grains and will retard the relative movement of groups of grains, causing the phenomena of elastic hysteresis.

John M. Lessells.[6] In this paper the work on mechanical springs is divided into two parts. There is an engineering side, which is concerned with the effect on the fatigue strength of such factors as surface defects and decarburization, as brought to notice by Mr. Eaton. There is also a scientific side, as represented by the work of Professor Sayre. Both are important, and to allow of sufficient rapidity of progress both must be studied in parallel.

Coming to Professor Sayre's report, the impression has been formed that there is some uncertainty regarding hysteresis at low stresses. There is evidence of this from other fields. If we consider the work of Mr. Kimball, we find that internal friction is expressed as a function of (stress)^2 and apparently this holds for zero stress. There is further evidence from atomic theory. The generalized equation for stress and strain is

$$e = \frac{1}{E}(p + b_1 p^2 + b_2 p^3 + \ldots\ldots\ldots\ldots\ldots)$$

where p = stress in lb. per sq. in.
e = strain
E = modulus of elasticity
b_1, b_2 = constants

Hence it is seen that Hooke's law is only true if the other terms but the first be neglected.

The work as outlined in the report is nevertheless of great interest to engineers.

Jos. Kaye Wood.[7] Although the experimental results presented in the paper have no immediate value in so far as direct application to engineering is concerned, they are extremely important to the solution of the more fundamental problems of fatigue, creep, proportional limit, and other similar properties. This fact will be demonstrated more completely in future reports of the committee. In direct practical application, Hooke's law may still be considered as a straight-line characteristic. This is true even for high stresses in which the continuous and minute deviation from Hooke's law causes an ultimate cumulative change in the modulus of elasticity varying from 2 to 4 per cent for the materials tested. This change might be of sufficient importance, however, to warrant serious consideration in the design of high-precision springs, such as those used in sensitive length-measuring instruments.

Both Joffe and Griffith speak of a slight curvature in Hooke's law, the former claiming to have made highly sensitive tests which showed a deviation of small magnitude. He attempts a theoretical explanation of this deviation based upon the electrostatic theory of crystal lattices. The writer will describe Joffe's theory briefly and without apology, because future progress in the fundamental knowledge of the physical properties of metals can be attained only by an understanding of the nature of atomic forces. According to this theory, the force exerted by two atoms constitutes a balance established between the attractive and repulsive forces. Symbolically, the force or stress

$$f = \frac{\delta E}{\delta r} = \frac{mA}{r^{m+1}} - \frac{nB}{r^{n+1}} \quad \ldots\ldots\ldots\ldots\ldots\ldots [1]$$

in which m is the exponent of attraction and n is the exponent of repulsion; A is the attraction and B is the repulsion; while r is the distance between the atoms. Griffith calls f_0 the intrinsic pressure, due to the thermal vibrations of the atoms and of which the total heat of vaporization is a measure. That is, Equation [1] may be presented by an infinite convergent series of the form

$$f = f_0 + f'\Delta r + \frac{1}{2!} f''(\Delta r)^2 + \frac{1}{3!} f'''(\Delta r)^3 + \ldots\ldots [2]$$

in which Δr is the strain. This is not a straight-line relation. Hooke's law is represented by the single term $f' \Delta r$ only, which assumes erroneously that all other terms are equal to zero. In the normal state (that is, at absolute zero temperature) the thermal pressure f_0 does equal zero, so that the repulsive force just balances the attractive force at an equilibrium distance r_1 that is

$$\frac{mA}{r_0^{m+1}} = \frac{nB}{r_0^{n+1}} \quad \ldots\ldots\ldots\ldots\ldots\ldots [3]$$

Applied stress, if it is tensile, assists the repulsive force much as the thermic pressure does, while if the applied stress is compressive, it assists the attractive force. Hence we should expect to find an increase in the modulus of elasticity in compression instead of a decrease, as was found for tension in this investigation. Griffith checks with this view and speaks of the curvature of Hooke's law as being due to the diminution of the modulus at very high stresses.

In the first tests conducted for the committee by A. Hoadley,[8] the testing equipment was arranged so as to induce a uniform flexural stress in the specimen. The resulting stress gradients therefore showed no shift of the neutral plane from the center of gravity. Now in the cold coiling of helical springs by the inside-mandrel method,[9] a considerable tension is put on the wire which combined with flexure causes an appreciable shift of the neutral plane from the center of gravity. This fact should be given some consideration in the further study of trapped stresses. In the mass production of cold-coiled helical springs by the outside-coiling method, however, very little tension is put on the wire, with the result that no shift of the neutral plane occurs. Consequently, this method by which 90 per cent of all cold-coiled springs are made, should be more suitable from the trapped-stress standpoint.

APM-52-11

The Effect of Occasional Overstress and Subsequent Annealing on Chain Steel and Welded Chain Steel

By H. IVAN ANDREWS,[1] ENFIELD, ENGLAND

The results of the tests reported in this paper indicate that occasional overload tends to increase the static and fatigue strength of unwelded chain steel at the expense of the ability to resist the energy of shocks. They also indicate that the effect of annealing after overstress is to reduce the static and fatigue strength of the unwelded metal to values as low or lower than those for the metal before overstress, and that the benefit of annealing consists in the complete or partial restoration of the shock-resisting capacity of the metal.

ONE of the most pertinent problems with which the chain-making industry is now faced is the heat treatment of chains in service. It is well known that chain material suffers considerably under constant handling or under occasional severe loading, and it has become customary for many chain users periodically to remove chains from service for heat treatment, usually an anneal following a slight overstress (stress above working load).

Several investigations of service damage to chains and of the effect of annealing have been made, of which two may be noted here. C. G. Lutts[2] made tests which showed a distinct development of brittleness in single links after overstress. Studying wrought-iron chains, H. J. Gough,[3] of the British National Physical Laboratory, made an extensive study of the damage due to repeated localized stress at points of contact of links.

The tests described in this paper were undertaken in order to study the effect of a single overload on chain material, and the effect of subsequent annealing. Tests were also made on welded material. The test results do not give any answer to the question as to the effect of repeated stresses at points of contact of links, but do give some information as to the effect of a few overloads, such as most chains receive in service, both on chain stock and on welded chain stock.

The tests were carried out by the writer in the Materials Testing Laboratories of the University of Illinois, under the direction of Prof. H. F. Moore, and formed a part of the work of the Engineering Experiment Station of that University.

A supply of representative chain material was obtained through the courtesy of the American Chain Company, who also supplied a number of lengths of the same material containing welds made by the electric-contact method. The material was a high grade of low-carbon steel, commonly used in the manufacture of chains. The unwelded chain material was supplied in the form of $^1/_2$-in.-diameter round rod, bright drawn, and wound into an open coil. From this coil a number of pieces each 22 in. long were cut, and numbered in the order in which they were taken from the coil. As these pieces were still curved they were heated to approximately 1600 deg. fahr. in an electric furnace and straightened, first by hammering, and finally in a press. To eliminate the effects of unequal hot working as far as possible, the straightened pieces were normalized by heating to 1600 deg. fahr. and cooling in air. This normalizing was intended to assure that the whole of the material was reduced to a fairly standardized condition for further treatment and testing.

The welded pieces were straight as received, and it was unnecessary to treat them further, particularly as they were in the condition of actual chain welds. The excess of metal at the weld was, however, removed by turning or grinding down to the diameter of the rod.

Before deciding on the amount of load to be used in overstressing specimens it was necessary to determine the yield point and the tensile strength of the material as normalized. This was done by means of a 100,000-lb. Amsler testing machine fitted with a semi-autographic[4] rig for drawing a stress-strain diagram. Several specimens of normalized rod and of welded rod were thus tested. For the normalized rod the mean value for yield point was 34,200 lb. per sq. in., and for tensile strength, 48,200 lb. per sq. in. For the welded rod the yield point (poorly marked) was 50,800 lb. per sq. in. and the tensile strength 60,200 lb. per sq. in. (see Table 1).

In order to compare the effects of various treatments, the specimens of normalized rod were divided systematically into five groups as follows:

Group 1 Specimens tested in normalized condition
Group 2 Specimens loaded in Amsler machine to a stress of 35,500 lb. per sq. in. (slightly above yield point)
Group 3 Specimens loaded to a stress of 45,700 lb. per sq. in. (nearly to tensile strength)
Group 4 Specimens loaded to a stress of 35,500 lb. per sq. in. and annealed at 1700 deg. fahr.
Group 5 Specimens loaded to a stress of 45,700 lb. per sq. in. and annealed at 1700 deg. fahr.

The welded specimens were divided into three groups as follows:

Group W1 Specimens as received
Group W2 Specimens loaded to a stress of 45,700 lb. per sq. in.

[1] Mr. Andrews is engaged as Mechanical Engineer to the English Electric Company, Preston, Lancaster. Late holder at the University of Illinois of the Traveling Fellowship of the University of London, and the Research Bursary of the Worshipful Company of Goldsmiths (England). Jun. A.S.M.E. Mr. Andrews was educated in London, England, later attending that university as Governor's Scholar of City and Guilds College, gaining the A.C.G.I. and B.Sc. (first-class honors) degrees in engineering. He continued post-graduate studies as Goldsmiths Research Bursar. He studied locomotive design under Prof. W. E. Dalby and electric traction under Sir Philip Dawson, M.P. In 1928 he was awarded the Traveling Fellowship of the University of London, to study American railways at the University of Illinois. He later visited the New York, New Haven & Hartford R.R. at Readville, Mass. He is now with the English Electric Company Ltd. (railway department), Preston.

Group W3 Specimens loaded to a stress of 45,700 lb. per sq. in. and annealed at 1840 deg. fahr.

The stress of 45,700 lb. per sq. in. was used for the welded material to correspond with the heaviest loading used for the normalized rod. The metal in the weld was found to be markedly brittle and the annealing was carried to the high temperature of 1840 deg. fahr. in order that it might be as thorough as possible.

The tests carried out included static tension tests, made on the Amsler machine, impact tension tests made on a Charpy pendulum machine fitted with attachment for tension specimens,

The general results of the tests are given in Table 1. In considering the results of the tests it must be noted that, with the exception of the direct tension tests the test conditions in the laboratory do not correspond exactly with conditions met in service. However, it must be remembered that the object of the tests was to make a comparative study of the effects of different conditions of overstress and annealing, and for such a study the test results are believed to have significance. For example, it is obvious that the fatigue tests consisted in the application of a large number of *reversals* of stress, whereas in service, chain material is subjected to repetitions of stress in the same direction.

TABLE 1 RESULTS OF TESTS OF CHAIN STEEL AND WELDED CHAIN STEEL

Group	Material and treatment	Static tension tests: Yield point, lb. per sq. in.	Static tension tests: Tensile strength, lb. per sq. in.	Fatigue test; endurance limit, lb. per sq. in.	Impact tensile test; energy for fracture, ft-lb.	Charpy notched-bar test; energy for fracture, ft-lb.
1	Chain steel without welds; normalized	34,200	48,200	26,000	111.4	38.0
2	Chain steel without welds; normalized and stressed to 35,500 lb. per sq. in.	46,000	56,300	29,000	101.2	36.1
3	Chain steel without welds; normalized and stressed to 45,700 lb. per sq. in.	60,400	62,100	33,000	100.6	28.6
4	Chain steel without welds; normalized, stressed to 35,500 lb. per sq. in. and annealed at 1700 deg. fahr.	23,200	40,000	23,000	111.9	26.4
5	Chain steel without welds; normalized, stressed to 45,700 lb. per sq. in., and annealed at 1700 deg. fahr.	24,700	40,600	23,000	103.6	28.3
W1	Welded chain steel as received	50,800	61,800	26,000	66.8	..
W2	Welded chain steel stressed to 45,700 lb. per sq. in.	....	....	25,000	64.8	..
W3	Welded chain steel stressed to 45,700 lb. per sq. in. and annealed at 1840 deg. fahr.	....	....	24,000	81.9	..

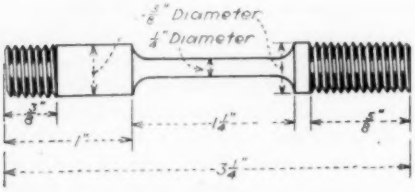

FIG. 1 TENSILE IMPACT SPECIMEN

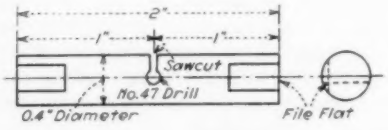

FIG. 2 SPECIAL CHARPY NOTCHED-BAR SPECIMEN FOR CHAIN STEEL

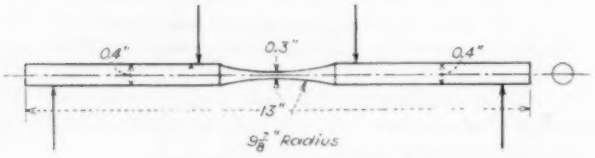

FIG. 3 FATIGUE SPECIMEN

Charpy notched-bar tests, made on the unwelded rod material only, and fatigue tests in reversed bending made on rotating beam machines of the Sondericker (or "Farmer") type. The static tension-test specimens were pieces of rod about 18 in. long, unmachined, and held in wedge grips. The impact tension specimens were of the form and size shown in Fig. 1, and for the welded specimens the weld was at the middle of length of the specimen. The notched-bar specimens were of the form and size shown in Fig. 2. The fatigue specimens were of the form and size shown in Fig. 3.

The test data for the fatigue tests are shown graphically in Fig. 4, which gives the *S-N* (or stress-cycle) diagrams for the fatigue tests plotted on semi-logarithmic paper. A glance at these *S-N* diagrams shows how the endurance limit was determined as the ordinate of the horizontal part of the diagram.

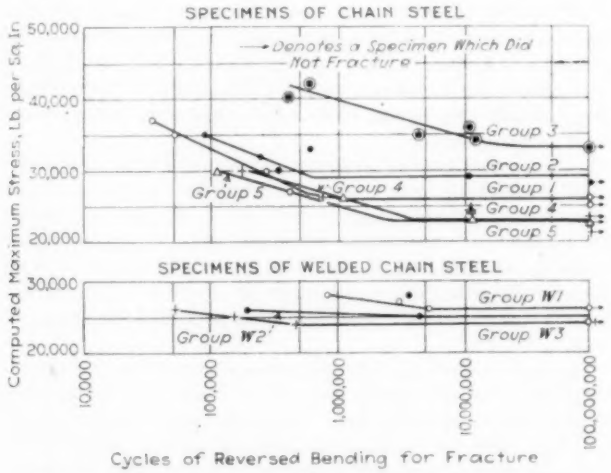

FIG. 4 *S-N* (STRESS-CYCLE) DIAGRAMS FOR FATIGUE TESTS

It does not seem unreasonable to assume that the resistance of a material to reversals of stress is a fair index of its resistance to repetitions of stress in one direction.

Again the impact tension tests, using unnotched tension specimens, are assumed to give a fair index of the resistance of the material to the energy of an impact load, such as would be caused by the slipping of hitches and jammed links. The results of the Charpy notched-bar tests are very difficult to interpret, but probably indicate something of the susceptibility of the metal to damage by notches, nicks, and cuts. It is to be noted that the results of the tension tests and of the fatigue tests are measured in pounds per square inch (stress), while the results of the impact tests are measured in foot-pounds (energy).

For the unwelded rod the effect of overstress without subsequent annealing is to increase both the yield point and the tensile strength, the increase of yield point being much more marked than the increase of tensile strength. Severe overstress increased both these values distinctly more than did stress just beyond the yield point. Overstress without subsequent annealing reduced the resistance to shock, as shown by the impact-tension test re-

sults. The endurance limit was increased by overstress in about the same proportion as the static tensile strength. Overstress without subsequent annealing slightly reduced the Charpy notched-bar values.

For the specimens overstressed and subsequently annealed the yield point, tensile strength, and endurance limit were found at somewhat lower values than for the normalized material. For the specimens subjected to slight overstress (just beyond the yield point) the shock-resisting value (as measured by the results of the tensile impact tests) was restored by annealing to that of the normalized material before overstress. For the heavily overstressed metal (stress nearly up to the tensile strength) the restoration of shock-resisting value was only partial.

Owing to the number of welded specimens available it was, unfortunately, not possible to get a full set of test results. Under a stress which severely overstressed the base metal, but probably did not seriously overstress the weld, the endurance limit was but very slightly affected. It is worthy of note that the endurance limit of the welded metal was about the same as that of the normalized rod. The resistance to shock, as measured by the results of the tensile impact tests, was not greatly affected for the specimens stressed to 45,700 lb. per sq. in. without subsequent annealing. The resistance to shock of welded specimens was markedly increased by annealing after the application of stress.

Conclusions

1 The tests here reported were made to study the effect of occasional overload and of subsequent annealing on chain steel and welded chain steel. They throw no light on the effect of many repetitions of working load in producing damage at points of contact of link.

2 The results of the tests here reported indicate that occasional overload tends to increase the static and fatigue strength of unwelded chain steel at the expense of the ability to resist the energy of shocks.

3 The results of the tests here reported indicate that the effect of annealing after overstress is to reduce the static and fatigue strength of the unwelded metal to values as low or lower than those of the metal before overstress, and that the benefit of annealing consists in the complete or partial restoration of the shock-resisting capacity of the material. This increase of shock-resisting capacity was especially noticeable in the annealed welded specimens.

APM-52-12

The State of Stress in Full Heads of Pressure Vessels

By W. M. COATES,[1] ANN ARBOR, MICH.

After a brief survey of the significant experiments upon which a comparison with the theory developed is to be based and a statement of the problem, the author derives expressions for stresses and displacements at any point of a thin-walled pressure vessel. Assuming that the shell offers no resistance to bending, an analysis is made considering it as a membrane. A study of the resulting equations indicates that in the neighborhood of the junction of head and cylinder, bending couples result, so that the plates may not be considered as membranes, at least in this locality. This leads to a consideration of the local effects of the reactions set up at the junction, the head and cylinder being considered as surfaces capable of carrying bending stresses with loads which are uniformly distributed edge shearing forces and bending couples. The resultant effect at any point is obtained by superposition. An illustrative example is given.
